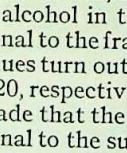
In the standard tracer experiments carried out previously,[2] the concentration of ethanol in the synthesis gas was always about 1 to 1.5% by volume. In such runs at one atmosphere over singly promoted catalysts, about 35% of the products were formed from the radioactive ethanol. Since in these runs, $^1/_3$ of the products originate from a C_2 chain initiator rather than the normal C_1 chain initiator, the net effect must be to skew the product distribution from that typical of normal synthesis. How much this will tend to obscure the normal mechanism of the synthesis can only be determined by experiment. In run no. K20, conditions were similar to the other one atmosphere tracer experiments over singly promoted iron catalysts, except that the ethanol activity was much higher and the concentration of alcohol in the synthesis stream was lower, *i.e.*, about $^1/_{25}$ that in the standard tracer runs. The data obtained (Table III) show that the synthesis details for this experiment were quite similar to those for run no. J4. The incorporation (C₂ *vs.* C₁) was only about 5% or $^1/_7$th that of J4; consequently, the effect of alcohol addition on the product distribution was relatively small. In Fig. 2, activity *vs.* carbon number curves are given for runs K20 and J4. The qualitative differences in these two curves are striking; in fact, the curve for run K20 more closely resembles the runs over doubly promoted catalysts (Fig. 1) than it does J4. These results suggest that the qualitative differences between run J4 and all the runs herein reported for iron catalysts are principally a result of the higher incorporation in run J4 and the concomitant skewing of the product distribution rather than any fundamental difference brought about by changes in synthesis pressure or catalyst composition.

In runs J4 and K20, the over-all reaction rate is comparable. Thus, the incorporation divided by the per cent. alcohol in the synthesis stream is roughly proportional to the fraction of the alcohol that reacts. These values turn out to be about 23 and 83 for runs J4 and K20, respectively. If the reasonable assumption is made that the rate of build-in of the alcohol is proportional to the surface concentration of alcohol, θ, the fact that the fraction of alcohol reacting falls off with increasing alcohol partial pressure indicates that the adsorption of ethanol is medium strong.

In the chain building scheme put forward by Kummer, *et al.*,[2] adsorbed alcohol complexes of the type



R′ = CH_3 or H
R = alkyl group

are presumed to be the chain initiators and the complex where both R and R′ are H may also act as a build-in unit. Hydrocarbons may be produced by a variety of reactions.[3] Alcohol production could most simply be allowed for by hydrogenation of the carbon–metal bond, *i.e.*, reversal of the adsorption process. In any case, if this proposed mechanism is correct, the alcohol products (C_3 and higher) from tracer experiments wherein the synthesis gas contains labeled ethanol should give the same molar activity *vs.* carbon number plot as the hydrocarbons, as these alcohols stem from common intermediates. Unfortunately, such an experiment is ordinarily difficult in the usual synthesis over iron catalysts because the yield of oxygen-containing or-

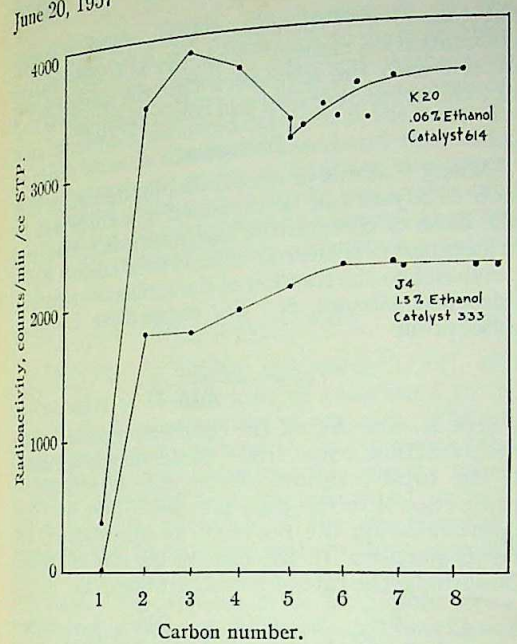

Fig. 2.—Concentration on incorporation over singly promoted catalysts. In run K20 the activity of the ethanol was 75,000 counts/min./cc. STP; in run J4, 6000 counts/min./cc. STP.

ganic products is so low. Recently,[11] however, it has been shown that nitrided iron catalysts yield a much higher percentage of alcohols than the reduced catalysts. This increased yield of alcohols does not require that the above discussed mechanism be discarded; it only requires that the relative rates of the various (particularly the chain termination) reactions involved be different on the nitrided catalyst. Tracer experiment No. K10 substantiates this view. In this experiment, the activities of the alcoholic products from C_3 through $C_{5,4}$ were determined. Synthesis details for this experiment are given in Table I, where it may be noted that it was considerably longer than any of the others. This was necessary in order to obtain a sufficient yield to permit an efficient separation of the alcohols. The activity data for the hydrocarbon products from this experiment are summarized in Table II, while results for the alcohol fractions are given in Table IV. These same data are also illustrated in Fig. 3. Qualitatively, the plots are similar to those obtained for the reduced doubly promoted catalyst at the same pressure. Quantitatively, there is a significant difference in the magnitude of the incorporation. That for the reduced catalyst is almost five times greater than that for the nitrided catalyst. This difference, together with the qualitative similarity of the curves, lends support to the contention that the mechanism of synthesis is similar over the two catalysts, but that the various rates involved are different. Although the activity data for the alcohols are subject to larger errors than those obtained from the hydrocarbons, it is quite evident that the *average* activities of the alcohols and hydrocarbons are the same within experimental

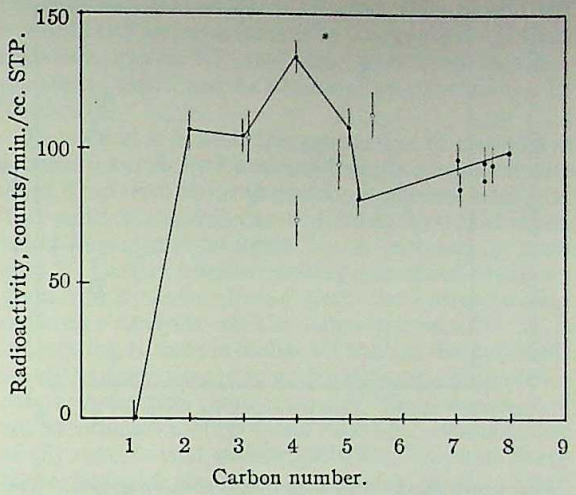

Fig. 3.—Ethanol tracer runs over a nitrided iron catalyst at 7.5 atm. and 215°. The assumed precision of the data is indicated by the length of the vertical lines: O, alcohols; ●, hydrocarbons.

error. This agreement would be expected on the basis of a mechanism which presumes that the alcoholic and hydrocarbon products both arise from the same complex. Qualitatively, the variation of alcohol activity with carbon number appears as if it might be different from that for the hydrocarbons insofar as it shows a minimum at C_4 rather than a maximum (Fig. 3).

TABLE IV

ACTIVITY OF ALCOHOL FRACTION OF LIQUID PRODUCTS FOR RUN NO. K10

Fraction[a]	Mol. wt.[b]	Carbon no.[b]	Activity, c./min./cc. CO_2	Activity, c./min./cc. Alcohol
5	62.4 (60.4)	3.1	33.5	104
6	59.4 (62.0)	4.0[c]	18.6[c]	74[c]
7	85	4.8	19.8	95
8	93.5	5.4	21.1	113
			Av.	96 ± 10
			Av. for hydrocarbons in this range	110

[a] These four samples were ethanol-free according to mass spectrographic analysis. [b] Molecular weights were determined vaporometrically. Check results are given in parentheses. Except for cut no. 6 carbon numbers were calculated using the data in column 2. [c] Mass spectrographic analysis showed this cut to be pure butanol plus some water. Distillation data also indicated this. Since small amounts of water would affect considerably the vaporometric molecular weight, the data in column 2 were ignored and those in columns 3, 4 and 5 were calculated assuming the cut was pure butanol.

In addition to the runs on iron catalysts, two runs were made on cobalt catalysts (K13 and K16). In these experiments, the H_2:CO ratio was 2:1 and, of course, the operating temperature was lower. In runs K16 and K13, the synthesis stream contained 1.5 and 0.04% ethanol, respectively. The plots of radioactivity *vs.* carbon number, constructed from the data obtained, are presented in Fig. 4. In contrast to the results with iron, the incorporation is quite low (~2%). The shape of the curves is such as to indicate that ethanol, on adsorption, forms a complex which acts primarily as a chain initiator. In striking contrast to *all* the re-

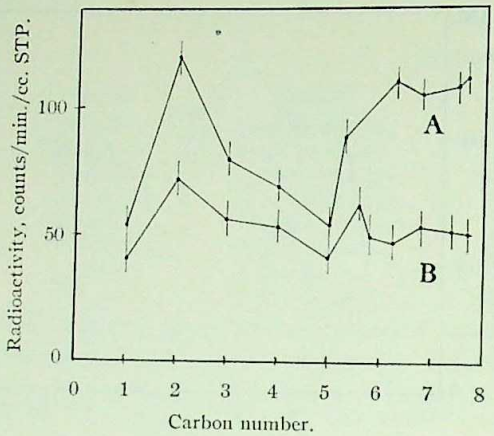

Fig. 4.—Ethanol tracer runs over a cobalt catalyst. The assumed precision of the data is as indicated by vertical lines. The activity of the ethanol in K13 was 75,000 counts/min./cc. STP; in run K16, it was 6030: A, K16, ethanol 1.5%; B, K13, ethanol 0.04%.

sults for ethanol tracer experiments with iron catalyst, however, the C_2 products had the highest activity. One possible explanation of this behavior is that the ethanol itself does not build-in, but that it does dehydrate to ethylene which will build-in over cobalt catalysts.[12] Since Co is an excellent hydrogenation catalyst, it would be expected that proportionately more ethylene would hydrogenate to ethane than would build-in, so that the C_2 products would have the highest radioactivity. An attempt was made to check this hypothesis by cracking the propane fraction. The results of this experiment were expected to show whether or not addition always took place preferentially on the carbinol carbon atom; unfortunately, the activities of the cracked products were so low that the experiment was inconclusive.

The activity of the methane fraction was quite high, indicating that appreciable cracking took place. If all of this came from the C_2 fraction, roughly one ethanol molecule cracked for every one that reacted to form higher molecular weight products. These results are definitely different from those obtained with iron catalysts. Even in the run in which cracking occurred to the greatest extent (K20), only about one ethanol molecule cracked to methane for every 10 or 15 that built in. It seems likely, therefore, that the same mechanism is not operative over iron and cobalt catalysts. This supposition finds some support in the available data on the product distributions and conditions required for synthesis over cobalt catalysts; these are quite different from similar data on iron catalysts.[3]

The effect of the ethanol concentration on its incorporation over cobalt catalysts is made evident by comparing runs K13 and K16 in Table III. Use of the same arguments here as for iron, shows that the fraction of the ethanol that undergoes build-in changes by less than a factor of 2 for an approximate 40-fold change in concentration, whereas in the case of iron the change was ~3.5 for a 25-fold concentration change. This, too, is in approximate accord with the suggestion that the mechanism is not the same over iron and cobalt catalysts.

Discussion

Many features of the ethanol incorporation with iron catalysts can be explained in a crude way on the basis of competitive Langmuir adsorption, if it is assumed that the *rate* of build-in of ethanol is proportional to the fraction of the surface covered with adsorbed ethanol, θ_2. For competitive Langmuir adsorption

$$\theta_2 = \frac{K_2X_2P}{1 + P\Sigma K_iX_i} \qquad (1)$$

where K_i and X_i are the equilibrium constant and mole fraction, respectively, of the ith species, and P is the total pressure. If the rate of synthesis is proportional to the total pressure,[12] then, to a first approximation the per cent. incorporation, I, will be proportional to the ratio of the rate of ethanol build-in to the rate of normal synthesis, *i.e.*

$$I = k' \frac{K_2X_2}{1 + P\Sigma K_iX_i} = k' \frac{K_2X_2}{1 + PK_2X_2 + \Sigma' PK_iX_i} \qquad (2)$$

where k' is a ratio of rate constants and where the Σ' excludes the term for ethanol. Table III contains data for runs (K20 and J4) at $P = 1$, which differed only in the concentration of ethanol in the synthesis stream. The ratio of the incorporation (7/1 is the ratio of the incorporation for J4 to that for K20) can be used to obtain estimates of the θ_2 in these runs. Equation 2 (assuming $\Sigma' K_iX_i$ is about the same for both runs) yields

$$\frac{7}{1} = \frac{0.015\ K_2}{1 + 0.015K_2 + \Sigma' K_iX_i} \times \frac{1 + 0.0006\ K_2 + \Sigma' K_iX_i}{0.0006\ K_2} \qquad (3)$$

which reduces to $1 + \Sigma' K_iX_i = 5 \times 10^{-3}K_2$. Insertion of this admittedly crude estimate back into (1), reveals that in run J4 about 80% of the surface is covered with the ethanolic complex, while in run K20 the corresponding value is 12%.[12a]

The above estimates readily can be extended to the variation of incorporation with synthesis pressure for a fixed amount of alcohol in the synthesis gas. The data in Table III show that the incorporation at atmospheric pressure with a doubly promoted catalyst (run H7) is only about 1/2 that observed for the singly promoted catalyst. Provided that k' of (2) is independent of the alkali promoter, then θ_2 on the doubly promoted catalyst is about 1/2 that on a singly promoted catalyst, *viz.*, about 0.4, as with the singly promoted catalyst it was concluded above that in the neighborhood of 80% of the available surface was covered with ad-

(12a) The calculations based on equations (1), (2), (3) and (4) are admittedly speculative and involve numerous assumptions. They should probably be considered as more qualitative than quantitative. A typical difficulty that arises from a quantitative interpretation is illustrated by the figure "80%" for the percentage of the surface covered by "adsorbed ethanol complex" in run J4. If this adsorbed complex were identical to that formed from carbon monoxide and hydrogen during synthesis, then most of the hydrocarbon products would have been radioactive. Actually only one molecule in three of the hydrocarbon products in run J4 was radioactive. Presumably one must therefore conclude that only a fraction of the adsorbed ethanol complex is of the type that participates in the actual synthesis [illegible] bonds.

sorbed ethanol. Within the framework of the present discussion, all precursors to hydrocarbon products may be viewed as adsorbed alcohols, so that in this instance there can be little bare surface. With the doubly promoted catalyst, if the same ratio exists between adsorbed ethanol and remaining alcoholic complexes, an upper limit for the coverage of the rest of the surface can be set, which cannot exceed 0.2. The total surface coverage then becomes ≈ 0.6 with the doubly promoted catalyst. Thus

$$1 - \theta = \frac{1}{1 + \Sigma K_i X_i} = 0.4 \qquad (4)$$

and $\Sigma K_i X_i = 1.5$. Using this value in (2), the incorporation at 21 atm. can be calculated to be about $^1/_{13}$th the incorporation at one atm. The actually observed value is about $^1/_8$, but in view of the crudeness of the approximations this may be taken as in fair agreement with the calculated value.[13] It is implicit in the solution of (4) that the relatively large uncovered fraction comes about through small values of the K_i, rather than mechanical blockage with alkali. This appears to be justifiable, since $\theta = \Sigma\theta_i$ may be taken as the fractional coverage of *available* surface, without altering the result.

This picture can be used to explain the fact that Kummer, *et al.*,[4] found that the addition of ethanol retards the synthesis, whereas in the present experiments, this was not found to be the case. Kummer found that when 1.5% ethanol was added to a synthesis gas stream, which was subsequently passed over a singly promoted iron catalyst, it was necessary to raise the temperature about 12° over that used for the control run with no ethanol added. Use of the experimentally determined activation energy (~20 kcal./mole)[14] indicates that the *normal* rate of synthesis should increase by a factor of 1.7 for such an increase in temperature. Moreover, since 35% of the products originate from the ethanol, the rate increase should be even greater (*i.e.*, ≈ 2.3). Thus, if the temperature were kept constant, the rate of synthesis from the normal C_1 complex would be reduced to about 40% of its value when the alcohol is introduced. Estimates presented above indicate that in the tracer runs of Kummer, *et al.*[2] (*e.g.*, J4, Table III), the adsorbed ethanol covered about 80% of the surface. Thus, at most, only about 20% of the surface was available for normal synthesis in those runs. Under the conditions where the ethanol build-in is small (run K20), only $\approx 12\%$ of the surface is covered with the ethanolic complex. In normal synthesis, therefore, as much as 85 to 90% of the surface is available for formation of the C_1 complex. Since it is likely that the rate of normal synthesis is proportional to the concentration of the C_1 complex,[7] a decided poisoning on ethanol addition would be expected for the former situation (*e.g.*, J4). This poisoning would be correspondingly less for runs in which the incorporation was small. In fact, in all the runs reported in Table III except for J4 and H7 it would not be experimentally observable. Unfortunately, in run H7 conditions were such that the poisoning could not be observed (see footnote *e* in Table III).

In normal synthesis the production of alcohols is generally smaller with reduced singly promoted catalyst than with reduced doubly promoted catalysts. The yield of alcohols can be further increased when using the latter catalysts by an increase in pressure.[3] Lastly, nitrided doubly promoted catalysts yield much more alcohol than the corresponding reduced catalysts at the same pressure.[11] It is interesting to note in Table III that as the synthesis conditions are altered in such a direction to make alcohol production more favorable, the percentage of tracer ethanol incorporated falls off. Examination of (2) reveals that such a fall off in I is most likely to be brought about by a decrease in K_2. Since presumably the adsorption of the alcohol-type complex is one point adsorption at the carbinol carbon atom,[2] this decrease in K_2 would indicate a similar decrease in the adsorption equilibrium constants for all the alcohols. This can be viewed as a relative increase in the desorption rate of the alcohols. This prediction, based on (2), would lead to the conclusion that in normal synthesis the alcoholic complex is more likely to evaporate from the surface and increase the yield of alcohols under the synthesis conditions which lead to a relatively low incorporation of ethanol in a tracer run.

It is interesting to note that whereas cobalt catalysts show a relatively low incorporation of ethanol it is also well-known that cobalt catalysts produce very low yields of alcohols. This discrepancy with the predictions of (2) in addition to the differences noted earlier between cobalt and iron catalysts, tend to support the suggestion that the predominant synthesis mechanism is not identical over the two metals.

In the discussion thus far, the qualitative differences in ethanol incorporation for different runs over iron catalysts under different synthesis conditions have been ignored. Figures 1, 2 and 3 illustrate the various types of behavior observed. In run J4 the incorporation was large (~35%). The activity per cc. was the same for the C_2 and C_3 products, but increased slightly between C_3 and C_6 ($\approx 20\%$); it again became constant for the C_6^+ hydrocarbons. In run K20, which like run J4 was carried out at one atmosphere over a singly promoted catalyst, the incorporation was low. This plot of radioactivity per cc. *vs.* carbon number shows a maximum in activity in the C_3–C_4 region and a local minimum at C_5 followed by a small increase in activity for C_5^+ products. The total variation in activity is about 20%. The curves for the reduced and nitrided doubly promoted catalysts all show the maximum in the C_3–C_4 region, although not all of them show the minimum at C_5. As already mentioned it appears that the maximum occurs whenever the incorporation is low, and is independent of the catalyst composition or the synthesis pressure.

In terms of the simple chain building picture mentioned earlier the molar activity should be independent of carbon number. The observed varia-

(13) In order to obtain a numerical estimate of the fall off in I with synthesis pressure, it is necessary to make some assumption regarding the surface coverage at one atmosphere, *i.e.*, that the surface was 60% covered. Even without this assumption, however, eq. 2 predicts, qualitatively, the fall off in incorporation as the pressure is increased.

Digitized by Arya Samaj Foundation Chennai and eGangotri

tion with carbon number appears to increase as the incorporation decreases. For example, the ratio of the peak activity to the C_2 activity (a measure of the variation) is 1.29 and 1.45, in runs H7 and H19, whereas the incorporation is 18 and 7.2%, respectively. This suggests that when the normal synthesis is least disturbed by the added alcohol the variation of radioactivity with carbon number is most pronounced. For the most part, however, the activity is fairly constant ($\sim \pm 20\%$) so that the simple hypothesis advanced by Kummer and Emmett[1] is probably close to the truth. These shortcomings of the theory do suggest, however, that even though the alcohol-type complexes are the principal chain initiators, some other species are also capable of acting in a similar capacity.

The nature of the chain initiator is indicated by the results obtained by Kummer, *et al.*[2] They found that 90% of the propane formed in ethanol tracer runs appeared to be obtained by addition to the α carbon atom of the methylene-labeled ethanol, and the remainder by the addition to the β-carbon atom. It was also established that the hydroxyl group of the unreacted ethanol had not migrated to the unlabeled carbon atom. Thus, it appears that a small fraction of the ethanol reacted to form some species *in which the two carbons were indistinguishable* and which could also build-in to form higher hydrocarbons. Clearly, this suggests that ethylene formed by the dehydration of ethanol is capable of build-in over iron catalysts to form higher hydrocarbons. This has been known to be the case with cobalt catalysts for some time[15] and the present authors have shown that when radioactive ethylene is introduced into the synthesis stream some build-in occurs.[7] Thus, the results with propane suggest that 80% of the propane comes from ethanol with all the addition taking place on the labeled (methylene) carbon atom and 20% of the propane comes from radioactive ethylene with the addition to the labeled carbon occurring only 50% of the time. It seems probable that this effect contributes heavily to the above-mentioned skewing of the radioactivity *vs.* carbon number curves.

In conclusion, it should be emphasized that the mechanism of synthesis appears to be complex, with two or more intermediates functioning as chain initiators. In spite of this, however, the mechanism suggested by Storch, *et al.*,[3] and Kummer, *et al.*,[1] is probably the predominant one operating in the synthesis over iron catalysts and is capable of explaining many of the observed facts.

The Free Radical Initiated Polymerization of Gaseous Unsaturated Hydrocarbons[1]

BY LESLIE C. LANDERS AND DAVID H. VOLMAN

RECEIVED JANUARY 26, 1957

Methyl radicals from thermally decomposing di-*t*-butyl peroxide were found to initiate the polymerization of gaseous acetylene, 1,3-butadiene, ethylene and propene in the temperature range 130–165°. The rate of polymerization of each unsaturated hydrocarbon was proportional to the first power of the concentration of monomer and to the square root of the concentration of di-*t*-butyl peroxide. This is consistent with a three-step polymerization mechanism consisting of initiation by a unimolecular split of the peroxide into free radicals, propagation by addition of radicals to a multiple bond and termination by radical combination. From a consideration of the relationship between the activation energies of chain initiation, propagation and termination, and of the known values of the activation energies for initiation and termination, the activation energies for propagation of polymerization of acetylene, butadiene, ethylene and propene were determined to be 5.1, 4.9, 8.2 and 5.6 kcal./mole, respectively.

Introduction

Few of the studies of the polymerization of the simpler unsaturated hydrocarbons in the gas phase have been concerned with obtaining values of the activation energies for the chain propagation reactions or, alternatively, for the addition of atoms or radicals to the multiple bond. Raal and Danby[2] reported 6.8 kcal./mole as the activation energy for propagation of ethylene polymerization initiated in the gas phase by methyl radicals. James and Steacie[3] give a preliminary value of 6–8 kcal./mole as the activation energy for the addition of ethyl radical to heptene-1. Volman[4] initiated the polymerization of butadiene by the thermal decomposition of di-*t*-butyl peroxide and reported 2.6 kcal./mole for the propagation activation energy. Volman and Graven[5] later initiated butadiene polymerization by the photolysis of di-*t*-butyl peroxide and acetone and reported 5.4 kcal./mole for the propagation activation energy, in good agreement with Gee's value of 5.5 kcal./mole for the propagation step in the gas phase mercury-photo-sensitized polymerization of butadiene,[6] and the estimate of White and Winkler[7] of 5 kcal./mole for the addition of a hydrogen atom to butadiene. More recently,

Mandelcorn and Steacie[8] reported values of the activation energies for the addition of methyl radical to unsaturated hydrocarbons: acetylene 5.5 kcal./mole, ethylene 7.0 kcal./mole, propene 6.0 kcal./mole and butadiene *ca.* 2.5 kcal./mole.

Previous studies[4,5] in this laboratory of butadiene polymerization have involved initiation by the thermal and photochemical decompositions of di-*t*-butyl peroxide, which occur according to the well known mechanism[5,9,10]

$$(CH_3)_3COOC(CH_3)_3 \longrightarrow 2(CH_3)_3CO \quad (1)$$

$$(CH_3)_3CO\cdot \longrightarrow CH_3\cdot + CH_3COCH_3 \quad (2)$$

$$2CH_3\cdot \longrightarrow C_2H_6 \quad (3)$$

The thermal initiation technique is very convenient, since the peroxide decomposes at a readily measurable rate at 125°. It is assumed that the *t*-butoxy radical formed in (1) decomposes rapidly by (2) at temperatures at which the peroxide decomposes, thus di-*t*-butyl peroxide is a convenient source of methyl radicals at temperatures well below those at which the direct thermal polymerization of unsaturated hydrocarbons takes place.

In the present work this technique was extended to the initiation of polymerization of gaseous acetylene, butadiene, ethylene and propene.

Experimental

The di-*t*-butyl peroxide, kindly donated by the Shell Chemical Corporation, was of unspecified purity. It was deaerated and distilled bulb-to-bulb on the high vacuum line and the middle fraction was retained and stored over Dry Ice. Its refractive index ($n^{20}D$) was 1.3888, which compares well with published values of 1.3888,[5] 1.3889[9] and 1.3890.[10] The acetylene was Matheson Purified Grade, the 1,3-butadiene was Matheson Extra Pure Grade, and the ethylene and propene were Matheson C.P. Grade. Samples of these were condensed and distilled bulb-to-bulb on the high vacuum line, the middle fractions of each being retained. The ethylene was stored over liquid air, and the acetylene, butadiene and propene over Dry Ice.

The polymerizations were carried out in a one-liter Pyrex bulb immersed in an oil-bath thermostat. The temperature was maintained constant to within ±0.05°. Pressure changes during polymerization were measured by a mercury manometer.

Results and Discussion

Di-*t*-butyl peroxide was decomposed at various temperatures in the range 124–177°, and the first-order rate constant obtained was $k_i = 1.6 \times 10^{16} e^{-33.4/RT}$ sec.$^{-1}$, which is within the range of previously reported values.[10–12]

The kinetic data obtained from the polymerization experiments are shown in Tables I–IV. The rates of pressure change given are the initial rates. The values of k were calculated from

$$-\frac{dp}{dt} = k(M)(C)^{1/2} \quad (4)$$

where (M) is the pressure of monomer and (C) is the pressure of di-*t*-butyl peroxide.

It is seen that in each case the rate of pressure change in the system is given by eq. 4. This is of the expected form for a free radical initiated polymerization involving initiation *via* a unimolecular

formation of free radicals, polymer growth by addition of radicals to monomer molecules and termination by bimolecular interaction of free radicals.[4] Since it has been shown that negligible amounts of ethane are formed when di-*t*-butyl peroxide is decomposed in the presence of butadiene,[4] it was assumed that each methyl radical formed adds to a monomer molecule, the polymerization proceeding as

$$(CH_3)_3COOC(CH_3) \xrightarrow{k_i} 2CH_3COCH_3 + 2CH_3\cdot \quad (5)$$

$$CH_3\cdot + M \xrightarrow{k_p} CH_3M\cdot \quad (6)$$

$$CH_3M\cdot + M \xrightarrow{k_p} CH_3M_2\cdot \quad (7)$$

$$CH_3M_x\cdot + CH_3M_y\cdot \xrightarrow{k_t} (CH_3)_2M_{(x+y)} \quad (8)$$

$$CH_3M_x\cdot + CH_3M_x\cdot \xrightarrow{1/2k_t} (CH_3)_2M_{(x+x)} \quad (9)$$

This formulation[13] yields, by the usual steady-state treatment

$$\frac{-d(M)}{dt} = k_p\left(\frac{2k_i}{k_t}\right)^{1/2}(M)(C)^{1/2} \quad (10)$$

For the determination of activation energies, the values of k in eq. 4 were calculated from the slopes of the straight lines obtained in plots of $-(dp/dt)/(C)^{1/2}$ *vs.* (M). These values are listed in Table V.

TABLE V

POLYMERIZATION RATE CONSTANTS

T, °C.	k, moles$^{-1/2}$/l. sec.$^{-1} \times 10^4$	T, °C.	k, (moles/l.)$^{-1/2}$ sec.$^{-1} \times 10^4$
Acetylene		Ethylene	
131.8	4.29	131.2	1.86
149.8	15.1	146.0	6.19
164.9	42.0	160.1	18.2
Butadiene		Propene	
129.4	0.85	135.8	0.73
140.5	1.93	147.9	1.77
151.0	3.91	160.2	4.07
166.2	10.5		

The activation energies E corresponding to the slopes in Fig. 1 were calculated to be as follows: acetylene 24.3, butadiene 24.1, ethylene 27.4 and propene 24.8 kcal./mole. Since

$$k = \left(\frac{2k_i}{k_t}\right)^{1/2}k_p \quad (11)$$

then

$$E = E_p + {}^1/_2E_i - {}^1/_2E_t \quad (12)$$

Although it is not possible to estimate E_t from the experimental data, there is abundant evidence that in general E_t is small, not far from zero. The kinetics of the liquid phase photopolymerization of vinyl acetate[14] and methyl methacrylate[15] have been studied by the rotating sector method and E_t was found to be zero in both cases. For the liquid phase benzoyl peroxide initiated polymerization of butyl acrylate, E_t has been found to be zero.[16] The combination of methyl radicals in the gas phase has been found to require no activation

(13) The justification for taking the termination rate constant for like radicals reacting equal to one-half the rate constant for unlike radicals reacting may be found in collision theory. *Cf.* P. J. Flory, "Principles of Polymer Chemistry," Cornell University Press, Ithaca, N. Y., 1953, p. 200.

energy,[17] and an examination of the published data on the reactions of ethyl radicals in the gas phase discloses no good evidence that the activation energy for ethyl radical combination is other than zero.[15] E_t was therefore assigned the value zero for this study, so that

$$E_p = E - {}^1/_2E_i \qquad (13)$$

Using the value of E_i = 38.4 kcal./mole, the values of E_p obtained for the systems studied are: acetylene 5.1, butadiene 4.9, ethylene 8.2 and propene 5.6 kcal./mole. The value for butadiene agrees well with previous values of 5.4[5] and 5.5[6] kcal./mole. The value for ethylene is in fair agreement with the value of 6.8 kcal./mole given by Raal and Danby.[2] However, the results of Raal and Danby depended upon the value of 9.7 kcal./mole for the activation energy for hydrogen atom abstraction from acetaldehyde by methyl radical. If the more recent value of 7.5 kcal./mole given by Volman and Brinton[19] is taken, however, the work of Raal and Danby indicates a value of 4.6 kcal./mole for the propagation activation energy in ethylene polymerization, which does not agree with our results. If the values for E_p obtained in this study are compared with those of Mandelcorn and Steacie previously cited,[8] it is seen that the correspondence is quite good in the cases of acetylene and propene and is certainly within experimental error for ethylene. Since their value for butadiene is a rough approximation, the discrepancy with our value is not significant.

The System Ammonia–Hydrazine–Ammonium Chloride

BY FORREST R. HURLEY AND HARRY H. SISLER[1]

RECEIVED JANUARY 5, 1957

A study of the solid–liquid equilibria in the general ternary system of ammonia, hydrogen chloride and hydrazine was restricted to that portion of the general diagram enclosed in the triangle NH_3–N_2H_4–NH_4Cl, and to pressures near one atmosphere. A ternary compound believed to be $NH_3 \cdot HCl \cdot N_2H_4$, but whose composition has not been established, melts incongruently at −2.5°. The conditions for removal of ammonium chloride from the system by crystallization were outlined.

Sisler and Mattair[2] have shown that hydrazine is formed when chloramine, produced from gaseous chlorine and ammonia, is dissolved in a large excess of liquid ammonia. Subsequent papers from this Laboratory[3] give additional details concerning this synthesis and the recovery of anhydrous hydrazine. In accordance with the equation

$$ClNH_2 + 2NH_3 = N_2H_4 + NH_4Cl$$

equivalent amounts of hydrazine and ammonium chloride are formed in the reaction. However, the over-all yield of hydrazine is reduced by its reaction with chloramine.

$$2ClNH_2 + N_2H_4 = N_2 + 2NH_4Cl$$

Therefore, the mole ratio of hydrazine to ammonium chloride in the product mixture is always less than unity. During the last stages of evaporation of excess ammonia, hydrazine, which has a lower volatility than ammonia, reacts with ammonium chloride in accordance with the equation

$$N_2H_4 + NH_4Cl = NH_3 + N_2H_5Cl$$

This reaction makes it difficult to distil the hydrazine from the reaction mixture since the ammonium chloride in the mixture is always in excess of the

hydrazine. If the mole ratio of ammonium chloride to hydrazine were reduced by fractional crystallization to a value less than one, a portion of the hydrazine (the excess over the equivalent of ammonium chloride) would thereby be made available for removal by simple distillation.

A study of the solid–liquid equilibria existing in the general ternary system of ammonia, hydrazine and hydrogen chloride was necessary in order to determine the most favorable conditions for crystallization of solid phases containing ammonium chloride but no hydrazine. The investigation was restricted to that portion of the general diagram enclosed in the triangle NH_3–N_2H_4–NH_4Cl, and further to pressures near one atmosphere. Phase diagrams for each side of the triangle were constructed prior to the investigation of the ternary system. The freezing point diagram for the NH_3–NH_4Cl side of the triangle was constructed from the solubility data compiled by Seidell[4] from the work of several investigators. The freezing point diagram for the NH_3–N_2H_4 system was constructed from solubility data published by Friedrichs.[5] Freezing points for various N_2H_4–NH_4Cl mixtures (the third side of the triangle) were determined as a part of this investigation.

Experimental

The solid–liquid equilibria in the binary system N_2H_4–NH_4Cl and the ternary system NH_3–N_2H_4–NH_4Cl were studied by the method of thermal analysis. The phase diagram of the N_2H_4–NH_4Cl system was investigated in the region from 60 to 100 mole % hydrazine. At lower concentrations of hydrazine the equilibrium pressure of the system is well in excess of one atmosphere. The ternary phase diagram was broken up into forty experimental sections for investigation. Each section was characterized by a fixed mole ratio of ammonia to ammonium chloride. Therefore, every ternary mixture investigated had a composition point falling on experimental sections which extended radially from the hydrazine corner to points on the NH_3–NH_4Cl side of the ternary phase diagram lying approximately between 10.5 and 98.7 mole % NH_3 (*e. g.*, see Figs. 3 and 4).

Apparatus.—All freezing point determinations were made in a glass freezing point cell shown in Fig. 1. The glass-spiral stirring rod was operated by intermittent magnetic interaction of a solenoid with the iron slug sealed into the top arm of the stirrer.

The time–temperature cooling curves were obtained by using a Leeds and Northrup Micromax Model S-40000 series self-recording potentiometer with a copper–constantan thermocouple immersed in the well of the freezing point cell. Petroleum ether (b.p. 30–60°) was used as a heat-transfer medium in the thermocouple well. The apparatus was calibrated at the freezing points of distilled water, carbon tetrachloride (−22.6°), chloroform (−63.5°), and the α- and β-forms of diethyl ether (−116.3° and −123.3°).

A cooling rate of 1 to 2 degrees per minute was regulated by the choice of coolant, and the type of jacket used to control the rate of heat transfer from the freezing point cell to the cooling bath.

Mixtures of N_2H_4 and NH_4Cl.—A weighed amount of ammonium chloride was transferred to the freezing point cell through a side arm which was then capped with a vaccine bottle stopper. It was necessary to cool the cell and ammonium chloride below −40° before hydrazine was added since a small amount of hydrazine coming in contact with solid ammonium chloride releases a considerable quantity of gaseous ammonia which could cause excessive pressures. Purified hydrazine was transferred to the freezing point cell from a glass syringe fitted with a No. 26 gage stainless steel hypodermic needle, 1.5 inches long. A glass syringe affords a convenient means of transferring and weighing hydrazine with a minimum of exposure to the atmosphere. At atmospheric pressure as many as 10–15 punctures of the Arthur H. Thomas No. 2330 vaccine bottle stoppers could be made without significant leakage. A freezing point of the mixture was obtained only after the contents of the cell was warmed sufficiently to completely melt the mixture. All freezing points were determined at least twice. The precision obtained was always within 0.5°. Successive additions of hydrazine were made so that freezing points of several compositions were obtained for one addition of ammonium chloride.

Mixtures of NH_3, N_2H_4 and NH_4Cl.—A weighed amount of ammonium chloride was transferred to the freezing point cell. Anhydrous ammonia was slowly distilled into the cell and condensed over the ammonium chloride by cooling the cell in a Dry Ice bath. The amount of ammonia condensed with the ammonium chloride was determined by one or both of the following methods: (1) by the difference in weight of the cell, and (2) by the freezing point of the binary mixture of ammonia and ammonium chloride. The first method was used in all cases where the mole per cent. of ammonia was less than 75. Both methods could be used for mixtures containing from 75 to 88 mole % ammonia, being restricted only by the ammonia pressure developed at the temperature of the measurement. For compositions greater than 88 mole % ammonia, the freezing point of the mixture was used as a measure of concentration, the percentage of ammonia being determined from the NH_3–NH_4Cl phase diagram (Fig. 5).

After the ammonia was added, the freezing point cell was sealed with a vaccine bottle stopper. Several additions of hydrazine were made in the manner described above. It was always necessary to cool the mixture with a Dry Ice bath before each addition of hydrazine.

Materials.—Synthetic anhydrous ammonia was obtained from the Verkamp Corporation. The ammonia was slowly distilled from a 50-pound cylinder through a glass wool plug, and condensed directly into the freezing point cell. Under these conditions the distilled ammonia froze at −77.5 to −78° which agrees well with the literature value.

Matheson Coleman and Bell anhydrous hydrazine was allowed to stand over flaked sodium hydroxide for 24 hours and then distilled. The distillate froze at 1.5 to 2.0° which agrees with the freezing point of hydrazine recorded in the literature.[6] The purified hydrazine was stored in the distillation receiver and under dry nitrogen at one atmosphere. A short side arm attached to the receiver was capped with a rubber vaccine bottle stopper so that the purified hydrazine could be pulled through the hypodermic needle into a glass syringe without exposure to the atmosphere.

Mallinckrodt Analytical Reagent grade ammonium chloride was dried overnight at 105°, and stored in a desiccator.

Results and Discussion

The System N_2H_4–NH_4Cl.—The freezing point diagram for mixtures of hydrazine and ammonium chloride is given in Fig. 2. Since it is known that the reaction $N_2H_4 + NH_4Cl \leftrightarrows NH_3 + N_2H_5Cl$ takes place, and since no satisfactory analyses of the equilibrium solid phase associated with the peritectic point could be obtained, there is uncertainty concerning the interpretation of these data. For the purpose of our study, we have assumed that the system N_2H_4–NH_4Cl is a quasi-binary section of the general ternary diagram NH_3–HCl–N_2H_4. For this assumption to be strictly valid, no ammonia or hydrazine must escape into the vapor phase, and the composition of the solid phases must be an additive compound of N_2H_4 and NH_4Cl. Under the conditions under which the system was studied, the amount of ammonia and hydrazine in the vapor phase was negligible. It is our belief that, in the presence of an appreciable concentration of ammonia, the more basic character

of ammonia over hydrazine will inhibit the conversion of hydrazine and ammonium chloride mixtures to ammonia and hydrazine hydrochloride. In any case, these uncertainties concerning the interpretation of the N_2H_4–NH_4Cl section do not in any way invalidate the important synthetic implications involved, for the results obtained in this study help to form the experimental basis for an interesting and unique method for isolating anhydrous hydrazine.

The freezing point diagram shows two invariant points for the system. A peritectic point is located on the diagram at −2.5° and 63.0 mole % N_2H_4. The crystals which melt incongruently at this invariant point have been tentatively assigned the formula NH_4Cl–N_2H_4, but, for the reasons stated above, the composition of this phase is uncertain. The eutectic composition and temperature were not accurately established because of the viscous nature of the solutions in the vicinity of the eutectic point. However, the eutectic point has been

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

estimated to be about −60° and 77.5 mole % N_2H_4. The significance of these two invariant points to the general ternary system NH_3–HCl–N_2H_4 will be discussed in the next section.

The Ternary System NH_3–N_2H_4–NH_4Cl.—The freezing points of various ternary mixtures of ammonia, hydrazine and ammonium chloride are not listed in this paper because of the voluminous amount of data[7] taken. A temperature–composition diagram was constructed for each group of freezing point data having a common mole ratio of ammonia to ammonium chloride. Forty such diagrams were prepared from the freezing point data. Two of these T–C Sections are shown in Figs. 3 and 4. The breaks in these diagrams are points at which the ternary liquidus is saturated with respect to two solid phases.

All the compounds and invariant points which occur in the binary systems NH_3–NH_4Cl, NH_3–N_2H_4 and N_2H_4–NH_4Cl also appear in the ternary system. The freezing point diagram for the condensed system N_2H_4–NH_4Cl has been given in Fig. 2 and already discussed. The freezing point diagram for the binary system NH_3–NH_4Cl is given in Fig. 5. Whereas the composition of the binary

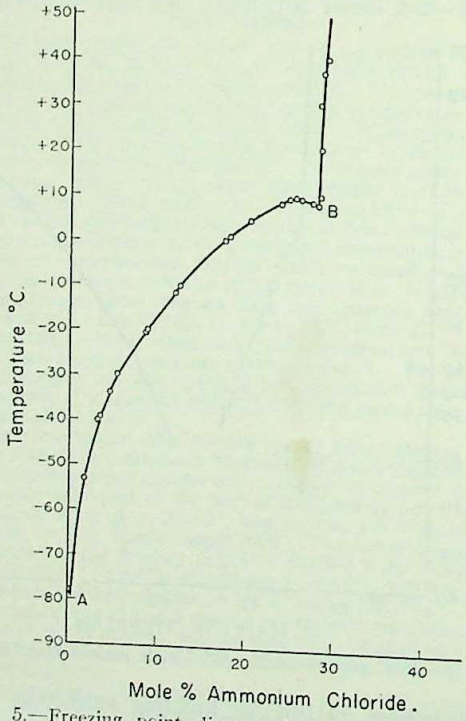

Fig. 5.—Freezing point diagram for the binary system NH_3–NH_4Cl.

compound $NH_4Cl{\cdot}3NH_3$ is well established, its melting point has been variously reported as 7, 7.6, 9.8 and 10.7°. The maximum in the curve in Fig. 5 occurs at 9.8°; however, Watt and McBride[8] in a recent paper seemed to prefer a lower value. Neither of the two eutectic points of the system are well defined by the data. The ammonia-rich eutectic point is estimated to be at *ca.* −81° and 0.5 mole % NH_4Cl, and the other eutectic point estimated to be at +8° and 27.5 mole % NH_4Cl. The phase diagram for the binary system NH_3–N_2H_4 is given in Fig. 6. No binary compound is formed; the eutectic point is at −80° and 7.36 mole % N_2H_4.

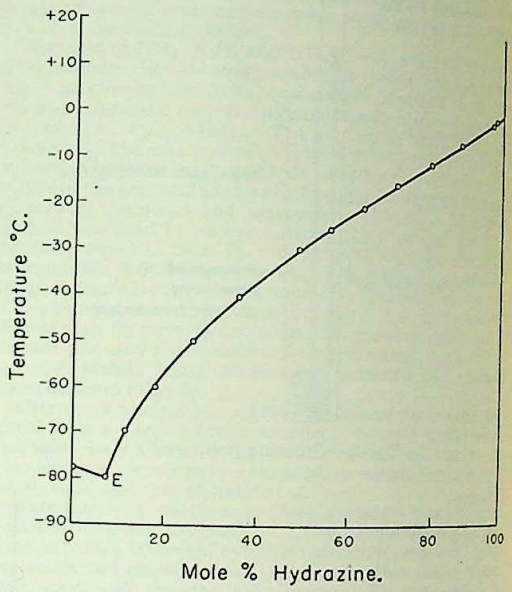

Fig. 6.—Freezing point diagram for the binary system NH_3–N_2H_4.

The invariant points in these binary systems are points of origin for curves of twofold saturation which divide the ternary liquidus into various primary fields of crystallization. The positions of these curves in the ternary phase diagram are set by the ternary breaks established by the ternary T–C Sections. The ternary phase diagram thus constructed appears in Fig. 7. Five primary

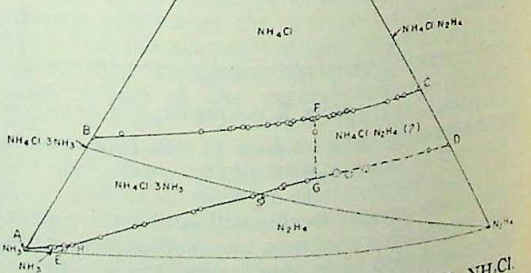

Fig. 7.—Phase diagram for the system NH_3–N_2H_4–NH_4Cl.

fields of crystallization appear in the ternary system NH_3–N_2H_4–NH_4Cl. The primary fields of crystallization for the congruent melting hydra-

zine, ammonium chloride and ammonium chloride 3-ammoniate were assigned by inspection to those areas in which their composition points lie. The remaining area in the ternary phase diagram is assigned as the primary field of crystallization for the incongruent melting compound which, as stated above, we have assumed but not yet proved to be $NH_4Cl \cdot N_2H_4$. The hydrazine field was further confirmed by the secondary temperature breaks in the thermal analysis curve. Mixtures having constant NH_3/NH_4Cl ratios in the hydrazine field showing the same secondary temperatures breaks have composition points which form a series of straight lines passing through the N_2H_4 corner of the ternary diagram.

A summary of all the invariant points in the ternary phase diagram is given in Table I.

TABLE I

INVARIANT POINTS

Point	Solids	Liquid composition, % NH_4Cl	% NH_3	% N_2H_4	Temp., °C.
A	$NH_3 + NH_4Cl \cdot 3NH_3$	0.5	99.5	...	*ca.* −81
B	$NH_4Cl \cdot 3NH_3 + NH_4Cl$	27.5	72.5	...	+ 8
C	"$NH_4Cl \cdot N_2H_4$" + NH_4Cl	37.0	...	63.0	− 2.5
D	N_2H_4 + "$NH_4Cl \cdot N_2H_4$"	22.5	...	77.5	*ca.* −60
E	$NH_3 + N_2H_4$	..	92.64	7.36	−80
F	$NH_4Cl + NH_4Cl \cdot 3NH_3$ + "$NH_4Cl \cdot N_2H_4$"	32.3	25.0	42.7	−17
G	$N_2H_4 + NH_4Cl \cdot 3NH_3$ + "$NH_4Cl \cdot N_2H_4$"	18	32	50	*ca.* −67
H	$NH_3 + NH_4Cl \cdot 3NH_3 + N_2H_4$	2.0	89.0	9.0	−83
S	$NH_4Cl \cdot 3NH_3 + N_2H_4$	15.0	44.9	40.1	−60

Point F, a ternary peritectic point, is at −17° and 42.7 mole % N_2H_4, 32.3 mole % NH_4Cl. The invariant reaction occurring at this point is

Liquid + NH_4Cl = $NH_4Cl \cdot 3NH_3$ + "$NH_4Cl \cdot N_2H_4$" + heat

The curves FG and GD are dashed lines because the viscous nature of the solutions in this area of the phase diagram made it difficult to obtain freezing points. Point G, a ternary eutectic point, is estimated to be at −67° and 50 mole % N_2H_4, 18 mole % NH_4Cl. Point H, a ternary eutectic point, is at −83° and 9.0 mole % N_2H_4, 2.0 mole % NH_4Cl.

The temperature along the twofold saturation curve between the ternary eutectic points G and H passes through a maximum at point S which is called a saddle point. The temperature at the saddle point is −60°. The composition points for $NH_4Cl \cdot 3NH_3$ and N_2H_4 are points of maximum temperature in their respective areas, and with the saddle point form a straight line known as a quasi-binary section line of the ternary system.

In order to make clear the importance of the results presented in this paper to the synthesis of anhydrous hydrazine, the following example is given: A typical hydrazine reaction mixture may be composed of 99 mole % NH_3, 0.4 mole % N_2H_4 and 0.6 mole % NH_4Cl. This composition point lies in the field of crystallization for ammonium chloride 3-ammoniate. The equilibrium ternary liquid compositions along the curve GH represent the practical limits for fractional crystallization of ammonium chloride from these solutions. An equilibrium liquid composition near the saddle point S may be obtained by proper adjustment of the ammonia concentration of the ternary mixture by evaporation and cooling to crystallize ammonium chloride 3-ammoniate. At the saddle point where the equilibrium temperature is −60° the mole ratio of hydrazine to ammonium chloride in the liquid phase is 2.7:1. At this mole ratio about 63% of the hydrazine is in excess over the equivalent ammonium chloride in solution, and this excess hydrazine can be separated in the anhydrous form by distillation. The maximum mole ratio of hydrazine to ammonium chloride is obtained if less ammonia is evaporated and crystallization of the 3-ammoniate is carried to the ammonia-rich ternary eutectic point H; however, more refrigeration is required since the equilibrium temperature is −83°. The N_2H_4 to NH_4Cl mole ratio in the liquid phase is 4.5:1. Thus, a maximum (theoretical) of about 78% of the hydrazine can be freed by this procedure.

Solvents Having High Dielectric Constants. V. Limiting Ionic Equivalent Conductances in N-Methylacetamide at 40°[1,2]

BY LYLE R. DAWSON, EUGENE D. WILHOIT, RICHARD R. HOLMES AND PAUL G. SEARS

RECEIVED FEBRUARY 13, 1957

Studies have been made concerning the conductance behavior at 40° of twenty uni-univalent electrolytes in N-methylacetamide at concentrations in the range 1–165 × 10^{-4} *N*. The limiting equivalent conductance for each electrolyte has been evaluated using a Shedlovsky plot of Λ'_0 *versus C*. Consistency within the results and with previous work is evidenced by numerous checks concerning independent conductances of ions. The results indicate that 2,4,6-trinitrophenol, hydrogen chloride and all of the salts are completely dissociated in dilute N-methylacetamide solutions. In contrast to the differentiating action of isomeric dimethylformamide, N-methylacetamide acts as a leveling solvent toward acids and partially substituted ammonium salts. Values of the limiting ionic equivalent conductances which are based upon the octadecyltrimethylammonium octadecylsulfate and the trimethylphenylammonium benzenesulfonate methods show good agreement.

Introduction

The second and the fourth papers in this series[3,4] have described the conductance behavior of thirty-one uni-univalent electrolytes in N-methylacetamide (NMA), an unusual organic solvent which is characterized by an extremely high dielectric constant (165.5 at 40°) and extensive dissolving and dissociating power. The results which have been reported heretofore indicate that most soluble salts are completely dissociated in dilute NMA solutions and that analyses of conductance data for solutions having concentrations greater than 1 × 10^{-2} *N* are complex owing to a very pronounced increase in viscosity with increasing concentration. NMA acts as a leveling solvent in its dissociating action toward partially substituted ammonium halides, and series of relative cationic and anionic limiting conductances provide considerable evidence that unusual relative solute–solvent interactions are operative in NMA solutions.

The objectives of the research which is reported herein were to determine the conductance behavior of some typical acidic electrolytes, to evaluate limiting ionic equivalent conductances by approximation methods and to extend generally the previous studies using NMA as an electrolytic solvent.

Experimental

Apparatus.—Resistances were measured with a Jones bridge assembly at frequencies of 500, 1000 and 2000 cycles per second. No significant dependence of resistance upon the frequency of the impressed signal was observed. Three flask cells, which have been described previously,[5] were used throughout this work. The cell constants were determined by the intercomparison method using Jones cells having constants which had been evaluated by the method of Jones and Bradshaw.[6] The cells and their contents were maintained at 40.00 ± 0.02° in a constant temperature bath filled with light mineral oil.

Salts.—Octadecyltrimethylammonium octadecylsulfate, octadecyltrimethylammonium nitrate, octadecyltrimethylammonium iodide and potassium octadecylsulfate were prepared by the methods described by Thompson and Kraus.[7] The observed melting points of the final products were 153–156°, 200–202°, 235–238° and 181–183°, respectively. These four salts and the two benzenesulfonates were considered suitable for use only when their equivalent conductances changed less than 0.15% after successive recrystallizations.

Reagent grade potassium and sodium bromates, ammonium perchlorate and ammonium nitrate were recrystallized twice from distilled water prior to drying under suitable conditions.

The preparation and/or purification of the remaining electrolytes have been described in previous papers.[5,8–10]

Solvent.—NMA was prepared and purified as described previously.[4] The solvent which was used in this work froze above 29.5° and had the following physical properties at 40°: conductivity, 1–3 × 10^{-7} ohm^{-1} cm.$^{-1}$; density, 0.9420 g./ml.; viscosity, 0.0302 poise; dielectric constant, 165.5 (at 10 megacycles).

Solutions.—All solutions were prepared on a weight basis and transfers were made in a dry box under a positive pressure of nitrogen. Friedman–La Mer weighing pipets were used for making successive additions of approximately 0.02 *N* stock solution to the solvent contained in a conductance cell. All weights were corrected to vacuum. The densities of the dilute solutions were assumed to be equal to that of the solvent. The conductivity of the electrolyte was obtained by subtracting the conductivity of the solvent from that of the solution. The maximum solvent correction usually did not exceed 3% of the total conductance.

Results

Owing to its extensive nature, a tabulation of corresponding values of the equivalent conductance and the concentration for each of the twenty electrolytes is not presented here.[11] The results are compactly summarized in Tables I, II and III. Similar trends in the data have been illustrated graphically in previous papers in this series.

Discussion

The plot of Λ *versus* $\sqrt{C}$ for each electrolyte is linear over the entire experimental concentration range which, as a result of limited solubilities in some cases, varied from 1–14 × 10^{-4} *N* for OctdMe$_3$NOctdSO$_4$ to 1–165 × 10^{-4} for KSCN. Ac-

cording to the Onsager equation[12]

$$\Lambda = \Lambda_0 - \left[\frac{8.204 \times 10^5}{(DT)^{3/2}}\Lambda_0 + \frac{82.42}{(DT)^{1/2}\eta}\right]\sqrt{C}$$

the theoretical limiting slope of a plot of Λ *versus* $\sqrt{C}$ for a uni-univalent electrolyte in NMA at 40° should be $-[0.0695\ \Lambda_0 + 11.99]$. With the single exception for hydrogen chloride, the data presented in Table I show that the experimental slope in every case is numerically greater than the Onsager slope; the differences range from 0 to 20% with a mean of 9%. Although the numerically greater experimental slopes perhaps suggest some extent of ionic association, it is believed that the nature of the slopes of the plots of Λ *versus* $\sqrt{C}$ for electrolytes in NMA is greatly influenced by the viscosities of the solutions rapidly increasing with increasing concentration (for example, the approximate relative viscosities of 0.01, 0.5 and 1.0 *N* solutions of a typical uni-univalent electrolyte in NMA are 1.01, 1.55 and 2.25, respectively[13]).

Values of the limiting equivalent conductances were calculated directly from the experimental equivalent conductance data using the Shedlovsky rearrangement of the Onsager equation.[14] Values of the limiting equivalent conductance calculated in this manner are designated as Λ'_0 and generally are found to deviate from the true value for the limiting equivalent conductance by a linear function of the concentration as

$$\Lambda'_0 \equiv \frac{\Lambda + \beta\sqrt{C}}{1 - \alpha\sqrt{C}} = \Lambda_0 + BC$$

which for electrolytes in NMA at 40° becomes

$$\Lambda'_0 \equiv \frac{\Lambda + 11.99\sqrt{C}}{1 - 0.0695\sqrt{C}} = \Lambda_0 + BC$$

As in previous studies,[3,4] the plot of Λ'_0 *versus* C for each electrolyte is linear over the entire experimental concentration range and is characterized by a small negative slope probably resulting from viscosity effects. Data pertinent to plots of Λ'_0 *versus* C are summarized in Table II. Corresponding values of Λ_0 in Tables I and II in some cases differ by a few hundredths of a unit; however, it is believed that those in Table II are probably more accurate inasmuch as a preferable extrapolation procedure was used.

A survey of the values of Λ_0 in Table II together with those obtained in previous studies reveals numerous confirmations of the Kohlrausch law of independent ionic conductances therein indicating consistency within the results reported herein as well as with those published previously.

On the basis of experimental and theoretical structural considerations, Thompson and Kraus[7] have suggested that the limiting equivalent conductances of the $OctdMe_3N^+$ and the $OctdSO_4^-$ ions are approximately equal and can be evaluated by halving the limiting equivalent conductance of $OctdMe_3NOctdSO_4$. If the limiting equivalent conductances of these two large similarly-shaped ions are known, other limiting ionic equivalent

conductances can be evaluated from properly related data for electrolytes containing either the $OctdMe_3N^+$ or the $OctdSO_4^-$ ion and for other electrolytes having common anions or cations. Table III contains values of limiting ionic conductances in NMA at 40° which are based upon this approximation method. Data from previous papers[3,4] were utilized also in order to provide an up-to-date comprehensive tabulation for NMA solutions.

The trimethylphenylammonium and the benzenesulfonate ions, like the $OctdMe_3N^+$ and the $OctdSO_4^-$ ions, are relatively large similarly-shaped species having comparable dimensions and are characterized by almost equal limiting conductances in aqueous solutions.[15,16] Consequently, it is worthwhile to note that the results in Table II would be altered less than 0.5% if Me_3PhNO_3SPh were used as the reference electrolyte instead of $OctdMe_3NOctdSO_4$. On the basis of data for aqueous and NMA solutions, therefore, Me_3PhNO_3SPh is potentially applicable as a reference electrolyte for approximating limiting ionic equivalent conductances in other solvents. Inherent advantages may be utilized also inasmuch as Me_3PhNO_3SPh, NaO_3SPh and Me_3PhNI are commercially available, easily purified and readily soluble in several common solvents in which $OctdMe_3NOctdSO_4$ and $KOctdSO_4$ are practically insoluble.

Based on the data in Table III, the limiting equivalent conductance–viscosity products for the Bu_4N^+ and the Pi^- ions in NMA are 0.236 and 0.356 ohm^{-1} $cm.^2$ $equiv.^{-1}$ poise and are about 35% greater than the corresponding products for aqueous solutions. Nevertheless, the ratio of the limiting equivalent conductance of the picrate ion to that of Bu_4N^+ ion in NMA differs less than 3% from the same conductance ratio for aqueous solutions and consequently indicates considerable parallelism in the relative conductance behavior of these large ions in NMA and in water.

Although the ratio of the viscosity of NMA at 40° to that of water at 25° is 3.4, the ratio of the limiting equivalent conductance of an ion in water at 25° to that of the same ion in NMA at 40° varies from 2.5 for the Bu_4N^+ ion to 8.7 for the potassium ion, excluding the solvated proton and several ions for which proper comparison data are unavailable. The broad range of values for the conductance ratio together with the very high values for the conductance–viscosity products for the Bu_4N^+ and Pi^- ions suggests that unusual relative solute–solvent interactions and perhaps significant variations between the macroscopic viscosities of the solutions and the microscopic viscosities in the immediate vicinities of the ionic species may be operative in NMA solutions. Novel positions which are occupied by several ionic species in series of decreasing cationic and anionic limiting equivalent conductances are readily discernible from the data presented in Table III.

In comparing the behavior of hydrogen chloride and 2,4,6-trinitrophenol (picric acid) in the isomeric amides, N-methylacetamide and N,N-dimethylformamide, it is interesting to note that the former and the latter[8] act as leveling and differentiating solvents, respectively, toward the acidic solutes. The extent of substitution on the amide-N not only drastically affects the magnitudes of physical properties but also apparently is reflected in the proton-accepting properties of the medium.

Other conductance studies involving the behavior of multivalent electrolytes in NMA and also the behavior of uni-univalent electrolytes in iso-viscous mixtures of NMA and tertiary butyl alcohol and in mixtures of isomeric NMA and N,N-dimethylformamide are in progress in this Laboratory.

Interaction of Polyelectrolytes with the Electrical Double Layer on Mercury–Water Interfaces. II. Influence of Added Ionized Polyacids on the Differential Capacity*

BY ISRAEL R. MILLER[1] AND DAVID C. GRAHAME

RECEIVED NOVEMBER 23, 1956

The differential capacity of the electrical double layer at the interface between mercury and aqueous 0.1 *N* NaF solutions containing various amounts of the salts of dibasic and polybasic acids at different temperatures has been measured. A series of polyacids has been investigated, starting with simple dibasic acids, through the relatively low molecular weight polyaspartic and polyglutamic acids, and extending finally to very high molecular weight samples of polymethacrylic acid of various degrees of polymerization. It has been found that the results can be interpreted by assuming (a) that even short hydrocarbon chains produce a squeezing-out effect which appears as an adsorption of anions, and (b) that polybasic anions are completely expelled from the interface when the mercury carries even a small negative charge, and strongly attracted when the charge is slightly positive. Adsorption–desorption peaks are produced at the potential of the electrocapillary maximum through the operation of this effect. It seems clear that a monolayer of anions is formed.

Introduction

From the electrocapillary properties of soluble acetates and oxalates it is known,[2–4] that the car-

boxylate ion is little or not at all adsorbed on an uncharged mercury surface. The object of the present work has been to investigate the coöperative influence of a series of carboxylate groups located on a polymeric chain. The plan has been to start with the simplest dicarboxylate ion, oxalate, and to work up to ionized polymethacrylic acid in easy stages.

The adsorption of ions on mercury takes place in four somewhat different ways, and it is helpful to have these in mind even though it is not always possible to sort them out experimentally. There is, in the first place, simple electrostatic attraction (Type I adsorption). On an uncharged surface this type of attraction is deemed absent, and whatever adsorption is found is attributed to something else.

Electrostatic attraction gives rise to the diffuse double layer, whose mathematical exposition was given by Gouy and Chapman, but the effects of electrostatic attraction are not wholly predictable by means of that theory because the ions in question have a finite distance of closest approach to the interface, and the thickness and dielectric properties of this "inner region" of the double layer are of controlling importance in most cases, as was first pointed out by Stern. These properties are not even yet fully understood, although they have formed the subject of many publications.[5]

A second type of adsorption of ions (to be called Type II) is related to what is commonly called chemisorption. Many anions form chemical bonds with mercury, the strength of the bond depending upon the surface charge density. The concept of adsorption on mercury as chemical bond formation was clearly stated as long ago as 1908 by Gouy.[6] The ions which show this phenomenon most strongly ($S^=$, I^-, SCN^-, Br^-) are those which form highly insoluble salts with mercury, and the two phenomena are obviously related. One can say either that a covalent bond is formed between mercury and the anion, or one can attribute the attraction to the polarizability of the anion. Undoubtedly a large polarizability leads to strong covalent bond formation, so that the two statements are equivalent.

Type II adsorption is most clearly recognizable at the potential of the electrocapillary maximum (e.c.max.) because Type I adsorption is then absent. The adsorption of anions (from whatever cause) lowers the surface tension and shifts the potential of the e.c.max. toward more cathodic values. A more distinctive test for Type II adsorption lies in the rather rapid rise in the differential capacity which occurs as the surface is positively charged, but since this also happens with Type I adsorption of bivalent and polyvalent ions (especially when the charge is concentrated at the center of an ion, as in $SO_4^=$ rather than distributed along a chain, as in the adipate ion), both tests must be positive before one can safely conclude that Type II adsorption is operative.

A third type of adsorption (Type III) is that exhibited by such anions as NO_3^-, ClO_4^-, ClO_3^- and some others. These anions are known to be adsorbed on mercury[2-4] at the potential of the electrocapillary maximum (by the criteria mentioned under Type II adsorption), but it is almost inconceivable that they should form covalent bonds with mercury under these conditions. A more probable explanation was given many years ago by Frumkin, Reichstein and Kulvarskaja[7] in connection with their study of the adsorption of anions at an air–water interface. It was found that nitrate and perchlorate ions are adsorbed at an air–water interface (though not so strongly as at a mercury–solution interface) and it was pointed out that these ions, by virtue of their size, possess what we should nowadays call large structure-breaking tendencies. The latter effect can be seen, for example, by comparing the relative partial molal entropies of water in various solutions of 1:1 electrolytes.[8] Frank and Robinson say[8] "For the univalent electrolytes the maximum disturbing effect is shown by KNO_3. This might be attributed to the plane triangle structure of the nitrate ion and its inability to fit smoothly into the four coördinated structure of water." Although data for perchlorates are not available, we would predict an almost equally strong effect upon the relative partial molal entropy of water. It seems clear that nitrate and perchlorate ions at an interface are at a lower potential energy than ions in the interior of the solution because of the fewer hydrogen bonds broken by an ion in that location. The adsorption of nitrate ion on mercury is probably favored relative to its adsorption at an air–water interface by the effectively infinite dielectric constant of the metal, since this makes it possible for the ion to lose water of hydration on the side of the metal without a major loss of its energy of solvation.

It is convenient to say that these anions are squeezed out of solution, and the reality of the effect can hardly be doubted in the case of the adipate ion, for instance, where the hydrophobic part of the molecule unquestionably squeezes the ion to the interface.

A fourth type of adsorption is to be expected when one stops to consider the possibility of lateral interaction between ions which have been squeezed out of solution. It is well known that a monolayer of un-ionized molecules can form at an interface, and it is clear that in many cases lateral interaction (van der Waals forces) will help to stabilize the layer. The same type of interaction is to be expected with anions of long-chain organic acids and, when found, it will be called Type IV adsorption. Strictly speaking it is a sub-class of Type III adsorption, since anions which show strong lateral interaction would normally be expected to be of a type which would be squeezed out of solution also.

Experimental Details

The differential capacity measurements were carried out on an apparatus developed by one of us and described previously.[9] Some surface tension measurements also were made by the drop-time method, but better results could be obtained by integrating the differential capacity data twice

(5) The most recent is that of J. R. Macdonald, *J. Chem. Phys.*, **25**, 364 (1956), which will serve as a key to the earlier literature.

with respect to potential in cases where this procedure is allowed. However, the most interpretable data turn out to be capacity values themselves, and the present paper will be concerned with these.

Although the adsorption process *per se* is usually very fast in measurements of this kind, considerable time is needed for large molecules to diffuse to the surface. The extent to which diffusion equilibrium is attained can be estimated by taking measurements at different times on a stationary droplet or by taking measurements on a moving droplet whose rate of growth is subject to control. In a series of control experiments the rate of flow of the mercury was altered, keeping constant the size of the droplet at the moment of measurement. No significant variations of capacity attributable to the slow rate of diffusion of the adsorbate could be noted except at or near the potential of the desorption peaks of polymeric anions. An example of the observed behavior in such a case is shown in Fig. 1 which shows the

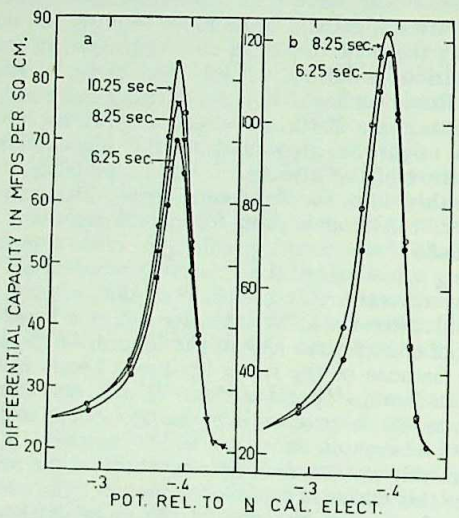

Fig. 1.—Differential capacity curves taken at same Hg drop size but different drop ages. Ionized PMA at 61°; $z = 4500$; supporting electrolyte, 0.1 N NaF + 0.001 N NaOH; concn. of PMA = 0.000125 N (a) or 0.00025 N (b).

diffusion lag to exert an appreciable effect on the measurements only in very dilute solutions of the adsorbate. To avoid this source of uncertainty, the measurements reported below deal only with solutions concentrated enough not to show this effect. The matter was very thoroughly checked over a wide range of conditions. For the purposes of the present paper, it does not matter greatly, however, since the capacity curves are to be used directly and not integrated. (It is the integrated curves which are most seriously in error if the diffusion is too slow.)

Results and Conclusions

Dibasic and Tribasic Acids.—The sodium salts of oxalic, adipic, glutaric and 1,2,3-propanetricarboxylic acids were dissolved in a supporting electrolyte composed of 0.1 N NaF + 0.002 N NaOH. The supporting electrolyte was added as a means of ensuring that the results would be comparable to those obtained later using polymeric acids in solution. The principal results are shown in Fig. 2.

It will be observed that the anions of these acids raised the capacity in a characteristic manner, different for each. The approximate values of the potential of the electrocapillary maximum (e.c. max.) are marked with short vertical lines on the figures. It is at these potentials that the influence of the anion is most simply seen.

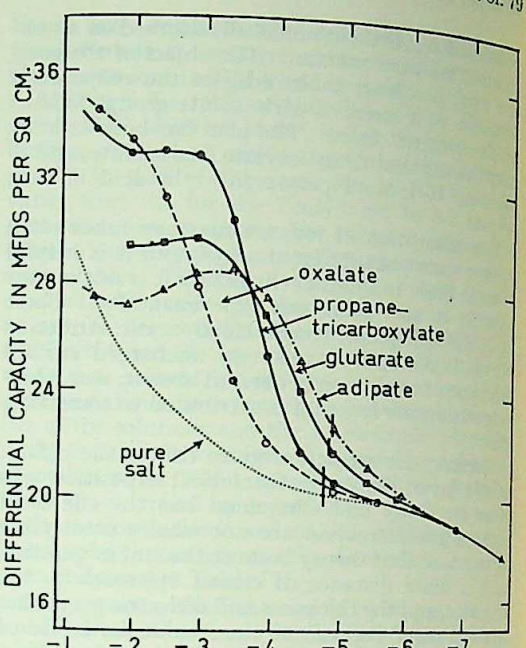

Fig. 2.—Differential capacity curves in presence of 0.06 N solutions of sodium salts as indicated. Supporting electrolyte, 0.1 N NaF + 0.002 N NaOH; $t = 25°$.

The oxalate ion raises the differential capacity of the double layer at the potential of the e.c.max. only very slightly, and its behavior is only a little different from that of the sulfate ion at all potentials (data not shown). From purely chemical considerations one would not expect either the sulfate or the oxalate ion to be chemisorbed even on positively charged mercury, and in spite of some conflicting evidence on this point with regard to the sulfate ion,[4] that is the assumption upon which we shall proceed to discuss further results.[10] Therefore the curve for the oxalate ion will be regarded as normal for a divalent anion with charges not much separated.

The glutarate ion, with three CH_2 links in the chain, would be expected to exhibit mild outsqueezing (Type III adsorption), and this is the presumed reason for the increased capacity (Fig. 2). It is usual for adsorption of an anion to increase the capacity of the double layer, no clear-cut exceptions to this rule being known, except as indicated below. The "hump" in the curve has been explained by one of us (D.C.G.)[11] as the result of the formation of a quasi-crystalline semirigid layer of solvent at the interface. A different interpretation relating to the orientation and re-orientation of the adsorbed molecules will be presented by the other author (I.R.M.) in a separate publication. In this paper we shall not defend either point of view.

The adipate ion, with four CH_2 groups, con-

(10) It does not really matter in the ensuing discussion whether this assumption is strictly correct or not, and it greatly simplifies the presentation.

tinues the trend set by the glutarate ion and reinforces our explanation of it. It is interesting, then, to compare the behavior of the anion of 1,2,3-propanetricarboxylic acid. This can best be thought of as a glutarate ion with one H atom replaced by carboxylate. The marked change in the differential capacity curve shows two effects of increasing the charge on the ion. First, it suppresses the out-squeezing effect at the e.c.max. By increasing the energy of interaction of the ion with water, the ion is kept in solution, away from the interface. At more anodic potentials the capacity rises rapidly, and this is characteristic of an ion of multiple charge. In other words, Type I adsorption becomes dominant.

Although we do not have comparable data for the formate ion, it seems reasonable to suppose that its differential capacity curve on mercury under these conditions would resemble that of the pure salt shown as a dotted line in the figure. If so, the curves for formate, oxalate and propanetricarboxylate ions would illustrate well the effect of increasing the charge on an anion.[11a] (Cations show no such effect.)

Polyaspartic and Polyglutamic Acids.—The polymers used for this investigation were of relatively low molecular weight (degree of polymerization about 30). Their behavior is closer to that of the dibasic and tribasic acids than to that of the high molecular weight polymethacrylic acid (PMA). The repeating unit in polyaspartic acid is NHCH(CH₂COOH)CO which makes it roughly comparable to butyric or valeric acid. The relatively large number of hydrophobic groups per carboxylate ion accounts for the rather large capacity seen in Fig. 3 even at the potential of the e.c.max. This is strong Type III adsorption. Although each anion carries a total of about 30 negative charges, these are so uniformly distributed and so widely spaced along the chain that adsorption takes place even when the mercury surface is negatively charged, a somewhat noteworthy result.

The data for the curve at 0.000048 *N* are reproduced as a matter of interest, but at this low concentration it would be unwise to disregard the effect of the low rate of diffusion of the adsorbate, which may lead to considerable error in the results.

The absence of a "hump" (except at the lowest concentration) should be pointed out, although no explanation will be offered at this point.

The anion of polyglutamic acid, with one more CH_2 group in the side chain, shows (in Fig. 4) the beginning of what we have called Type IV adsorption. At the highest concentration studied a peak appears in the capacity curves, and the height of the peak is strongly frequency dependent. These peaks are characteristic of adsorption–desorption phenomena of the type studied extensively in the past using un-ionized adsorbates.[12–14] The appearance of such peaks has always been associated with the formation of a monolayer, and this appears to be a reasonable explanation here also, except that in this instance the monolayer is probably incomplete as indicated by facts which will be explained presently. The layer will be called a monolayer in what follows to avoid cir-

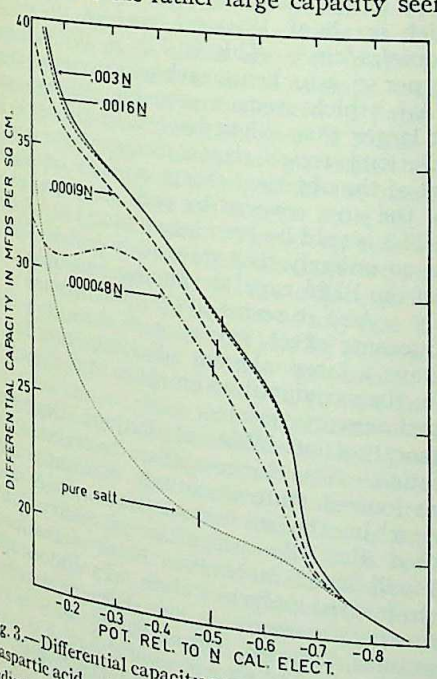

Fig. 3.—Differential capacity curves in presence of ionized polyaspartic acid. $t = 25°$; drop age = 30.25 sec.; concn. as indicated. Supporting electrolyte as in Fig. 2.

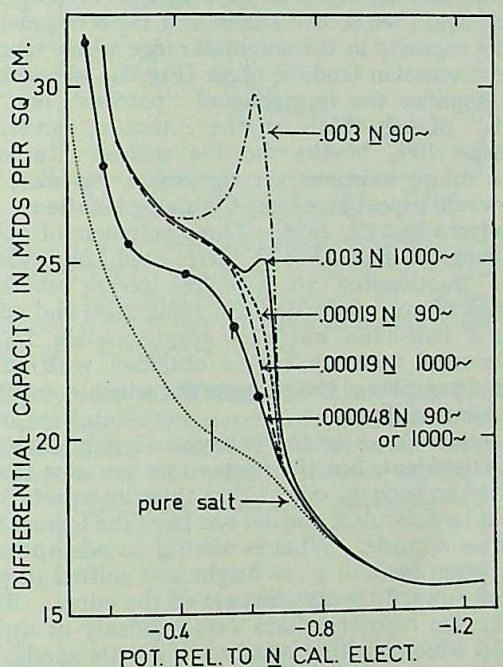

Fig. 4.—Differential capacity curves in presence of ionized polyglutamic acid. $t = 25°$; drop age = 30.25 sec.; freq. and concn. as indicated. Supporting electrolyte, 0.1 *N* NaF + 0.0015 *N* NaOH.

(11a) NOTE ADDED IN PROOF.—Strictly speaking one should compare the acetate, succinate, and tricarboxylate ions. The trend is the same as that shown in Fig. 2.

cumlocution. The significance of the peak in the capacity curve is that at the potential involved there is a sudden potential-dependent change in the composition of the double layer corresponding to the displacement of solvent by adsorbate. It is of interest that in Fig. 4 the peak occurs approximately at the potential of the e.c.max., which indicates, as one would expect, that a monolayer of anions does not form readily on a negatively charged surface even when the molecule has a considerable number of hydrophobic groups tending to put it there.

With non-electrolytes two desorption peaks are generally observed.[12] A second peak has not been observed in any of the work described in this paper, presumably because it is impossible to desorb a negatively charged ion from a positively charged surface by making the surface more positive.

In somewhat more dilute solutions of polyglutamic acid (~0.0002 *N*) there is a small dispersion of the capacity in the potential range where monolayer formation tends to occur (Fig. 4). Probably this signifies the formation of "patches" or "islands" of adsorbate at the interface, covering perhaps 10% of the metallic surface. In still more dilute solutions the dispersion vanishes, as one would expect according to this explanation.

Polymethacrylic Acid.—Three polymers of polymethacrylic acid (PMA) were used, and these were fractionated to samples having average degrees of polymerization z of 1950, 2600 and 4500 with a half-band width of approximately 7%.[15] Differential capacity curves obtained with fully ionized samples of the polymer for which $z = 1950$ are shown in Fig. 5.

A resemblance to the behavior of polyglutamic acid is evident, but the phenomena are now exaggerated to such an extent that their interpretation would be difficult if one did not have the former results as a guide. What is seen is an adsorption–desorption peak of great height and shifted in potential toward the anodic part of the curve. The rise in the capacity starts very suddenly at a potential which is either equal to or a little anodic to that of the e.c.max. To the left of the peak there is undoubtedly a surface layer of anions (analogous to the surface layer of polymethacrylic acid reported earlier[16]). The low value of the capacity in this state is attributed to the fact that once a monolayer of anions is formed, further increase in the concentration of anions occurs only slowly. Since the capacity was not abnormally low under similar conditions in Fig. 4, it was assumed that monolayer formation was incomplete, as stated above.

It is of interest that the results shown in Fig. 5 are frequency independent and occur at low temperatures (0°) as well as at higher temperatures, where the results (not shown) are not qualitatively different except that at higher temperatures (*i.e.*, 61°) the peak is about 20% higher than at 0°. The frequency independence indicates that whatever reorientation of molecules or bonds is needed for the formation of the adsorbed layer does not involve a significant activation energy. This fact is in agreement with the observation that the height of the peak is not strongly temperature dependent. A rather more complicated situation exists with un-ionized PMA, where the height of the peak is strongly temperature dependent and only in certain cases frequency dependent.[16] The difference is almost surely attributable to the well known dependence of configuration upon degree of ionization, the anion being relatively uncoiled. This uncoiling presumably involves the breaking of hydrogen bonds, which leaves the ion free to adsorb without further breaking of such bonds.

Samples of ionized PMA of higher molecular weight were indistinguishable in their behavior from the results here presented. The same result was also observed with un-ionized PMA and is attributed as before[16] to the fact that diffusion of whole molecules plays a negligible role. Those molecules which were able to reach the surface in the eight or ten seconds during which the mercury droplet was being formed in the solution gave rise to the observed results; the rest played no part.

The surface area per structural unit of the polymer can be computed as follows. At a potential somewhat to the left of the peak (say +0.180 v., relative to the e.c. max.) the total surface charge density is about 12 μcoul./cm.^{2} or 12×10^{-11} monomoles/cm.^{2}. This is 7.2×10^{13} structural units per sq. cm., hence each unit covers an area of 140 Å.^{2}, which seems reasonable, although somewhat larger than might have been guessed. This calculation is rough, since it disregards the fact that a part of the observed charge could be fluoride ion. If so, the area covered by each structural unit of the PMA would be even larger than 140 Å.^{2}, which seems so unlikely that we tend to believe that the ions of the PMA expel the fluoride ions almost completely. Also it seems likely that because of the outsqueezing effect, ions such as those from PMA will have a large inherent advantage over fluoride ions in their competition for space at the positively charged mercury surface.

Adsorption of PMA at Various Degrees of Ionization.—The electrocapillary behavior of PMA in the ionized state is entirely different from its behavior in the un-ionized state. It is to be expected that the properties of partly ionized PMA will stand in between those of the ionized and un-ionized polyelectrolyte. In Fig. 6 differential capacity curves at four different degrees of ionization are shown. From the figure it is clear that the height and sharpness of the peak diminish as the degree of ionization diminishes and the potential at which the rise starts to occur also becomes more cathodic. At $\alpha = 0.5$ traces of another peak are perceptible at a potential of about −0.7 volt. At $\alpha = 0.1$ this peak is much more pronounced and

(15) The approximate degree of polymerization of the PMA before fractionation was 4000. From this mixed polymer 14 fractions were obtained in a range of z-values from 500 to 5500. The degree of polymerization of the different fractions was obtained by light scattering measurements in a 90° turbidimeter coupled with a Pulfrich visual split-field photometer and also by viscosity measurements in an Ostwald–Fenske viscosimeter where the PMA was present first in 2 *N* NaOH and then in 0.002 *N* HCl. The results were interpreted by means of Figs. 6 and 7 of A. Katchalsky and H. Eisenberg, *J. Polymer Sci.*, **6**, 145 (1951). The mean half width of z was estimated from the differences in the z's as determined by the three methods.

has moved to a more negative potential. Nevertheless, the potential of this peak is more positive than the corresponding desorption potential of un-ionized PMA. The shift in the potential of the peak with the degree of ionization recalls the similar behavior of the peaks which are seen in the presence of monomeric substances at various concentrations (*cf.* behavior of butyric acid in paper I[15] or of aliphatic alcohols in the work of Melik-Gaikazyan[14]). In paper I attention was called to the fact that the desorption potential in the presence of un-ionized PMA does not depend upon the concentration of the polymer. The given reason for this behavior was the assumed constant concentration of polymer segments in the adjacent layers (called the surface phase) to the adsorption layer. This concentration was assumed to be close to the segment concentration in the polymeric coil. By ionizing part of the carboxylic groups and by diluting the surface phase as a consequence of electrostatic repulsion, which increases with the degree of ionization, the over-all concentration of the ionized groups in the surface phase decreases. Thus in this respect increased ionization of a polyelectrolyte is analogous to decreased bulk concentration of a monomeric surface-active substance.

The analogy just drawn is not complete, however, because each un-ionized segment of the chain is terminated by two ionized segments, and these inhibit and tend to prevent the adsorption of the un-ionized segments on the negatively charged surface. For this reason the change with concentration of the potential of the peak shifts in the opposite direction from that of un-ionized monomeric substances.

phase. Differences may arise from the tendency of protons to be attracted toward or repelled from the charged surface, and indeed it was apparent in paper I[15] that undissociated PMA undergoes partial dissociation at a positively charged surface. Another way of looking at the matter is to say that conditions at the interface are so different from those in the interior of the solution that one could hardly expect to find the same values of K_a there if K_a is expressed in terms of the *concentrations* of the species concerned.

In order to be more sure about the extent of ionization at the interface, copolymers of methacrylic acid with methyl methacrylate were prepared and studied. At sufficiently high *p*H values there is no doubt that these copolymers are fully ionized and that the number of ionized groups for a given length of chain depends merely upon the methacrylic acid content of the polymer. Figure 7 shows the results obtained in this way with two copolymers. The peaks occur at the same potentials, and their heights are about what one would expect if the degree of ionization shown in Fig. 6 (computed from the *p*H) is correct. The striking similarity of the two figures indicates that the degree of ionization in the interior of the solution is close to the degree of ionization at the interface.

At sufficiently anodic potentials (below −0.23 v.) the capacity values are almost independent of composition in the case of the two copolymers. The significance of this fact, and also of the sudden upturn at the left-hand end of the two curves, remains in doubt. The polymers of methacrylic acid (Fig. 6) do not show this behavior but exhibit the expected properties on anodic polarization. Thus the fully ionized material shows the lowest capacity and not much turning up, whereas the less fully ionized samples show a larger capacity and an upturn at the end corresponding to the phenomenon of induced ionization discussed in part I.[15]

Summing up, we find that it is usually possible to interpret the differential capacity curves of PMA, both ionized and un-ionized, obtained at a mercury–solution interface and that the results are in accord with previously held views concerning the structure of the double layer.

Anomalous Optical Rotations of Coördination Compounds[1]

BY BODIE E. DOUGLAS AND WILLIAM C. ERDMAN

RECEIVED FEBRUARY 9, 1957

The previously reported change in sign of optical rotation of *d-cis*-$[Co(en)_2Cl_2]Cl$ with a change in concentration is not observed if the light used is monochromatic. Results are compared using a sodium lamp, white light filtered through colored glass filters, and white light filtered through an interference filter plus colored glass filters. The effectiveness of the filter combinations in removing all but the NaD doublet from the spectrum produced by the sodium lamp are compared. A change in magnitude but not in sign of optical rotation was noted for K[Co(edta)] using different light sources.

It is well known that the specific rotations of highly colored coördination compounds can change with wave length of light from large negative values to large positive values. Differences in magnitude or even in sign of rotation also have been reported for solutions of the same complex at the same wave length for different concentrations. The specific rotation of a 0.4% solution of *d-cis*-$[Co(en)_2Cl_2]Cl$ was reported to be −200° and that of a 0.1% solution +215°.[2] Such results have led to expressions of caution that concentrations should be reported in addition to the wave length of light used.[3]

The difficulties have arisen because of the need to increase the light intensity for densely colored solutions and this has been accomplished at the expense of spectral purity. The sodium lamp, with an orange cut-off filter to eliminate any light of shorter wave length, is commonly used as the source of the NaD doublet. For densely colored coördination compounds a more intense source has been obtained by using various filter combinations which give very broad bands of transmitted light.

The purpose of this investigation was to study the change in sign of rotation with change in concentration and to determine the limits of usefulness of several light sources or filter combinations.

Experimental

The *d-cis*-$[Co(en)_2Cl_2]Cl$ was prepared and resolved by the method described by Bailar.[2] The directions refer to the compound as the *levo* form, but the rotation is actually positive at all concentrations for NaD light. The negative rotations are erroneous. The *d*-K[Co(edta)] (edta represents the ethylenediaminetetraacetate ion) was generously provided by Professor Francis P. Dwyer of the University of Sydney. The *d* prefix refers to the rotation of +1000° at 5461 Å.

Optical rotations were obtained with a Rudolph Model 70 Polarimeter. The readings for 0.3 and 0.4% solutions of *cis*-$[Co(en)_2Cl_2]Cl$ using the sodium lamp were obtained using a photoelectric attachment built by W. C. Erdman. All measurements were made at room temperature (25–30°) immediately after mixing the solutions.

The spectra of the sodium lamp with various filters were obtained with a Hilger constant deviation glass prism spectrograph. The transmission curves for the filters and solu-

tions of the complexes were obtained with a Beckman Model DU spectrophotometer. The transmission curves for solutions of *cis*-$[Co(en)_2Cl_2]Cl$ in methyl alcohol were found to be essentially identical with those obtained for freshly prepared aqueous solutions. However, the methyl alcohol solutions did not undergo color changes on standing for periods of an hour or two as was the case for aqueous solutions because of aquation reactions. For this reason methyl alcohol solutions of *cis*-$[Co(en)_2Cl_2]Cl$ were used for the spectral studies of the sodium lamp. The exposures required for the spectrum of the sodium lamp filtered through the solution of *cis*-$[Co(en)_2Cl_2]Cl$ were 30–60 minutes.

Discussion

For densely colored solutions such as *cis*-$[Co(en)_2Cl_2]Cl$ the intensity of the sodium lamp is inadequate for measurements over a wide range of concentrations. In such situations workers[4] have used filter combinations such as a solution of 9.4 g. of $K_2Cr_2O_7$ and 8.9 g. of $CuSO_4 \cdot 5H_2O$ in 300 cc. of water, or for a more intense source a 3% solution of $K_2Cr_2O_7$ has been used. Frequently the authors have not given information concerning the light source used. Werner[5] reported a rotation of −200° for a 0.25% solution of *d*-*cis*-$[Co(en)_2Cl_2]Cl$ in a 2 dm. tube, but does not give details concerning the light source used. The optical density of such a solution is only slightly greater than for a 0.4% solution in a 1 dm. tube for which the reported value[2,4] is also −200°. Presumably Werner used white light and a filter similar to the $CuSO_4$–$K_2Cr_2O_7$ solution.

Figure 1 shows the transmission curves for the $CuSO_4$–$K_2Cr_2O_7$ solution used by Bailar and Auten, for an interference filter (Baird Associates), and for

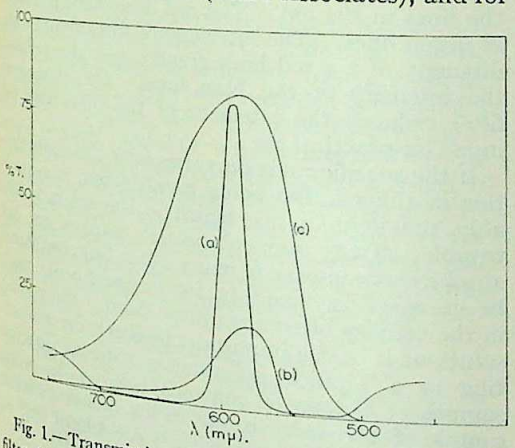

Fig. 1.—Transmission curves for a Baird interference filter, (a) a combination of Corning blue-green and orange cut-off filters, (b) and a $CuSO_4$–$K_2Cr_2O_7$ solution in a 1 cm. cell (c).

the combination of an orange cut-off filter (Corning 3-66) and a blue-green filter (Corning 4–70). The $CuSO_4$–$K_2Cr_2O_7$ solution gives a broad band which is not suitable for use with a solution which absorbs strongly in the vicinity of the NaD doublet. In fact the light transmitted through such a filter and a solution of *cis*-$[Co(en)_2Cl_2]Cl$ is red, not yellow. The 3% $K_2Cr_2O_7$ solution would be much worse as an effective filter. The combination of colored glass filters gives lower intensity in the vicinity of the NaD doublet than the $CuSO_4$–$K_2Cr_2O_7$ solution but the transmission in the red is also somewhat less which makes the glass filter slightly more effective. The interference filter gives a very narrow band with high transmission in the vicinity of the NaD doublet, but the transmission increases in the red and blue portions of the spectrum. The interference filter is provided with a yellow cut-off filter which is very effective in removing the blue light, but does not remove the red. It is the red light which is troublesome for the compounds investigated here.

The low transmission in the vicinity of the NaD doublet and high transmission in the red portion of the spectrum for $[Co(en)_2Cl_2]Cl$ and K[Co(edta)] are shown in Fig. 2. If one uses a filter combination which gives a broad band of yellow light the wave length of the maximum of the transmitted band is shifted appreciably toward the red after passing through a solution of either complex. Any shift in the wave length of the band of transmitted light will vary with the concentration of the solution of the complex through which the light passes and a shift in optical rotation is to be expected.

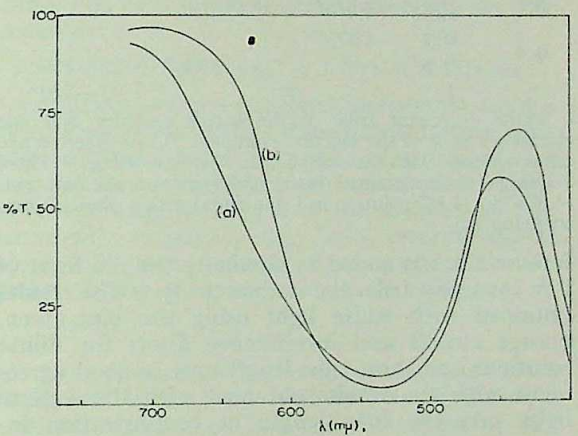

Fig. 2.—Transmission curves for a 0.4% solution of *cis*-$[Co(en)_2Cl_2]Cl$ (a) and a 0.2% solution of K[Co(edta)] (b) in 1 cm. cells.

The specific rotations for three different filter combinations and several concentrations of *d*-*cis*-$[Co(en)_2Cl_2]Cl$ are given in Table I. The values obtained with the sodium lamp using the orange cut-off filter for 0.05, 0.1 and 0.3% solutions can be considered to be identical within experimental error. An increase of 0.01° in the observed rotation of a 0.05% solution in a 0.5 dm. tube would increase the specific rotation by 40°. The dry sample used for the preparation of the 0.3 and 0.4% solutions used for readings with the sodium light had stood for over a year and a 0.1% solution in a 1 dm. cell gave a specific rotation of +575° indicating slight racemization. The readings for these solutions were obtained with a photoelectric attachment since the intensity of the transmitted light was too low for visual readings. The 0.3% solution in a 0.5 dm. tube represents the most dense solution (for concentration and tube length) for which reliable readings could be obtained. The specific rotation is slightly low for this solution unless an inter-

[a] One decimeter tube of the active complex and one decimeter tube of the inactive complex. [b] The interference filter was used with the orange filter for this reading. [c] These readings were obtained for a different sample (sp. rot. +575° for 0.1% solution in 1 dm. tube) with a photoelectric attachment.

ference filter is added to eliminate the red light of low intensity from the sodium lamp. The results obtained with white light using the blue-green, orange cut-off and interference filters for dilute solutions and short tube-lengths are in good agreement with the results obtained with the sodium light. As the tube length or concentration increases, a decrease in the specific rotation is observed.

The specific rotations for 0.1 and 0.4% solutions in 1 dm. tubes are nearly the same as the reported values[2,4] if one uses white light and the combination of blue-green and orange cut-off filters. The change from positive to negative values can be accomplished by increasing the tube length instead of changing the concentration. The fact that the effect is due to the filtering action of the complex is clearly demonstrated by the decrease in the rotation of a 0.1% solution in a 1 dm. tube which is brought about by introducing another 1 dm. tube containing the racemic complex. If the tube length of a 0.1% solution is decreased to 0.5 dm., the specific rotation is raised to a value almost as large as that obtained with the sodium lamp.

The absorption spectrum of K[Co(edta)] (Fig. 2) is similar to that of *cis*-$[Co(en)_2Cl_2]Cl$ and one might expect a similar change in specific rotation with change in concentration. The results in Table II indicate that a change in specific rotation with a change in concentration is observed using white light, but the negative rotation increases instead of changing sign.

TABLE II

SPECIFIC ROTATIONS OF SOLUTIONS OF *d*-K[Co(edta)]

Concn. and tube length	Na lamp orange filter	White light orange and interference filters	White light blue-green and orange filters
0.05% 0.5 dm.	−200°	−200°	−280°
0.2% 1 dm.	....	−440°	−525°

The change in rotation with concentration using filtered white light is understandable when one considers the filtering effect of the complex. Even the interference filter transmits enough red light to give erroneous readings except at low concentrations. The sodium lamp with an orange cut-off filter has been considered as an ideal light source for any concentration for which readings could be obtained. However, a slight deviation was observed at high concentration.

The spectrum of the sodium lamp was recorded with a spectrograph, but no lines in the red were observed unless the exposure was long enough to give a considerable amount of fogging in the vicinity of the NaD doublet. However, when the light was filtered through a solution of *cis*-$[Co(en)_2Cl_2]Cl$ or K[Co(edta)], the intensity of the NaD doublet was reduced to something comparable to some of the lines in the red. The red lines were identified as argon lines. The interference filter reduced the intensity of the red lines greatly, but also reduced the intensity of the NaD lines. The blue-green filter reduced the intensity of the NaD lines too much for practical use.

If the specific rotation varies with the concentration of the solution being investigated, it is probably the light source which is the origin of the trouble. Truly monochromatic sources are not absolutely necessary in many cases, but care should be exercised particularly for measurements made in the vicinity of an absorption band. For colored solutions it is also important to check the zero setting of a Lippich polarimeter with an inactive sample of the same concentration as the active sample if the light is not truly monochromatic. The zero setting shifts with wave length and an error can be introduced for colored solutions.

The Activity Coefficients and Complex of Mercury(I) Sulfate in Sulfuric Acid Solutions at 25°[1]

BY SHIRLEY A. BROWN AND JAMES E. LAND

RECEIVED FEBRUARY 1, 1957

The solubility of mercury(I) sulfate in sulfuric acid solutions of various molalities was measured at 25°. By employing the values for the ratio of the concentration of hydrogen sulfate ions to the concentration of sulfate ions in these sulfuric acid solutions as given from Raman spectra, the ionic strengths of the mercury(I) sulfate, sulfuric acid solutions were calculated. From a plot of the reciprocal of the mean molality of the mercury(I) and sulfate ions *vs.* the cube root of the ionic strength, an extrapolation gave the theoretical solubility product constant for the mercury(I) sulfate in water. This constant then was used to compute the mean ionic activity coefficients of the mercury(I) sulfate in sulfuric acid solutions with concentrations between 0.002 and 2 *m*. A mechanism for the formation of the species $H[Hg_2(SO_4)(HSO_4)]$ was postulated and proof of its existence in solution advanced.

The use of mercury(I) sulfate in the preparation of standard e.m.f. cells has prompted many studies on its solubility in water and sulfuric acid solutions. A most complete and conclusive article on this topic is that of Craig, *et al.*,[2] who reported on the solubility of mercury(I) sulfate in sulfuric acid solutions from 0.002 to 3.5 *c* at 0 and 28°, and also they showed that a linear interpolation of their results to 25° agreed very closely with those reported by Hulett.[3]

Our interest in the mean ionic activity coefficients of mercury(I) sulfate grew out of an attempt to overcome certain difficulties in the calculation of the E^0 for the H_2, H_2SO_4, solvent, Hg_2SO_4, Hg e.m.f. cell used in determining the mean ionic activity coefficients of sulfuric acid at low molalities in mixed solvents.[4]

Not being able to compute the practical activity coefficients of mercury(I) sulfate in sulfuric acid solutions from the solubility results given in the literature, since they were recorded in molarities and density values were not reported, we performed enough solubility measurements over the range of acid molalities reported to give a relationship between concentration and density at 25°. With such results and those in the literature the mean ionic activity coefficients of mercury(I) sulfate in sulfuric acid were calculated and also it was possible to postulate the presence of a soluble mercury complex.

Experimental

Solid mercury(I) sulfate, prepared by the method of Hulett,[5] was added in excess to the sulfuric acid solutions contained in brown, ground glass stoppered bottles. The sealed bottles were agitated mechanically in a constant temperature bath maintained at 25 ± 0.02° for 3–4 days. After agitation the solutions were allowed to stand in the bath until clear, a sample removed by suction into a special pycnometer (previously described[6]) for the density determination, then analyzed for Hg and sulfuric acid using techniques described in reference 2.

Results and Discussion

Over the range of concentrations of sulfuric acid studied it was found that the density at 25° of the mercury(I) sulfate–sulfuric acid solutions could be represented as a function of acid molarity by the equation

$$d = 0.9975 + 0.0624c_{(H_2SO_4)} + 1.0918 \times 10^{-3}c_{(H_2SO_4)}$$

The molalities of the dissolved mercury(I) sulfate determined agreed within experimental error with those computed from the results of Craig, *et al.*,[2] using the above density, concentration relationship.

From a large scale plot of the molality of the mercury(I) sulfate (using both our measured values and those computed from reference 2) against the log of the molality of the sulfuric acid,

the values recorded in the accompanying table were taken.

To calculate the mean ionic molality of the mercury(I) sulfate, the needed molality of the sulfate ion was computed from the mass law equation for the dissociation of the HSO_4^- ion

$$K_{HSO_4^-} = \frac{(m_{H^+})(m_{SO_4^=})}{(m_{HSO_4^-})} \times \gamma_R$$

Values for the factor γ_R listed in the accompanying table were taken from a large scale plot of the values reported by Smith.[7]

The concentration of the HSO_4^- ion can be taken as the difference between the molality of the sulfuric acid and the $SO_4^=$ ion since Smith's work demonstrated no undissociated sulfuric acid to be present in the range reported here. The value used for $K_{HSO_4^-}$ was 0.0120.[8]

The mean ionic activity coefficients listed in the accompanying table were determined from the equation $\gamma_\pm = (1/m_\pm)K^{1/2}$, where $m_\pm$ is the mean ionic molality and K is the hypothetical thermodynamic solubility product constant for the mercury(I) sulfate. $K^{1/2}$ was determined by plotting $1/m_\pm$ *vs.* the cube root of the ionic strength and extrapolating to zero ionic strength. The value found for K was 6.81×10^{-7}.

The behavior of $\gamma_\pm$ with changing ionic strength is illustrated in Fig. 1.

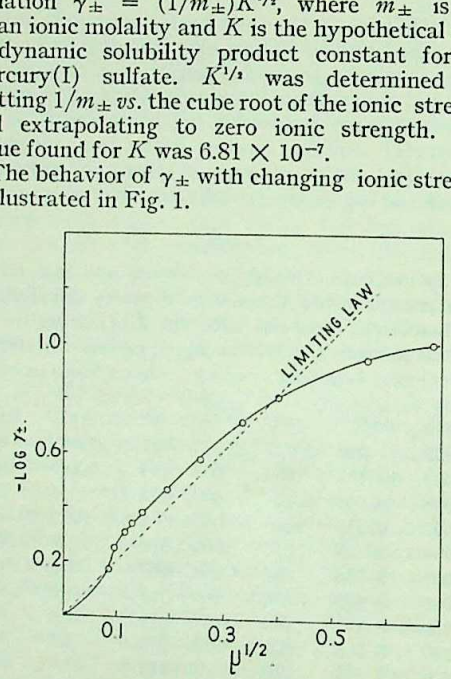

Fig. 1.

The shape of the solubility curve of mercury(I) sulfate in sulfuric acid solution indicated the formation of a soluble complex. Eppley[9] suggested that between 0 and 0.15 *c* sulfuric acid a basic, normal and acid species of Hg_2SO_4 existed. Craig, *et al.*,[2] postulated the formation of the compound $HgHSO_4$ to account for the increased solubility of the mercury(I) sulfate. Kendall and Davidson[10] reported the formation of the unstable acid salt $Hg_2SO_4 \cdot H_2SO_4$ from the analysis of the solid plase in contact with solutions of mercury(I) sulfate in 100% sulfuric acid.

Since the increase in solubility of the mercury(I) sulfate coincides with the increase in the HSO_4^- ion concentration, it was reasoned that such an equilibrium as this is possible

$$Hg_2SO_4 + n(HSO_4^-) \rightleftharpoons [Hg_2(SO_4)(HSO_4)_n]^{n-}$$

Taking the logarithm of both sides of the mass law equation for this equilibrium and rearranging gives

$$\log a_{[Hg_2(SO_4)(HSO_4)_n]^{n-}} = n \log a_{HSO_4^-} + \log K$$

thereby indicating that a plot of the log $a_{[Hg_2(SO_4)(HSO_4)_n]^{n-}}$ *vs.* log $a_{HSO_4^-}$ should produce a straight line of slope n and intercept equal to log K, if such an equilibrium is the case.

The concentration of the soluble mercury complex was taken as the difference between the molality of the mercury(I) sulfate at all values of $m_{H_2SO_4}$ between 0.06 and 0.4 and that at $m_{H_2SO_4} = 0.03$, since the mercury(I) sulfate concentration at this latter molality may be considered to be the maximum possible concentration of the Hg_2SO_4 species in sulfuric acid solutions more concentrated than 0.03 *m*. A plot of $-\log m_{[Hg_2(SO_4)(HSO_4)_n]^{n-}}$ *vs.* $-\log m_{HSO_4^-}$, shown in Fig. 2,[11] gave

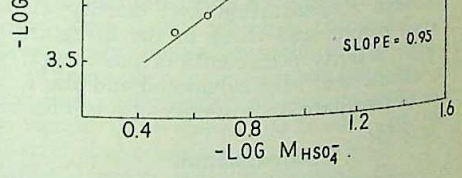

Fig. 2.

a series of points that fall close to a straight line with a slope of 0.95, thereby indicating the probable complex ion to be $[Hg_2(SO_4)(HSO_4)]^-$.

On the Crystal Structures of the Magnus Salts, $Pt(NH_3)_4PtCl_4$[1]

BY MASAO ATOJI, JAMES W. RICHARDSON AND R. E. RUNDLE

RECEIVED FEBRUARY 9, 1957

The crystal structure of the Magnus green salt, $Pt(NH_3)_4PtCl_4$, is tetragonal, $a = 9.03$ Å. and $c = 6.49$ Å., with space group D_{4h}^9–P4/mnc, and two formula units per unit cell, showing that the structure previously reported is incorrect. The planar $Pt(NH_3)_4^{++}$ and $PtCl_4^{--}$ ions are stacked over one another along the c-axis with Pt–Pt distance, $c/2 = 3.25$ Å. The bond distances of Pt–Cl = 2.34 Å. and Pt–N = 2.06 Å. are obtained with high accuracy by means of the generalized Fourier synthesis. The interatomic distances and the infrared spectrum indicate no significant NH...Cl hydrogen bonding in this compound. The comparison between the radial distribution functions of this salt and its isomeric pink salt reveals that there is no direct Pt–Pt contact in the Magnus pink salt, but other distances are comparable.

Introduction

The slightly soluble Magnus salts, Magnus green salt (MGS) and Magnus pink salt (MPS), result promptly from the mixing of solutions of K_2PtCl_4 and $Pt(NH_3)_4Cl_2$.[2] The reaction is capricious; which salt will result is as yet beyond control. The analysis of both salts is $Pt(NH_3)_4PtCl_4$, making the elucidation of their differences an interesting problem in chemical isomerism.

MGS has been studied previously by X-ray diffraction methods.[3] X-Ray rotation diagrams were indexed using a tetragonal unit cell with $a = 6.29$ Å. and $c = 6.42$ Å., and the suggested space group was C_4^1–P4. These results, as well as the structure, placing all $Pt(NH_3)_4^{++}$ groups in one layer and all $PtCl_4^{--}$ in the next, are found to be incorrect, though platinum positions are correct. Apparently, the former X-ray diagrams did not reveal the presence of very weak reflections.

The isomeric pink salt, MPS, was studied previously by the X-ray method,[3] but without any conclusive result regarding its color and its structural difference from MGS. The present study will show some details in this respect.

Methods and Results

The single crystal of MGS used in this study was a tetragonal needle, elongated along c. It approximated a cylinder 0.04 mm. in radius. Zero to sixth-level Weissenberg diagrams were taken by rotation about the needle axis, using Mo Kα and Cu Kα radiation. Precession diagrams, ($h0l$) and (hhl), were also obtained using Mo Kα radiation. The timed exposure and multiple film techniques were combined in both intensity determinations. The lattice constants are: $a = 9.03 \pm 0.02$ Å. and $c = 6.49 \pm 0.01$ Å. The calculated density of 3.77 g./cc. for two formula units in the unit cell agrees with the average value of the experimental density, 3.7 g./cc.[3] Systematic extinctions of ($0kl$) with $k + l$ odd, (hhl) with l odd, lead to the space group D_{4h}^9–P4/mnc or C_{4v}^6–P4nc.

The appropriate Lorenz and polarization factors were employed for reduction of the visual intensity estimates to structure factors. Phillips correction[4] was applied. The best available atomic scattering factors were used for Pt,[5] Cl[6] and N.[7] No calculations were made involving hydrogen atoms.

In both of the space groups above, there are two sets of Pt atoms. In P4nc both occupy 00z, $\frac{1}{2}\ \frac{1}{2}\ \frac{1}{2} + z$. In P4/mnc these positions with z-values of 0 and $\frac{1}{2}$ are required for the two sets. Since general reflections with $h + k = 2n$ and $l = 2n$ are very strong at low angles and show approximately normal decline of intensities, z-values of about 0 and $\frac{1}{2}$ are indicated. Point symmetries at Pt atoms are C_4 and C_{4h} for the two space groups, so that square planar ions in the planes $z = 0$ and $\frac{1}{2}$ are required for P4/mnc, and only slight deviations from this are reasonable for the lower space group.

Data from ($hk0$) are dominated by platinum scattering, and the Patterson projection onto (001) revealed only the Pt-Cl vectors. Data from (hkl) with l odd contain little or no platinum contributions (none if $z = 0$ and $\frac{1}{2}$) and are consequently of importance in determining positions of light atoms. The generalized Patterson projection[8] onto (001) using ($hk1$) data showed clearly both Pt–Cl and Pt–N vectors.

The light atom parameters were refined successively by means of the difference generalized Fourier-syntheses using ($hk1$) data. The final generalized electron density projection onto (001) is shown in Fig. 1. The peak positions were located by the twenty points graphical least square method. The final parameters obtained are listed in Table I. The observed and calculated structure factors for ($hk1$) and ($hk3$) reflections, which were found to contain no Pt atom contributions, are listed in Table III. The discrepancy factor, $\Sigma||F_0| - |F_c||/\Sigma|F_0|$ is 10.5% for these 89 reflections. The temperature factor

$$\exp\left\{-(B_1l^2 + B_2)\left(\frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2}\right)\right\}$$

with $B_1 = 0.13_8$ Å.^{2} and $B_2 = 1.06$ Å.^{2}, has been applied.

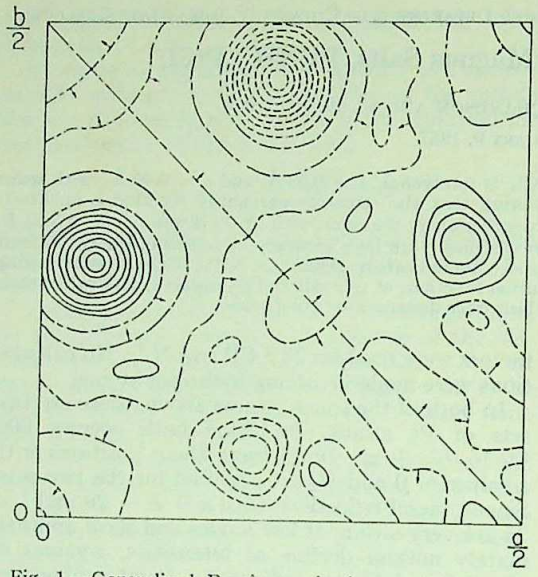

Fig. 1.—Generalized Fourier projection on (001) using (hkl) data. Contours are 0, 4, 8 . . . e.Å.$^{-2}$, but 0, 8, 16 . . . e.Å.$^{-2}$ for chlorine atoms. Positive, negative, zero contours are in solid, dotted and broken lines, respectively. Small arrows indicate the direction of the negative region.

Accuracy of the Structure.—Standard deviations of random errors were determined using Cruickshank's procedure,[9] which was modified appropriately for the generalized Fourier projection. For ($hk1$) data, $\sigma(A_h) = \sigma(A_k) = 1.624$ e.Å.$^{-3}$ and the peak constants are listed in Table II. The resultants, $\sigma(x) = \sigma(y) = 0.0037$ Å. for Cl and 0.018 Å. for N, give the standard deviations, 0.005 Å. for the Pt–Cl and 0.025 Å. for the Pt–N bond lengths.

TABLE II

OBSERVED AND CALCULATED PEAK CONSTANTS

	$\rho_L(0)$obsd. (e.Å.$^{-2}$)	$\rho_L(0)$calcd. (e.Å.$^{-2}$)		$\rho_L''(0)$obsd. (e.Å.$^{-4}$)	$\rho_L''(0)$calcd. (e.Å.$^{-4}$)	
N	10.2	11.4[a]	10.6[b]	− 92	−121[a]	− 92[b]
Cl	35.0	32.6	34.8	−440	−420	−440

[a] From equations 1 and 2. [b] From the generalized electron density map using the calculated structure factors.

The possibility that the structure was non-centrosymmetric was examined as follows. The peak height ρ_L (0) and the peak curvature ρ''_L (0) in the generalized Fourier projection along the z-axis, namely, using ($hk1$) data, are[10]

$$\rho_L(0) = \cos\left(2\pi\frac{LZ_0}{c}\right)\int_{L/c}^{s_{max}} 2\pi s f(s)\exp\left(-\frac{Bs^2}{4}\right)ds \quad (1)$$

and

$$\rho''_L(0) = \cos\left(2\pi\frac{LZ_0}{c}\right)\left[-\int_{L/c}^{s_{max}} 4\pi^2 s^2 f(s)\exp\left(-\frac{Bs^2}{4}\right)ds + \frac{2\pi^2L^2}{s^2}\rho_L(0)\right] \quad (2)$$

where z_0 is the atomic parameter in Å., c is the lattice constant along the z-axis, $f(s)$ is the atomic scattering factor and $s = 2(\sin\theta)/\lambda$. Although isotropic thermal vibrations are assumed in these equations, this should not cause the mean value of the observed peak constants to deviate greatly from the calculated value.[11] If $z = 0$ or $1/2$, $|\rho_L(0)|$ and $|\rho_L''(0)|$ give the maximum possible values. The graphically integrated results using equations 1 and 2 with $z = 0$, $B = 1.2$ Å.^{2}, $s_{max} = 1.275$ Å.$^{-1}$ and $L/c = 0.190$ Å.$^{-1}$ are listed in Table II. The chlorine peak constants are as high as expected for $z = 0$ or $1/2$, while those for the nitrogen atom may indicate some deviation. However, the latter peaks could be considerably affected by the Fourier ripple error. Moreover, the peak values in the observed and calculated Fourier maps are in good agreement, as can be seen in Table II. Ac-

cordingly, no definite conclusion was deduced from these data.

In the series of generalized ($F_0 - F_c$) Fourier maps, the origin peak was always negative. In the final difference map, only the origin showed a density value larger than 1 e.Å.$^{-2}$, namely, 1.88 e.Å.$^{-2}$. $\rho_{Pt}(0)$ of equation 1 is 196 e.Å.$^{-2}$ for the Pt atom. Therefore, the separation of Pt atoms along c needs to be changed from $c/2$ by only ± 0.013 Å. to account for peak height at the origin in the generalized difference map made from ($hk1$) data and only 0.003 Å. in the map made from ($hk3$) data. Similar calculations were carried out for the peak curvatures with similar results. It is our conclusion that the experimental data do not disagree with the proposed centrosymmetric structure within the limits of ± 0.02 Å. in the z-parameters.

Radial Distribution Studies.—Since no success was met in obtaining a sufficiently large single crystal of MPS for single crystal diffraction work, the integrated intensities of the Debye–Scherrer lines of both MGS and MPS were measured on a Norelco X-ray diffractometer. Although the average particle size of the powdered crystals was less than 5 μ the preferred orientation effect was not avoidable by the usual mounting technique.[12] Moreover, the mica-like cleavage of the pink salt raises great difficulty in obtaining finer powders with spherical or random shapes. However, it was observed that by mixing and diluting MPS with a considerable amount of granular starch the preferred orientation effect was reduced appreciably. The absolute intensities were obtained approximately by scanning the diffraction lines of the powdered mixture of these salts and NaCl.

The radial distribution function derived by Schomaker[13]

$$A(r) = \sum_{s>0}^{s_{max}} \frac{\sin 2\theta}{1 + \cos^2 2\theta} I(s) \exp(-Bs^2) \sin 2\pi sr$$

where $I(s)$ is the observed intensity, was summed at intervals of 0.1 Å. in r. In our case, s_{max} was 0.8 Å.$^{-1}$, and summations made with and without an artificial temperature factor were similar in main details. In the resultant distribution functions, as shown in Fig. 3, with $B = 8$ Å.$^{-2}$, Pt–Cl peaks I and I′ appeared in both salts, while the shortest Pt–Pt interaction, II, in MGS was not observed in MPS. Since there existed many ambiguities in interpreting peak III′, attempts to solve the structure of MPS from the radial distribution function failed. Nevertheless, it may be concluded that in MPS there is no direct contact of Pt atoms as found in MGS, and that in MPS the smallest Pt–Pt vectors lie under peak III′ at about 5.6 Å.

(13) J. Waser and V. Schomaker, THIS JOURNAL, **67**, 2014 (1945). The correct expression to define $A(r)$ is as follows: If we define

$$D(r) = \int_0^{2\pi}\int_0^{\pi} P(\vec{r}) \sin\theta \, d\theta \, d\phi$$

where $P(r)$ is the Patterson function, we have then

$$A(r) = \frac{2rV}{\lambda}\left[D(r) - \frac{4\pi}{V} F^2(000)\right]$$

where V is the volume of the unit cell.

Discussion of Structure

In MGS, Pt–Cl = 2.34 Å. and Pt–N = 2.06 Å. are in good agreement with the sum of the covalent radii, Pt–Cl = 2.31 Å. and Pt–N = 2.02 Å.[14,15] Other important interatomic distances are shown in Fig. 2. These indicate no strong hydrogen bonding in MGS. Moreover, the NH stretching frequencies recorded on the infrared spectrometer with a LiF prism are 3182 and 3277 cm.$^{-1}$ for symmetric and asymmetric vibrations, respectively. Although the corresponding frequencies of NH_3[16] are 3337 cm.$^{-1}$ and 3414 cm.$^{-1}$, these differences probably do not arise from strong hydrogen bonding for reasons previously reported.[17]

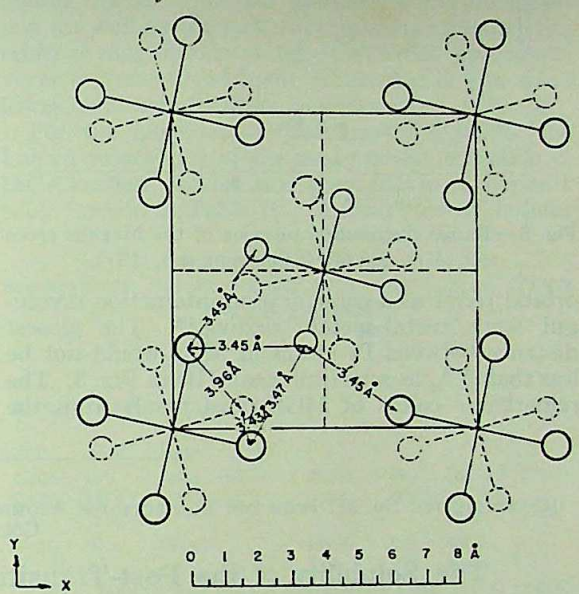

Fig. 2.—Atomic arrangement of the Magnus green salt projected on (001). Large circles represent chlorine atoms and small circles nitrogens. Solid and broken lines indicate $z = 0$ and $1/2$, respectively. Platinum atoms are at centers of square ions.

Remarkable dichroism of a single crystal of MGS was observed in the visible and ultraviolet region by Yamada.[18] His result and the chains of Pt atoms along the c-axis with a distance of 3.25 Å. suggested to him that there exists an interaction among Pt atoms. This seems to occur frequently in all square planar complexes except those of copper(II).[19] In valence bond terms the interaction can possibly be described as a slight mixing of octahedral with the square planar bonding with two of the octahedral bonds to adjoining metal atoms,[19a] or in molecular

orbital terms as a configuration interaction involvgni some metal–metal bonding.[19b] The closest distance between Pt atoms in MPS would not be less than 5 Å. as seen from peak III′ in Fig. 3. The remarkable colors of MGS must result from the metal interaction, while MPS, which has no such interaction, does not differ materially in color from finely divided $Pt(NH_3)_4Cl_2$, and its pink color must be due to $Pt(NH_3)_4^{++}$ ions. Experimentally there is little doubt that MGS is the stable form of the Magnus salts, and this may be due to the extra metal interaction. Presumably accidents of nucleation produce the pink salt, but it may well be that packing considerations, by themselves, would favor the pink salt since the type of packing in the green salt is rare. It would also be interesting to learn whether there is an appreciable activation energy for forming the Pt–Pt bond in the green salt.

Acknowledgments.—The authors wish to express their thanks to Messrs. Russell A. Bonham and Peter Vossos for their assistance in some of the numerical computations and to Mr. E. Miller Layton for obtaining the infrared spectra. Dr. Don S. Martin and his students kindly supplied MGS and MPS, and contributed to our interest in this problem.

The Solubility of the Post-Transition Metals in their Molten Halides[1]

BY JOHN D. CORBETT, SAMUEL VON WINBUSH AND FRANK C. ALBERS

RECEIVED FEBRUARY 20, 1957

The solubilities of the respective metals in molten PbI_2, $SbCl_3$, SbI_3, $ZnCl_2$, ZnI_2, CdI_2 and $GaBr_2$ are reported. An interpretation of the solution of the post-transition representative metals in their molten halides is presented in terms of the formation of slightly stable subhalides. The apparent stabilities of the lower halides increase both with increasing atomic weight of the metal within a group, and with increasing atomic weight of the halide with a given metal, except for cadmium. The halide effect is attributed to a corresponding decrease in the extent to which the higher oxidation state of the metal is stabilized by complex formation with halide. The relative stabilities of the metal–halide complexes observed parallel those reported in aqueous solution for the same ions, including the inversion in order found for cadmium. The formation of gaseous subhalides of antimony, bismuth and gallium is indicated by transport experiments. A direct correspondence is found between those systems in which gaseous subhalides of appreciable stability are formed and those in which metal dissolves in the molten salt to an appreciable extent. Diamagnetic solutes are formed in the zinc, cadmium, gallium, antimony and bismuth systems.

Introduction

The problem presented by the apparent solution of such metals as cadmium,[2] bismuth,[3] cerium,[4] the alkalies,[5,6] and the alkaline earths[7] in their respective molten halides has not received a completely satisfactory explanation. Although the possibility of the formation of colloidal metal or "pyrosoles" in the process has been eliminated, interpretations in terms of energy bands for the metal's electrons,[8] the formation of subhalides,[2,3,9] or a combination of these concepts[5] has been suggested. The phenomenon appears to be limited to the liquid state, in that only an intimate mixture of the original components is obtained on solidification of these solutions.

Although generally small metal solubilities had been found previously in this Laboratory for lead, tin, aluminum, thallium and silver systems,[10] subsequent investigations have revealed larger interactions in other post-transition metal–metal halide melts. In addition, evidence has been obtained supporting the interpretation of these solubilities in terms of the formation of slightly stable lower halides.

Results

The data obtained are given in Table I. The number of significant figures reported is indicative of the reproducibility of the measurement. In the liquid state only the Cd–CdI_2 system is different in color from the pure salt. The resulting solids are quite distinctive, however, for all but the Pb–PbI_2 and Zn–$ZnCl_2$ systems at the lowest temperatures

reported, and for the Ga–$GaBr_2$ system. These observations will be discussed subsequently.

Ga–$GaBr_2$	170	9.30	B	Clear	Yellow

[a] Methods: B, loss in weight of metal phase; C, weight of dissolved metal.

Literature values are available for only the zinc chloride and the cadmium iodide systems. Von Hevesy and Löwenstein[2] reported that 10^{-4} mole % zinc dissolved in zinc chloride at 500°, as determined by a "titration" of a colored melt. Since no colored melts have been observed in the course of this work, it is uncertain as to what they were measuring. The same authors[2] reported a solubility of 7.8 mole % cadmium in cadmium iodide at 600°, about five times larger than that found here. As described in the Experimental section, values of this magnitude can be obtained readily by method B under non-isothermal conditions where metal may be transported to cooler portions of the salt or the container, for such distributed metal apparently does not readily reaggregate with the bulk phase.

Discussion

Any interpretation of the so-called "solution" of metals in their molten salts should account for a number of facts concerning these interactions. The formation of true solutions has been well substantiated for a large number of systems, where a marked depression of the freezing point of the salt is observed on solution of metal.[2–9] Moreover, these metals apparently are soluble only in salts of the same metal, indicating a specific interaction between the metal and the cation of the salt,[11] and yet only a mixture of the original components is usually obtained on solidification of the melt. In addition, any explanation should give reason to the marked variation in solubility of the various metals in their salts.

It will be seen that the formation of a class of slightly stable subhalides offers a satisfactory interpretation for the behavior of systems involving the post-transition representative metals and their halides. Although this concept has been suggested by previous workers, it has not received a general acceptance. This has been due to both the absence of a substantiated isolation of such a subhalide among the better known examples of this phenomenon, as well as the lack of correlation of either the relative magnitudes of the solubilities among diverse systems or with the occurrence of the same lower halides under other conditions.

For the purposes of qualitative discussion, the known solubilities of the post-transition metals in their molten halides are arranged in a periodic table fashion in Table II. Known "lower" halides

TABLE II

SOLUBILITIES OF POST-TRANSITION METALS IN THEIR MOLTEN HALIDES[a]

II		III		IV		V

[a] Data for the four groups in mole per cent. metal at 600, 230, 500 and 270°, respectively (*cf.* footnote 12). [b] This work. [c] Ref. 2. [d] L. M. Foster, A. S. Russell and C. N. Cochran, THIS JOURNAL, 72, 2580 (1950); L. M. Foster, private communication. [e] Calculated from ref. 10 and ΔH^0 given by F. Irmann, *Helv. Chim. Acta*, 188, 1449 (1950). [f] Ref. 10. [g] Ref. 13. Similarly small temperature coefficients of solubility have been found in the other gallium systems. [h] Value reported in ref. 10 was in error. [i] Ref. 3.

are indicated in parentheses. For consistency the data are given at a fixed temperature in each group.[12]

Two systematic relationships are apparent in this arrangement. First, without exception, an increase in atomic weight of the metal within a group results in an increase in the solubility in a given halide. In the second and third groups this effect culminates in the formation of stable mercury(I) and indium(I) halides. A similar behavior is well known for the relative stabilities of the +2 and +3 states in the fourth and fifth groups. The implications of the trend observed in these two groups for still lower states will be discussed later.

These systems also show a rather marked regularity in the change in solubility of a given metal with variation in halide ion. In the third, fourth and fifth groups the solubility of metal, or the amount of the lower halide formed, increases in the order chloride, bromide, iodide. The trend is particu-

(11) The more trivial examples of direct reduction of the salt by added foreign metal are, of course, being disregarded. For example, the apparent solution of lead in cadmium chloride, as well as a large number of metals in bismuth trichloride, seemingly involves simple oxidation–reduction reactions. The initial metal addition produces the characteristic color of the metal–metal halide melt of the original salt; ultimately, the separation of a pure or alloyed phase containing the metal of the initial salt occurs.

(12) These temperatures, 600, 230, 500 and 270°, resp., were chosen so as to best fit the temperatures at which solubilities had been determined. For interpolation and extrapolation, plots of log solubility *vs.* $1/T$ were used; these have been found to be linear for all systems with solubilities of less than 2% that have been investigated at three temperatures. This behavior would be expected for equilibria of the type discussed herein. Exactly the same conclusions that follow could be obtained using a fixed temperature interval above the melting points of the salts in each group.

larly striking in the gallium systems; metal is precipitated when the metal-saturated chloride melt is solidified, while $GaBr$[14] and GaI,[13] stable in the solid state, are formed with the heavier halides.[15] Generally speaking, the stabilities of solid subhalides with respect to disproportionation show a corresponding relationship, being greatest with the iodide. At least in the molten state this halide effect can be attributed primarily to the decrease in basicity of the halide ion that accompanies an increase in atomic weight, in turn diminishing the extent to which the more acidic, higher oxidation state is stabilized by complex formation with halide ion. As a result greater reduction by metal, corresponding to greater stability toward disproportionation, is observed with the heavier halides.[16] Although the solubilities in the zinc systems show the same halide relationship, the inversion of the apparent stabilities of the cadmium(I) halides is quite evident (Table II). It is interesting to note that solid mercury(I) chloride, bromide and iodide behave similarly,[9] with standard free energies of disproportionation of 8.0, 6.6 and 2.5 kcal./mole, respectively.[17] Moreover, the reversal in the relative stabilities of the halide complexes of cadmium(II) and mercury(II) that is implied by these results is not without precedent. In aqueous solution the formation constants of the halide complexes of these two ions are in the order $I^- > Br^- > Cl^-$, whereas zinc(II) shows the more common relationship $Cl^- > Br^- > I^-$.[18] The anomalous behavior of cadmium and mercury has been attributed to multiple bond formation with the ligand.[19]

A strong point in favor of the interpretation of these metal–metal halide systems in terms of the formation of lower oxidation states is afforded by observations on the same systems in the gaseous state at comparable temperatures. In the cases under consideration there is a direct correspondence between the systems in which the metal dissolves in its fused halide to a significant extent and those in which gaseous subhalides of appreciable stability are known. As described in the Experimental section, rather definite evidence for a lower halide of antimony, bismuth and gallium has been obtained from observations on the transport of metal by vapors of the normal salt at temperatures where the vapor pressure of the metal alone is negligible. Similar or equivalent results have been reported for zinc, cadmium and bismuth, and for aluminum at higher temperatures.[20] On the other hand, visible transport of metal is not found in the lead and tin systems (Experimental section)[10,17] where the small solubilities are indicative of less stable, lower halides.

In this light the existence of these particular subhalides in the liquid but not the solid state is not unexpected. Although these compounds have insufficient stability to exist as pure solid phases, their presence at elevated temperatures when dissolved at less than unit activity in the parent salt is quite reasonable. Thus a stable solid subhalide can be obtained from such a solution only when reduction by metal produces a liquid that exceeds the composition of the normal halide–lower halide phase eutectic. Again, such a situation is observed in the Ga–$GaBr_2$ and Ga–GaI_2 systems, but not with Ga–$GaCl_2$. It may be that the inability to isolate cadmium(I) as well as possibly alkaline earth(I) and Ce(I?) halides from their respective binary systems, in spite of the rather large solubilities of metal observed,[2,4,7] is a consequence of the hypothetical eutectic being considerably removed in composition from the parent salt. Relatively low melting points for these lower halides might account for this. The possibility of the formation of lower oxidation states in the alkaline earth and cerium systems has been considered by Brewer.[21] However, extension of this concept to the rather unique alkali metal–alkali halide systems[5,6] would be quite speculative, particularly in view of the unusual M_2X product that would be involved.

In most cases it is possible to formulate the lower halides present in the systems under consideration on the basis of chemical knowledge and the observed magnetic properties. The formation of diamagnetic solutes has been specifically established for metal–metal halide melts involving $CdCl_2$,[22] $ZnCl_2$, GaX_2, SbI_3 and $BiCl_3$; the solubilities in the tin and lead halides are too small to allow detection of possible paramagnetic products (see Experimental section). Thus it seems fairly certain that Cd_2^{+2}, analogous to Hg_2^{+2}, occurs in the cadmium systems.[9,16] Similarly, Zn_2^{+2} is the most likely product from the solution of zinc in its halides. The simple monohalides are unquestionably formed in the aluminum and gallium systems.[10,15,16] The much smaller solubilities in the tin and lead systems only indicate a low stability for either the M_2^{+2} or M^+ products. In this connection it should be noted that Karpachev and co-workers[23] have concluded on the basis of e.m.f. measurements that Pb^+, Cd^0 (or Cd_2^{+2}) and Li^0 or Li_2^+ are formed in the respective metal–metal chloride solutions.

Bismuth(I) halides doubtless are formed in the bismuth systems,[16,24] although the observed dia-

(14) J. D. Corbett and A. Hershaft, unpublished research.

(15) Although the simplest formula has been used for the gallium "dihalides," these compounds have been shown to be $Ga(I)[Ga(III)X_4]$ (R. K. McMullan and J. D. Corbett, to be published; L. A. Woodward, G. Garton and H. L. Roberts, *J. Chem. Soc.*, 3723 (1956)).

(16) A reduction in the amount to which the higher oxidation state is complexed by halide ion and thereby stabilized can also be brought about by the introduction of a stronger Lewis acid. Use of $AlCl_3$ for this purpose has allowed the preparation of stable Cd(I), Bi(I) and Ga(I) tetrachloroaluminates from the respective metal–metal chloride systems (J. D. Corbett and R. K. McMullan, THIS JOURNAL, **78**, 2906 (1956)). The concepts developed in the present paper, together with the elucidation of the nature of $GaCl_2$ (footnote 15), led to these acid-stabilization results.

magnetism is rather unexpected. Seemingly, either pairing of the $6p^2$ valence electrons or the formation of metal–metal bonds has occurred. The oxidation state present in the diamagnetic solutions of antimony in its triiodide is not as obvious. By analogy with bismuth a less stable Sb(I) might be expected. However, the +2 oxidation state, as known in P_2I_4 and As_2I_4,[25] cannot be ruled out solely by the magnitude of the solubility. Investigations of the equilibria in the gas phase are expected to allow a distinction to be made.

Experimental

Solubility Determination Methods.—In cases where the metal is liquid at the equilibration temperature, suspension of metal droplets in the salt is usually not observed.[10] In these cases, direct determination of the loss in weight of metal when equilibrated with a known amount of salt (method B) results in a considerable gain in accuracy and ease of measurement over that possible by direct analytical determination. The clear melt in the Sb–$SbCl_3$ system also allowed this method to be used with a solid metal. For the zinc halides, $SbCl_3$ and $GaBr_3$, the weight of salt sublimed *in vacuo* from the broken ampoule onto the weighed metal in the equilibration vessel was obtained by difference, as previously described for the tin systems.[10] The cadmium and lead iodides were weighed in air (see Materials).

The known amounts of salt and metal were equilibrated, except as later noted, in small evacuated tubes in tubular furnaces controlled with Celectray or Brown Proportioning controllers. The temperatures were measured with chromel-alumel couples calibrated by Leeds and Northrup. Equilibration times of 3–16, 1–2, 5–8, 5–10 and 24 hr. for PbI_2, $SbCl_3$, ZnX_2, CdI_2 and $GaBr_2$, resp., were used. The Pyrex or Vycor containers were then quenched with an air blast or cold water; there was no evidence of segregation during this process. The coherent metal button was recovered, washed with water and reweighed. With the Ga–Br_2 system, the metal was frozen prior to opening the tube. Acetone was used to separate the button from adhering salt in order to avoid the additional metal produced when $GaBr_2$ reacts with water. In cases where occlusion of salt within the button was suspected, the metal was remelted under vacuum, alone or with an alkali halide flux.[10] The buttons both before and after use could be so remelted with weight losses of 0.1 to 0.7 mg. No evidence for solution of salt in liquid metal was found in these systems.

With the Cd–CdI_2 system, the application of method B initially gave very erratic values of 2 to 5 mole % metal dissolved at 410°. More constant temperature control, as obtained with a shunted Marshall Tube Furnace and a proportioning controller, resulted in values of 0.8 to 1.5% at 410° and 6 to 10% at 600°. The scattered and, as were later found, high values were probably due to transport of the volatile metal, either directly (b.p. 765°) or as a subhalide, to the cooler upper walls of the container. This difficulty was substantially eliminated by equilibration of the salt and metal in containers in which the free volume was as small as possible. After the salt had been fused, the Vycor apparatus was sealed from the line and the salt quantitatively melted and sublimed down onto the metal in a 13 × 20 mm. bulb, which was then detached. In this fashion a sample was obtained which filled greater than 95% of the container (and only once exceeded that volume), thus reducing the possible temperature gradients within the system to a minimum. The bulbs were also jacketed by a closed tube within the furnace. The average deviations obtained at 410 and 600° were 0.014 and 0.17 mole %, respectively; the values reported are probably, at worst, 10% higher than the true solubilities.

With Sb–SbI_3, since the metal was solid at the temperature used, the saturated samples initially were gravity-filtered *in situ* through a medium or coarse sintered-glass disk sealed in the container. Sublimation of the salt from a weighed portion of the filtrate allowed a direct determination of the weight of metal therein (method C). This sublimation was initiated at 100° and the temperature slowly raised to 250° over a period of 12 hours; under these conditions loss of metal by entrainment or by subhalide formation (see Transport) was not encountered. However, particularly for equilibrations above 300°, erratic values were obtained due to transport of metal *via* a subhalide to other portions of the tube during the initial equilibration. Crystals of metal were often readily visible on the filtrate side of the sintered disk before the sample was inverted for filtration. The following technique was devised to overcome this difficulty: a 12 × 25 mm. tube, with a disk sealed near the middle, was almost completely filled with sublimed SbI_3. Metal had been previously placed on top of the filter, so that saturation of the lower portion of the salt was effected only by diffusion through the disk. In addition, the container was immersed in a molten $NaNO_3$ bath within the furnace. The values at 400° were thus reduced from a range of 3 to 8% to 5.8 ± 0.2% dissolved metal. Microscopic examination of metal remaining after sublimation of the salt showed the presence of only amorphous metal, and no crystals >1 μ in size.

During preliminary studies on this system, the formation of true solutions of metal in salt was established by the observation that metal lowered the vapor pressure of the triiodide. A small tube containing metal in a well in one end and salt in the other was placed in a furnace with a known temperature gradient; temperatures were also checked with couples in glass fingers projecting into salt and metal. It was observed that the salt distilled against a 4° temperature gradient onto the metal at 430°.

As indicated in Table I, the appearance of the quenched salts in most cases was typically that of an intimate mixture of salts and metal. However, with $ZnCl_2$ containing 0.18% metal, the water-quenched solid was a clear glass, quite similar to that obtained on rapid cooling of the pure molten salt. On heating, crystallization of the salt occurred at 120°, while the darkening characteristic of finely divided metal appeared rather sharply at 180°. The colorless glass was completely soluble in anhydrous ether, with the precipitation of metal after about 4 hr. Preliminary attempts to isolate the probable zinc (I) chloride therein were unsuccessful.

Materials.—The determination of solubilities by weight loss of the metal phase required the absence of non-metallic impurities soluble in the salt. For this reason zinc (Bunker Hill Electrolytic, 99.99%) was vacuum-fused and washed with acid to remove the oxide. Cadmium (Fisher Reagent) was repeatedly fused in a helium atmosphere alone, or with $CdCl_2$. Gallium (Aluminum Company of America, 99.9%) was treated with dil. HCl, frozen in small pellets and washed with distilled water. Lead (Fisher, Test Lead) was treated as previously described.[10] Antimony (Fisher Reagent) was used directly. The success of these procedures, as well as the absence of metallic reducing impurities, was shown by the consistency in results obtained on re-use of the same metal sample.

In order to avoid erroneous metal solubilities resulting from reactive impurities in the salts, particularly water and the resulting hydrolysis products, all the salts were prepared and handled by techniques dictated by their sensitivity to moisture, and, except for CdI_2, were vacuum sublimed onto metal just previous to equilibration.

Lead(II) iodide was precipitated from solutions of Reagent grade KI and $Pb(NO_3)_2$, vacuum dried and sublimed. The 20 to 30-g. portions used were weighed in air. For some of the measurements, metal-saturated salt was purified for re-use by heating the salt in a closed tube at 500° with excess I_2, separating the iodine in a side arm at −80° and then vacuum subliming the salt.

Antimony(III) chloride was prepared from the elements, using excess metal, and was vacuum-sublimed at about 100° into small fragile ampoules for storage.

Antimony(III) iodide (Fisher purified) was found to be sufficiently pure to be used directly after one sublimation. Measurements made with salt prepared from the elements

---

Akad. Nauk. SSSR, **21**, 159 (1952)). ADDED IN PROOF.—The preparation of pure BiCl has been accomplished recently in this Laboratory, J. D. Corbett, unpublished research.

(25) F. Jaeger and H. Doornbosch, *Z. anorg. allgem. Chem.*, **75**, 261 (1912). The phase diagram presented by these authors for the Sb–SbI_3 system certainly seems in error. Although they indicate the formation of a solution of 13 mole % salt in metal at 169°, such a process has not been observed below 400°. They did not investigate the salt-rich phase.

Zinc chloride also was prepared from the elements. Since $ZnCl_2$ cannot be separated from metal by sublimation, the salt was heated extensively with excess chlorine. It was then sublimed at 500°, and melted into fragile containers containing 3 to 5 g. each. The resulting salt evolved no hydrogen when contacted with metal; considerable amounts of this gas, presumably from dissolved water and HCl, were obtained when commercial $ZnCl_2$ was used after one vacuum sublimation.

Zinc iodide was prepared in a V-shaped Vycor tube from metal and excess, vacuum-sublimed iodine, heating the metal to 700° and the iodine to 200°. The product was transferred in air, triply sublimed after removal of the I_2, and similarly stored in 2 to 3-g. batches.

Owing to thermal decomposition, CdI_2 cannot be vacuum sublimed without appreciable contamination of the product with free metal. Hence it was prepared directly from the elements in a sealed tube and the excess I_2 and traces of HI condensed in a side arm at −190° and sealed off. The salt was then sublimed at 450° in the closed tube. For equilibration a 10 to 15-g. sample was weighed in air and then melted *in vacuo* (without decomposition) before the metal was introduced under helium.

For the Ga–$GaBr_3$ system, $GaBr_3$ was prepared from the metal and excess, P_2O_5-dried bromine, sublimed and sealed in ampoules. The $GaBr_2$ was then formed as the initial product during the equilibration with a weighed excess of metal.

Transport Studies.—Observations on the stabilities of gaseous subhalides were carried out in the manner already described for tin and lead.[10] Transport of antimony was obtained when SbI_3 was distilled at $<10^{-2}$ mm. over metal heated as low as 300°. Metal alone would not sublime at this temperature, as expected from a calculated vapor pressure of *ca.* 10^{-10} atm.[26] Similarly, $BiCl_3$ caused transport of Bi, and GaX_2 of Ga at 400°. Studies of this type with lead are, however, limited by the vapor pressure of the metal to temperatures below about 575°.[10] With PbI_2, where the natural color of the solid salt prevents visual detection of metal at less than about 0.1 mole %, transport of lesser amounts either directly or *via* a subhalide does occur below 500°, as detected by direct solubility measurements with salt sublimed from a metal-saturated sample.

Magnetic Susceptibility Observations.—A qualitative Gouy method was used to establish the diamagnetism of metal-containing melts of SbI_3, $ZnCl_2$, GaX_2 and $BiCl_3$. The salts, containing less metal than necessary for saturation at the temperature used, were sealed in small fused silica tubes equipped with evacuated jackets to lessen the rate of cooling. These were lowered from the furnace to between the pole pieces of a magnet with an inhomogeneous field of maximum intensity of about 12000 gauss. A deflection out of the field, indistinguishable from the pure molten salt, was always observed when the magnet was turned on. Experiments with dilute aqueous solutions of paramagnetic salts indicated that the method should be quite capable of detecting paramagnetism in the systems studied if such species had been formed in the expected amounts.

Praseodymium Oxides. IV. A Study of the Region $PrO_{1.83}$–$PrO_{2.00}$[1]

BY C. L. SIEGLAFF AND L. EYRING

RECEIVED JANUARY 19, 1957

This is a study of the phase relationships of the higher praseodymium oxides. X-Ray powder diagrams of quenched, analyzed samples were taken to determine the phases present. A two-phase system was found for the region $PrO_{1.83}$–$PrO_{2.00}$ at preparation temperatures below 350° and oxygen pressures less than ten atmospheres. Lattice constants are given for the various phases found.

Introduction

Several investigations of the praseodymium oxides beyond Pr_2O_3 have been reported recently.[2-8] The oxide system below Pr_6O_{11} has been extensively studied, but in the region Pr_6O_{11} to PrO_2 there is apparent disagreement as to the phases present. Through the use of X-ray diffraction techniques on samples prepared under equilibrium conditions a study of this region has been carried out.

Experimental Methods

Materials.—The Pr_6O_{11} used in these experiments was obtained from Professor F. H. Spedding, Iowa State College, Ames, Iowa, as 99.9+% pure Pr_6O_{11} with no other rare earth cations present in detectable amounts. The oxygen used in the preparation of quenched samples was commercial tank oxygen.

Apparatus for the Preparation of Quenched Samples.—The constant volume apparatus used in preparing the samples below ten atm. oxygen pressure was similar in principle to the one described previously.[8] Since the measurements were made at relatively high pressures, the system was constructed of metal instead of glass. The reaction vessel was an "Inconel X" cylinder bored and fitted with a flanged platinum liner. The brass valves used in the system were designed to have a very small internal free space and were constructed in a manner such that the volume was reproducible in either the open or closed positions.

The pressure was measured by a Wallace and Tierman, Model No. FA 145, 0-5080 mm. dial manometer. In order to maintain constant volume conditions the manometer had to be isolated from the sorption system, since the manometer worked on an expanding capsule principle. The isolation of the manometer was accomplished by means of a sensitive, specially designed small volume differential pressure gage operating as a null instrument.

The maximum uncertainty in the composition, as measured by the pressure change, is estimated at 0.4%. Weighing of the samples before and after the oxidation-quenching procedure gave a check of the method since there was no appreciable change in oxygen content when the samples were quenched.

Samples prepared at high temperatures and high oxygen pressures were treated in an "Inconel X" autoclave. The procedure and a similar apparatus have been previously described.[3]

X-Ray diagrams were taken in a 114.6 mm. diameter camera using exposure times of about 12 hours.

1.868	720	72	5.468 ± .005		10
2.01	720	92	5.392 ± .001	5.469 ± 0.002	Cooled slowly, pressure
1.833	760	112	$PrO_{1.83}$		10
1.839	760	224	5.467 ± 0.001		5
1.956	760	140	$PrO_{1.83}$	$PrO_{2.00}$	Quenched, pressure
1.997	450	231	5.3938 ± 0.0003		Cooled slowly, pressure

Results and Discussion

Table I shows the results of the X-ray analysis on quenched samples. All cell dimensions are reported in Å. units based on the wave lengths Cu K_1 1.5405 Å. and Cu K_2 1.5443 Å. The values for the cell dimensions reported in Table I are calculated by an analytical extrapolation of the back reflection data.[9]

Oxidation of a Pr_6O_{11} sample at 350° and an oxygen pressure of 4.25 atm. results in two crystalline oxide phases with lattice constants of 5.3919 ± 0.0008 Å. and 5.4694 ± 0.0007 Å. The phases are Pr_6O_{11} and PrO_2. A sample which was prepared by oxidation to PrO_2, and then reduced to a composition intermediate to Pr_6O_{11} and PrO_2, showed two phases, Pr_6O_{11} and PrO_2 with lattice constants of 5.3918 ± 0.0001 Å. and 5.471 ± 0.001 Å. One experiment, listed third in the table, gave only one phase, Pr_6O_{11}. This sample was only 12% oxidized which would give at best a very weak minor phase. Since the praseodymium oxides are highly absorbant it is not surprising that a minor phase did not appear.

Oxidation of Pr_6O_{11} with pressures up to 331 atm. and temperatures up to 760° yielded PrO_2 and/or $PrO_{1.83}$. No evidence of an intermediate phase was found. These high temperature-high pressure samples were prepared with questionable quenching techniques, since no check could be made of the sample composition before and after quenching. It is possible that an intermediate phase was present and changed into two phases during quenching.

A high temperature camera capable of keeping the sample under 300 atm. oxygen pressure near 1000° is needed to be certain that no phase changes occur when the sample is quenched. All that can be said is that at pressures less than ten atmospheres there was no appreciable composition change upon quenching.

From their studies, Gruen, *et al.*,[4] and Martin[5] concluded that a single phase inhabited the region $PrO_{1.83}$–$PrO_{2.00}$, whereas McCullough[2] observed a miscibility gap in this range. Also the extensive studies of mixed rare earth oxides by McCullough[10] and others,[11,12] indicated complete solid solution in this range.

It should be pointed out that in the study of the praseodymium system reported by Ferguson, *et al.*,[7] there were at least three regions of continuous non-stoichiometric composition which tended toward separation into two phases. Although these diphasic regions were not observed from X-ray studies, they were inferred from the nature of the $(P, X)_T$ isotherms. As the oxygen content increased, the apparent critical transition temperature decreased. Also, the dissociation pressure at the critical temperature increased. An extrapolation of this trend to the region above $PrO_{1.83}$ indicates a critical temperature of less than 585° and a dissociation pressure above one atmosphere should be expected.

Gruen, *et al.*,[4] using atomic oxygen to treat the praseodymium oxides, reported a reaction temperature of 450°. Similar experiments carried out in the present study showed that the surface of the oxide sample was heated to incandescence by the recombination of oxygen and reaction at the surface. Therefore, the temperature reported by Gruen, *et al.*, might have been that of the bulk of the material, not the surface temperature. It is then probable that the true reaction temperature was considerably higher than 450°.

The one mixed oxide study carried out at low temperatures was the Nd–Pr system studied by McCullough.[2] It was reported that at 300° one phase inhabited the region $RO_{1.83}$–$RO_{2.00}$. It is possible that the substitution of Nd^{+3} for Pr^{+3} lowers the critical temperature.

The existence of a solubility loop between similar phases is not unique. Grønvold and others[13–15] have shown that the uranium oxide system in the region UO_2–U_4O_9 is monophasic at low temperatures (equilibrium here is questioned) changing to a diphasic region as the temperature is raised to 250°. At approximately 350° the system again be-

comes monophasic.[15] The phases present in this region are anion excess fluorite structures with lattice constants of 5.4704 and 5.4411 Å. for UO_2 and U_4O_9, respectively.[15]

It is apparent, then, that there is a solubility loop in the fluorite region between $PrO_{1.83}$ and $PrO_{2.00}$ below a temperature of at least 350° with a probable transition to a homogeneous system at elevated temperatures. This observation based on the present study apparently explains much of the work of others previously thought to be contradictory. It also appears to be a reasonable extension of the known facts of the PrO_x system, as determined by equilibrium dissociation pressure measurements, and is not at variance with observations on related oxide systems including many of the mixed oxides.

It is not possible from the present study to fix the transition temperature exactly, but it must be above 350°. From the extension of the lower oxide studies and the Nd–Pr system an upper limit of approximately 585° would be expected.

Reasonably complete studies of the oxide systems of cerium and praseodymium and preliminary studies on the oxides of terbium[7,8,16,17] have now been reported. It is of interest to compare the phase relationships of these lanthanide oxides. Each oxide system changes from a body-centered cubic to a rhombohedral to a face-centered cubic phase as the oxygen content is increased. Similar stable compositions exist in each system, with the major difference being the lack of an intermediate face-centered cubic phase in the cerium system. A given region of any of these systems can be either diphasic or monophasic depending upon the temperature and pressure of the preparation.

Species of Molybdenum(VI) in Hydrochloric Acid[1]

BY H. M. NEUMANN[2] AND NANCY C. COOK

RECEIVED DECEMBER 21, 1956

Ultraviolet spectrophotometry has been applied in a study of the species of Mo(VI) present in hydrochloric acid solutions. Compounds of Mo(VI) containing molybdenum and chlorine in the ratios 1:2, 1:3 and 1:4 have been prepared and their spectra determined in ether solutions. Although all three types display a maximum at 226 mμ, each has a second maximum at longer wave lengths that is characteristic of the particular Mo:Cl ratio. These results have been applied to the analysis of the spectra of solutions of Mo(VI) in hydrochloric acid. The species containing two chlorines is the most important in these solutions, its maximum amount occurring in 6 *M* HCl. At greater acidities a species containing three chlorines becomes important. There is no evidence for species containing a larger number of chlorines. The species containing two chlorines is apparently the one extracted by ethers and bound by anion-exchange resins.

Although molybdenum is most commonly encountered as molybdenum(VI), the aqueous chemistry of this oxidation state is, to a large extent, unknown. The greatest difficulties in working out the details of molybdenum(VI) chemistry arise from the fact that in acidic solution polymerization occurs to form polymolybdates. By using an acid whose anion could become involved in complex formation, one is more likely to find the molybdenum(VI) present in monomeric form, and hence have some chance of identifying the species actually present. The work reported here is based upon the use of hydrochloric acid as the medium and ultraviolet absorption spectrophotometry as the means of studying the composition of the various solutions. This seemed a promising method since any chloro complexes would be expected to have absorption maxima in the ultraviolet region. In addition, several compounds of Mo(VI), containing various numbers of chlorine atoms, have been reported in the literature, and it seemed likely that a comparison of their spectra with those of solutions of Mo(VI) in hydrochloric acid would give information about the species of Mo(VI) present in the acid solutions.

The ultraviolet spectra of the compounds themselves are of interest, since at the present time there is little apparent correlation between the spectra and structure of halo complexes. In part, this is due to insufficient data, so that any additional data from known compounds, as is possible in the molybdenum(VI) case, may ultimately lead to some correlations.

Experimental

Analytical Methods.—Determinations for molybdenum in macro concentration were performed by the method described by Kolthoff and Sandell.[3] The chloride determinations employed the method suggested by Michael and Murphy[4] for chloride in the presence of molybdenum. The determination of the total molybdenum(VI) in ether solutions when the molybdenum concentration was of the order of 10^{-4} *M* was accomplished by completely transferring all the Mo(VI) into an aqueous 6 *M* HCl solution by evaporating a measured aliquot of the ether solution while in contact with the 6 *M* HCl solution, boiling to remove all the ether, and then diluting with additional 6 *M* HCl to a fixed volume. The absorption spectrum of the solution was then measured, and compared with the spectra of solutions of known concentrations in 6 *M* HCl.

Measurements of Absorption Spectra.—All absorption spectra were measured with a Beckman Model DU spectrophotometer using matched, fused silica cells having a light path of 1 cm. The cells were maintained at a constant temperature of 25° by means of a water jacket. The spectra of hydrochloric acid solutions were obtained from 212 to 350

mμ, and in ether solutions from 218 to 350 mμ. Readings were taken at 2 mμ intervals from 212 to 300 mμ, and at 5 mμ intervals thereafter. The slit width was varied from one wave length to another, but was maintained constant for a given wave length for all solutions in the same solvent.

A stock solution 0.114 *M* in Mo(VI) was prepared in concentrated hydrochloric acid. The solutions to be used for spectral determination were prepared by placing a measured aliquot of the stock solution in a 50-ml. volumetric flask and diluting to the mark with hydrochloric acid of the desired concentration.

The ether solutions used for spectral determination were prepared in the following way. A saturated solution was obtained by contacting the solid compound with anhydrous ether. The solution was then diluted until the optical density reached a reasonable value, and the spectrum then determined. The concentration of the Mo(VI) in the ether was then determined in the way previously outlined.

Preparation of Compounds: MoO_2.—The method of Guichard[5] was used. An approximately 1:1 volume ratio of molybdenum trioxide and ammonium molybdate was pulverized and heated to red heat in a platinum crucible. The molten mass was solidified by pouring it into cold water. The crystals were washed several times with ammonium hydroxide by decantation, then with 6 *M* hydrochloric acid until the hydrochloric acid ceased to be colored red. The crystals had a dark blue color.

MoO_2Cl_2.—The method of Wasmuht[6] was employed for the preparation of molybdenum dioxydichloride. A reaction chamber was constructed of two glass tubes 18 inches long, the smaller of which was 3/4 in. in diameter. The tubes were fitted together tightly with resistance wire wrapped between them, and the ends of the wire connected to a Variac. About 5 g. of MoO_2 was placed inside the tube at the center. One end of the tube was attached to a cylinder of anhydrous chlorine gas, and the other to the receiver, a large-mouthed bottle. The temperature was set at 360° and gradually increased until yellow powder crystals began to be formed rapidly in the receiver. These crystals were yellow in color, were not appreciably hygroscopic, and discolored only very slowly on exposure to air. *Anal.* Calcd. for MoO_2Cl_2: Mo, 46.4; Cl, 37.8. Found: Mo, 46.3; Cl, 37.7.

$MoO(OH)_2Cl_2$.—The general method given by Weinland and Knoll[7] was followed. Molybdic anhydride, which had been dried at 150° for two hours, was used as the starting material. The same reaction tube was used as for the preparation of MoO_2Cl_2. The chamber was heated to 150° at which time approximately 15 g. of the dry MoO_3 was spread inside the inner tube. A cylinder of anhydrous hydrogen chloride was connected to one end of the tube and the gas was allowed to stream slowly over the MoO_3. A large-mouthed bottle was used as the collection vessel. At 150° very little product was formed, so the temperature was increased slowly. At 250° yellow needle-like crystals formed abundantly in the collection vessel. The color of the crystals was like that of MoO_2Cl_2, but the compound was unlike MoO_2Cl_2 in that it was very hygroscopic, and rapidly turned from yellow to blue. Keeping the product in a dry atmosphere, in a vacuum, or in the dark did not prevent the rapid change in color. The blue material formed was similar in behavior to "molybdenum blue" that is formed as the first product in the reduction of molybdate in acid solution. The blue solid could be converted to a yellow form both by treatment with dilute sulfuric acid and with dilute sodium hydroxide. *Anal.* Calcd. for $MoO(OH)_2Cl_2$: Mo, 44.2; Cl, 31.6. Found: Mo, 44.2; Cl, 32.2.

$MoO(OH)Cl_3 \cdot 7H_2O$.—According to Weinland and Knoll,[7] when $MoO(OH)_2Cl_2$ is made into a mush with fuming hydrochloric acid and the mixture warmed with evolution of hydrogen chloride, the mass solidifies to form $MoO(OH)Cl_3 \cdot 7H_2O$. The compound is also formed by saturating with hydrogen chloride gas a solution of $MoO(OH)_2Cl_2$ in fuming hydrochloric acid and evaporating the liquid over sulfuric acid. The latter method was found more satisfactory. Freshly prepared $MoO(OH)_2Cl_2$ was dissolved in concentrated hydrochloric acid. Hydrogen chloride gas was bubbled into this viscous yellow solution for ten minutes and the solution was placed over sulfuric acid in a vacuum desiccator. As the solution decreased in volume over a period of days it also developed a greenish color. After several days light green crystals were formed which were very hygroscopic, and which turned slightly blue on exposure to air. *Anal.* Calcd. for $MoO(OH)Cl_3 \cdot 7H_2O$: Mo, 26.6; Cl, 29.4. Found: Mo, 26.5; Cl, 30.4.

Other Compounds.—Weinland and Knoll[7] have also reported the preparation of $KMoO_2Cl_3 \cdot H_2O$ and $K_2MoO_2Cl_4 \cdot 2H_2O$ by crystallization from solutions containing $MoO(OH)_2Cl_2$, HCl and KCl; the preparation of $(NH_4)_2MoO_2Cl_4 \cdot 2H_2O$ by crystallization from solutions containing $MoO(OH)_2Cl_2$, HCl and NH_4Cl. Compounds were prepared by these methods, and their properties agreed with those reported by Weinland and Knoll, and the molybdenum and chlorine analyses corresponded to the formulas as written above.

Results and Discussion

Spectra of Compounds in Ether.—The spectra of ether solutions of the prepared compounds were measured as previously described. Aqueous solutions could not be used as all the compounds react rapidly when added to water. Although reaction in ether is a possibility, the results indicate that if any reaction occurs it is limited to the loss of coordinated water molecules from the Mo(VI) complex.

The compounds MoO_2Cl_2 and $MoO(OH)_2Cl_2$ were expected to show good solubility in ether; the most concentrated solutions prepared indicate a solubility in the range 0.02–0.03 *M*. The solubility would be expected to be smaller for $MoO(OH)Cl_3 \cdot 7H_2O$, with a further decrease for $KMoO_2Cl_3 \cdot H_2O$, and with extremely small solubility for $K_2MoO_2Cl_4 \cdot 2H_2O$ and $(NH_4)_2MoO_2Cl_4 \cdot 2H_2O$. Because of the method of preparation of the last three compounds, $MoO(OH)Cl_3 \cdot 7H_2O$ is a possible contaminant. Even though its percentage abundance is small, its greater solubility might result in its being the predominant species present in the solution when the solid is contacted with ether. As a result, the spectra obtained from these three solutions must be interpreted with caution.

Spectra representative of these compounds are shown in Fig. 1. All show a maximum at approximately 226 mμ. The spectra of MoO_2Cl_2 and $MoO(OH)_2Cl_2$ are very similar, having in addition to the maximum at 226 mμ a shoulder in the region of 240–250 mμ. Some variations in the spectra were observed for different preparations and solutions of $MoO(OH)_2Cl_2$, and the same behavior was exhibited by solutions of MoO_2Cl_2. There was no change in the wave length of maximum absorption, but the value of the molar absorbancy index at the maximum varied from 5,500 to 6,200. Although the shoulder was more clearly defined in some samples than others the total variation in molar absorbancy index values did not exceed 5% in this region. The cause of these variations may be the varying amounts of water in the solutions, which can change the extent of oxygen coördination to the molybdenum.

The compounds $MoO(OH)Cl_3 \cdot 7H_2O$ and $KMoO_2Cl_3 \cdot H_2O$ do not have the shoulder, but have instead a second maximum at 290 mμ. The spectra of solutions of the compounds $K_2MoO_2Cl_4 \cdot 2H_2O$ and $(NH_4)_2MoO_2Cl_4 \cdot 2H_2O$ were similar to these, except that the second maximum occurred at 310 mμ rather than at 290 mμ.

Reconstructed spectra of species present in aqueous HCl solutions: ———, the species containing two chlorines; – – – –, the species containing three chlorines.

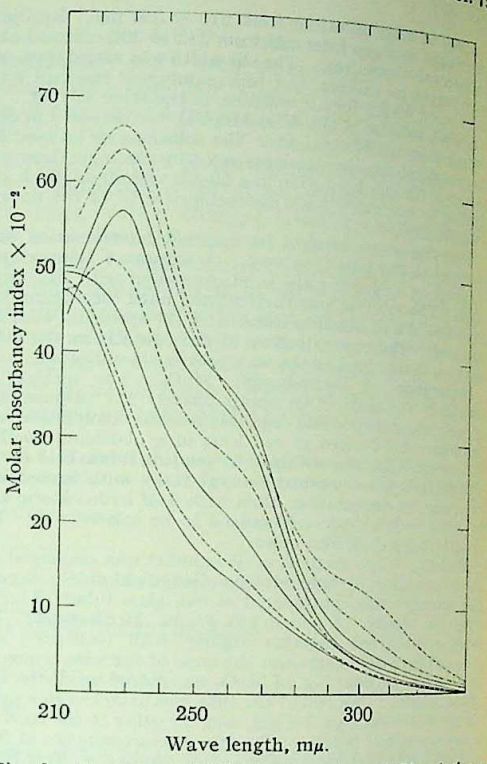

Fig. 2.—Spectra of Mo(VI) in various HCl solutions. Curves in ascending sequence are for the following HCl concentrations: 0.99, 1.98, 2.97, 4.00, 4.94, 6.94, 8.90 (curve only partially shown) and 10.82 *M*.

On the basis of these observations we conclude that all the chlorines appearing in the formula are coördinated to molybdenum, and that the position of the second (*i.e.*, longer wave length) maximum can be used as a measure of the number of coördinated chlorides.

Compounds with a Mo:Cl ratio of 1:2 are characterized by the shoulder at 240–250 mμ; 1:3 compounds by the maximum at 290 mμ. Because of the possibility of $MoO(OH)Cl_3 \cdot 7H_2O$ contributing to the spectra of the 1:4 compounds it cannot be stated that the second maximum for pure 1:4 compounds occurs at 310 mμ; but the maximum certainly must occur at a wave length greater than or equal to 310 mμ.

These spectra are also of interest in connection with the ether extraction of Mo(VI) from hydrochloric acid solutions. The spectra of ether phases obtained by extraction from 3, 6, 7, 8 and 9 *M* hydrochloric acid solutions were measured. All of these ether phases gave spectra characteristic of a compound containing Mo and Cl in the ratio of 1:2. This is in agreement with the ratio obtained by chemical analysis of the ether phase.[8]

Spectra of Hydrochloric Acid Solutions.—Solutions near integral molarities from 1 to 12 *M* were examined. The general characteristics of the spectra are apparent from the selected curves shown in Fig. 2. There is a general similarity to the curves of the pure compounds in ether, but with some shifts in the wave lengths of the maxima. The maximum at 226 mμ is present in the solutions 5 *M* or greater in acidity. The shoulder at 240–250 mμ in the ether solutions, characteristic of compounds containing two chlorines, has shifted to 260–270 mμ. At the highest acidities a second shoulder develops at approximately 300 mμ. This is the region in which we expect a peak due to a species containing three chlorine atoms.

The spectral changes in hydrochloric acid solutions have been interpreted on the assumption that the species containing two chlorines has an absorption maximum at 226 mμ in addition to the shoulder at 260–270 mμ, while the species containing three chlorines has absorption maxima at 226 and 290–300 mμ. The growth of the absorption maximum at 226 mμ with increasing acidity in the range 5–12 *M*, while that at 260–270 mμ decreases and that at 290–300 mμ increases, quite clearly indicates that the species containing two chlorines has a less intense absorption at 226 mμ than the species containing three chlorines.

It was found possible to resolve these spectra into their component parts by the following method, which is illustrated in Fig. 3. The logarithm of the absorbancy was first plotted *vs.* wave length. It was assumed that on this type of plot the tail from the peak at 226 mμ would be a straight line, and the most reasonable line was drawn. Subtraction of these values from those of the total spectrum gave a curve containing one or two maxima.

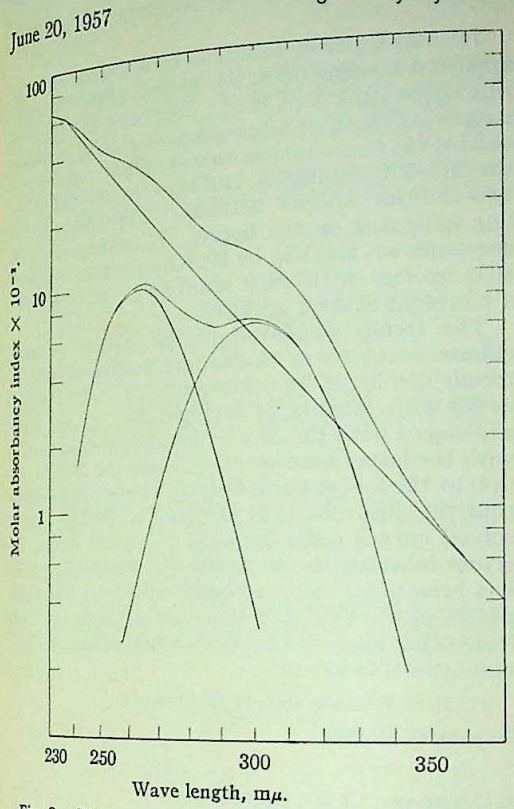

Fig. 3.—The spectrum of a solution 10.82 M in HCl, and the resolution of the spectrum into its component parts.

The absorption that causes the shoulder in the 260–270 mμ region resolved nicely by this method to give a maximum at 264 mμ (the species with two chlorines). In the solutions 10 M or greater in HCl a second maximum occurred at about 300 mμ. Since the resolved spectrum from the 6 M HCl solution was predominantly that of the two-chlorine species, it was used to further resolve the spectra in the higher acid concentrations. Figure 3 shows an example of how this leads to a resolved peak with a maximum at 302 mμ (the species with three chlorines). The height of each resolved peak then served as a measure of the amount of that component. The solutions 8–12 M in HCl display isosbestic points at 256 and 274 mμ, indicating the presence of only two species. This fact, in conjunction with the observed peak heights, allowed calculation of the peak heights for the pure components and the abundance of each component in the various solutions. Table I shows the abundances determined in this way.

It was possible to reconstruct the entire spectrum for each of these species in the following way. For a solution containing only two components, I and II, it is true that $A_{obsd} = A_I F_I + A_{II} F_{II}$, where A_{obsd} is the observed molar absorbancy index, A_I and A_{II} are the corresponding values for the pure components, and F_I and F_{II} are the fractional amounts of Mo(VI) present in the respective forms. Plotting A_{obsd} *vs.* F_I should then give a straight line which has A_I as an intercept when $F_I = 1$, and has A_{II} as an intercept when $F_I = 0$. The absorbancy data for the five solutions of greatest acidity were treated in this way, using values of F corresponding to the percentages of Table I. For the majority of wave lengths all five points fell on a line; at no wave length was more than one point badly off a line. This consistency lends additional support to the results listed in Table I. The values of the intercepts from these graphs gave the data necessary to reconstruct the spectra of the two components. These are shown in Fig. 1.

TABLE I

ABUNDANCES OF Mo(VI) SPECIES IN HYDROCHLORIC ACID

HCl, M	% present as 2-chlorine species	% present as 3-chlorine species

0.99	20	..

Conclusions

Figure 4 shows an interesting relationship between the abundance of the 2-chlorine species and the behavior of these solutions with respect to ether extraction and retention on an anion-exchange resin. The extraction work is that of Nelidow and Diamond[8] and the anion-exchange report that of

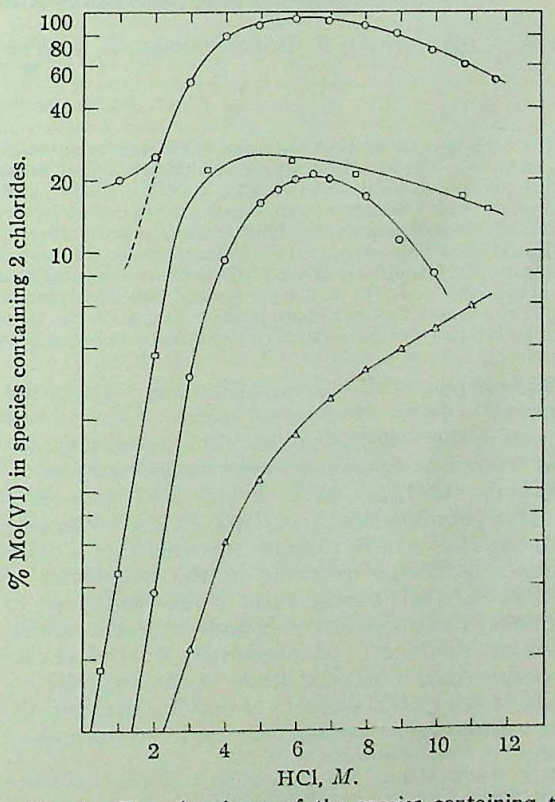

Fig. 4.—The abundance of the species containing two chlorines (upper curve, left hand ordinate), compared to distribution ratios for an anion-exchange resin[9] (□), isopropyl ether[8] (○), and diethyl ether[8] (△).

Kraus, Nelson and Moore.[9] The values of the ordinates for the distribution data are purely relative for each of the functions plotted; the shapes of the curves are the feature of consequence. Although all the evidence relating to the extraction by ethers indicates that the extracted species contains two chlorines, the fact that the extraction curves do not correspond to the spectral data is not surprising; the distribution depends on many factors other than the equilibrium in the aqueous phase, and this equilibrium itself is shifted due to the presence of ether in the aqueous phase. For example, a decrease in the distribution ratio for isopropyl ether would be expected at the highest acidities even if there were no decrease in the amount of the extractable species in the aqueous phase.[10] The rapid rise of all curves for acidities up to 4 *M* indicates that the equilibrium in the aqueous phase is the most important factor in determining the distributions at these conditions.

The anion resin data corresponds sufficiently well with the spectral data to suggest that the species containing two chlorines is the form bound by the anion exchanger.

(10) D. E. Campbell, A. H. Laurene and H. M. Clark, *ibid.*, **74**, 6193 (1952).

The most glaring failure of correspondence is the apparent leveling off in the amount of the two-chlorine species in 1–2 *M* HCl. The most likely explanation is that these solutions contain another species of Mo(VI) that also has an absorption maximum in the 260–270 mμ region, and that the amount of the two-chlorine species actually follows the dashed line indicated on the figure. Examination of the spectrum of Mo(VI) in $HClO_4$ solutions indicates that species with such absorption characteristics are present at such acidities.

The trends displayed in the spectra of these chloro complexes of Mo(VI) are consistent with the trends displayed by other elements. The resolved peaks with maxima at 264 and 302 mμ are those associated with the Mo–Cl bond, and the complex with the larger number of chlorines has the absorption at the longer wave length. It is also of interest that the absorptions at the maxima of the two resolved curves differ by only 3% (well within the errors inherent in the method). This relationship has been observed previously with the chlorocomplexes of Sb(V),[11] but there are not sufficient data from other elements to decide whether this is a general type of behavior.

Metal Chelate Compounds as Catalysts in the Hydrolysis of Isopropyl Methylphosphonofluoridate and Diisopropylphosphorofluoridate[1]

BY R. C. COURTNEY, R. L. GUSTAFSON, S. J. WESTERBACK, H. HYYTIAINEN, S. C. CHABEREK, JR., AND A. E. MARTELL

RECEIVED SEPTEMBER 7, 1956

The rates of hydrolysis of Sarin and DFP have been studied in the presence of a wide variety of metal chelate compounds as catalysts. The metal ion which yielded the largest number of catalytic metal chelates was found to be Cu(II), while a number of metal chelates of UO_2(VI), ZrO(IV), Th(IV) and MoO_2(VI) were also found to have considerable activity. Although the Cu(II) catalysts were apparently in a class by themselves, the following characteristics were found to be required in these hydrolytic catalysts: 1, incomplete coördination of the metal ion by the ligand; or 2, presence of oxy groups (or hydrated oxy groups) attached to the metal in certain cases where coördination was apparently complete. The wide variety of active metal complexes of Cu which were investigated made it possible to observe the following factors which favor maximum catalytic activity: 1, the presence of two aquo groups on the metal; 2, low stability of the metal chelate compound; and 3, the presence of maximum positive charge on the metal chelate. The importance of steric factors is indicated by the high activity of Cu(II) chelates of highly substituted diamines.

The purpose of this investigation was to study the catalytic effects of various metal chelate compounds in the hydrolysis of the cholinesterase inhibitors known as Sarin (isopropyl methylphosphonofluoridate $(C_3H_7O)(CH_3)POF$ and DFP (diisopropyl phosphorofluoridate, $(C_3H_7O)_2POF$). Wagner-Jauregg, *et al.*,[2] have recently reported that Cu(II) chelates active as catalysts in the hydrolysis of DFP contain a 1:1 molar ratio of the Cu(II) ion to a number of ligands, which include various α-amino acids and diamines. More recently Ryland, *et al.*,[3] have described a detailed study of the catalytic activity of the Cu(II) chelates of ethylenediamine, dipyridyl and *o*-phenanthroline, and have proposed a mechanism to explain the observed rates as a function of the metal chelate species present under their experimental conditions. The only other study of metal ion catalysis of hydrolysis of cholinesterase inhibitors is a report by Augustinsson and Heimbürger[4] which describes the effectiveness of Cu(II), Ni(II), Co(II), Ag(I), Au(III) and Pd(II) salts in accelerating the hydrolysis of Tabun (N,N-dimethyl - ethylphosphoroamidocyanidate). No previous reports on the catalysis of Sarin hydrolysis by metal chelate compounds have appeared in the literature.

Experimental

The liberation of acid during hydrolysis of Sarin was measured as a function of time with a Beckman automatic titrator, which was operated so as to automatically maintain the experimental solution at constant *p*H by addition of

(4) K. B. Augustinsson and G. Heimbürger, *Acta Chem. Scand.*, 9

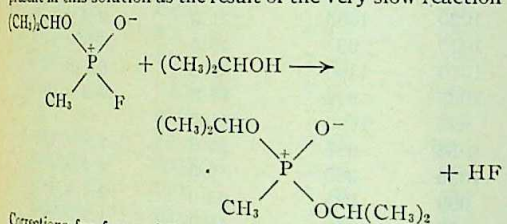
Digitized by Arya Samaj Foundation Chennai and eGangotri

standard base from a micro-buret. The reaction was carried out in a multinecked glass flask fitted with a mercury-seal stirrer, nitrogen-inlet and outlet tubes, delivery tips for Sarin and potassium hydroxide solutions, and glass and calomel electrodes. The reaction vessel and the titrator head unit were mounted in a high-speed hood, the flask being immersed in a constant temperature bath which was maintained at 25.3 ± 0.05°.

In operation, an aliquot of metal chelate solution was introduced into the titration cell, presaturated nitrogen was bubbled through the solution to exclude CO_2, and the *p*H was adjusted as desired by means of the automatic titrator unit. An anticipation setting of 5 was used in most of the experiments. An aliquot of Sarin (approximately 150 μ moles) was now added by means of an automatic micro-buret. Time measurements were begun at the point at which half of the Sarin solution had been added. Readings of time *vs.* corresponding KOH consumption were recorded over the course of the titration. A plot of t *vs.* $\log a/(a-x)$ (where a is the amount of base required for complete hydrolysis and x is the amount of base consumed at the corresponding time t) gave a straight line in all cases studied. The half-time, that is the time required for the hydrolysis of one-half of the Sarin, is the time corresponding to a log $a/(a-x)$ value of 0.301. Two moles of acid per mole of Sarin are liberated upon hydrolysis.

The Sarin was used as a 0.05 *M* stock solution in anhydrous isopropyl alcohol. A small amount of free acid was present in this solution as the result of the very slow reaction



Corrections for free acidity were made by adding a corresponding amount of base to the reaction mixture before the introduction of the Sarin. The total volume of the solution at the start of a titration was 150 ml.

The electrode system was calibrated at *p*H 4, 7 and 9 by means of suitable buffers which were checked against an acetate buffer as the primary standard.

Reagent grade nitrates of all metals were used except for ZrO(IV) and Sn(IV) which were used in the form of chlorides, and VO(IV), which was obtained as the sulfate. Standardization of the metal solutions consisted for the most part of evaporation and subsequent ignition to the corresponding oxides. Copper was standardized by titration with standard Na_2EDTA reagent with murexide as an indicator in ammoniacal solution.[5] Thorium was standardized by means of Na_2H_2EDTA with alizarin red indicator,[6] while manganese was determined by titration with the salt of nitrilotriacetic acid, brom thymol blue being used as an indicator.[5] The vanadyl solution was standardized by titration with standard NaOH in the presence of excess Na_2H_2EDTA according to the method of Schwarzenbach.[7]

Samples of ethylenediaminetetraacetic acid, N-hydroxyethylethylenediaminetriacetic acid, N,N'-dihydroxyethylethylenediaminediacetic acid, N-hydroxyethyliminodiacetic acid, nitrilotriacetic acid, aspartic acid, N-hydroxyethylaspartic acid and N-aminoethylaspartic acid were obtained through the courtesy of Versenes, Inc., Framingham, Massachusetts. Samples of N-hydroxyethylethylenediamine, diethylenetriamine and triethylenetetramine were obtained from Carbide and Carbon Chemical Co., purified by fractional distillation, and converted to the corresponding hydrochlorides. Ethylenediamine, 5-sulfosalicylic acid and 1,8-dihydroxynaphthalene-3,6-disodium sulfonate were purchased from Eastman Kodak Co. The ethylenediamine was dried over solid potassium hydroxide, redistilled and isolated as the dihydrochloride. Pyrocatechol-3,5-disodium sulfonate was purchased from LaMotte Chemical Products Corp., Baltimore, Maryland. The 1,3-diaminopropane was obtained from the Sharples Chemical Company while the dipicolinic acid (pyridine-2,6-dicarboxylic acid) was donated by Dr. Stanley Chaberek, of the Dow Chemical Co., Framingham, Massachusetts. Samples of the dihydrochlorides of N,N'-dimethylethylenediamine and N,N,N',N'-tetramethylethylenediamine were prepared and recrystallized by conventional methods. Standardization of the aqueous solutions of the above chelating agents was effected by means of potentiometric titration with either standard carbonate-free potassium hydroxide or hydrochloric acid.

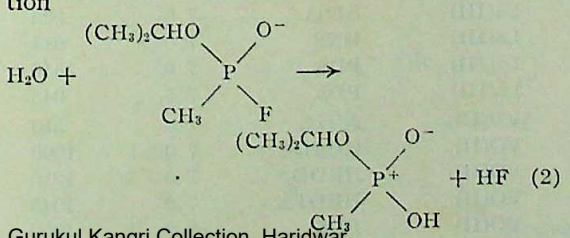
The Sarin was obtained through the courtesy of the Army Chemical Center. Standardization was effected using the automatic titrimeter in two ways: 1, neutralization of the hydrogen ions produced when an aliquot of Sarin was introduced into a 0.1 *M* nitrate solution at *p*H 10.0; and 2, neutralization of the acid produced upon catalytic hydrolysis by copper dipyridyl at *p*H 7.0. In the former case, hydrolysis was complete after approximately 40 minutes, while in the latter case, no further uptake of base was recorded after 60 minutes using approximately a five to one molar ratio of Sarin to copper dipyridyl.

In addition to the Sarin experiments, several metal chelate systems were studied to determine their effect as hydrolysis catalysts upon diisopropyl phosphorofluoridate (DFP). The DFP was obtained from the Colgate–Palmolive Company and had the following physical properties: b.p. 60–61° (8.2 mm.); density 1.055 at 25°; refractive index 1.3792 at 25°. A solution in anhydrous isopropyl alcohol was standardized by titration of acid liberated during catalytic hydrolysis by the copper chelate of N,N,N',N'-tetramethylethylenediamine at *p*H 9.0. Hydrolysis was complete in approximately 40 minutes when a molar ratio of ten to seven (copper chelate to DFP) was used. Attempts at standardization of DFP solutions by direct reaction with hydroxyl ion at a *p*H of 11.5 or greater required more than the theoretical two moles of base per mole of DFP. The exact nature of this phenomenon has not been determined but it is possible at such a high *p*H that alkyl groups also split off with consequent uptake of additional hydroxyl ions.

In order to check the accuracy of the instrument, several check runs were made using manual addition of base while recording the *p*H using a Beckman model G *p*H meter. Hydrolysis rates as determined by the manual method were approximately 10–16% greater than those observed using the automatic system. This increase in rate is probably due to the fact that in the former method the solution *p*H ranged from slightly below to slightly above the desired value, whereas due to a small lag in the instrument, the average *p*H in the automatic runs was probably lower than the desired value. For comparative purposes, the instrument seems to be quite suitable, since duplicate results agreeing within a few per cent. have been obtained in the great majority of cases.

Results

The metal chelate systems investigated for catalytic activity in the hydrolysis of Sarin are listed in Table I. The concentrations of metal chelate, Sarin and the solution *p*H are given in all cases. The metal chelates listed refer to the 1:1 chelates, unless otherwise noted. The stabilities of the metal chelate compounds investigated are sufficiently high (log $k \geq 10$) that they are not appreciably dissociated at *p*H 7. The total activities of the metal chelate species in solution are expressed as first-order hydrolysis rate constants for the reaction



Corresponding half-times of reaction also are listed.

The definitions of the abbreviations used to identify the various ligands employed are given in Table II. The corresponding catalytic activities of a number of Cu(II) chelates in the hydrolysis of DFP are listed in Table III.

Discussion

Effect of Ligand on Activity of Cu(II) Chelate Compounds.—The 29 catalytically active Cu(II) chelates listed in Table I may be classified into the following groups on the basis of the type of ligand involved: amino acids (7), phosphates (2), *o*-diphenols (2), peptides (2), diamines (12), hydroxyethylsubstituted diamines (2), and polyamines containing more than two basic nitrogen atoms (2). Of these, the diamines form the most active Cu(II) chelates, and have been explored to the greatest extent. The chelates of amino acids, peptides and phenolic ligands have somewhat less activity. The least active compounds listed in Table I are the Cu(II) chelates of the polyphosphates and of ligands with more than two donor groups per molecule. Not listed in Table I is a wide variety of chelate compounds which were not of sufficiently high activity to be interesting. These compounds

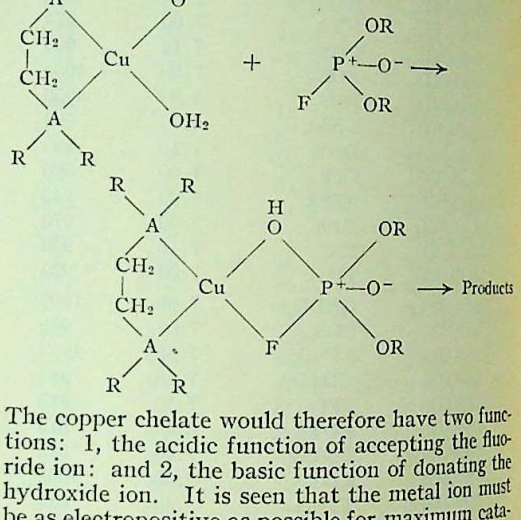
include the Cu(II) chelates of ligands which are quite negative, or form very stable chelates, or both, such as the Cu(II) chelates of EDTA, NTA, citrate and tartrate.

Influence of Charge.—The qualitative observation mentioned above indicates that the charge of the complex may have a great deal to do with the activity of a copper chelate as a hydrolytic catalyst. There are two general mechanisms by which a Cu(II) chelate compound may act as a catalyst in the hydrolysis of Sarin and DFP. The first involves the combination of the metal chelate compound with the substance being hydrolyzed, followed by attack of this complex with the hydroxide ion. Thus the nucleophilic attack of the phosphorus atom by the hydroxide ion is greatly increased by the interaction of the metal ion with the groups attached to the phosphorus atom. It is evident that the more electropositive the Cu(II) atom is, the greater will be its effect on the acceptor activity of the phosphorus atom. Therefore, one would expect that an electron donor which carries considerable negative charge would tend to decrease the rate of the reaction outlined above. The alternate reaction mechanism may be considered analogous to the push–pull mechanism advanced by Swain[8] to explain the action of pyridone in the mutarotation of glucose. Thus the hydroxy form of the Cu(II) chelate may be considered to act as an amphoteric substance in the catalytic reaction, which may be formulated as



The copper chelate would therefore have two functions: 1, the acidic function of accepting the fluoride ion: and 2, the basic function of donating the hydroxide ion. It is seen that the metal ion must be as electropositive as possible for maximum catalytic activity. The more positive the metal ion in the normal 1:1 chelate, the greater will be its tendency to hydrolyze to give the monohydroxy chelate compound illustrated above. Also, the more positive the metal, the greater will be its residual affinity for attracting the fluoride ion from the phosphate group.

The results listed in Table I indicate that the reaction rate decreases with increasing negative charge of the Cu(II) chelate. The following ligands are arranged in the order of decreasing catalytic activities of their Cu(II) chelates in the hydrolysis of Sarin: HEN > HxG > HIMDA > ASPA > EDTA. A similar series may be taken from the data of Wagner-Jauregg, *et al.*,[2] for the catalysis of DFP hydrolysis by Cu(II) chelates: *o*-PHEN, EN > glycine, alanine >> EDTA. Further examples are the greater activity of the Cu(II) pyrophosphate chelate over that of the corresponding tripolyphosphate compound, and the higher activity of the Cu(II) HEDDA chelate over that of HEDTA.

Influence of Number of Donors in Ligand.—Inspection of the catalytic activities of Cu(II) chelates of various ligands listed in Table I indicates that the highest activity is obtained with bidentate donors, and that additional donor groups per mole of ligand reduce the effectiveness of the

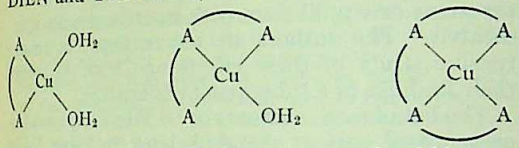
metal chelate as a catalyst. Thus the hydrolysis of Sarin in the presence of the 1:1 Cu(II)–ethylenediamine chelate is three times faster than it is in the presence of the corresponding chelate of diethylenetriamine. It is, of course, difficult to separate the simple structural or steric effect of the number of positions of the Cu(II) ion which are coördinated (see below), from allied effects such as the enhanced stability which results from the increased number of donor positions on the ligand. In the series of Cu(II) chelates of EN, HEN and 2-HEN, there is no additional stability resulting from the relatively weak coördination of the auxiliary hydroxyl groups, in contrast to analogous series EN, DIEN and TRIEN. (The steric factors resulting



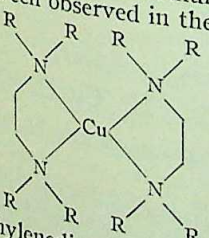
Bidentate Terdentate Quadridentate

Cu(II) chelates formed with bi-, ter-, and quadridentate ligands

from the substitution of alkyl groups on the basic nitrogen atoms are nearly compensated for by coördination of the hydroxyl groups so that the stabilities in the former series do not differ significantly.)

Since the catalytic activities of the HEN and 2-HEN chelates are about half of that of EN, it is seen that a bidentate chelate compound containing two water molecules bound directly to the metal ion is apparently the most favorable structure for producing catalytic activity in Cu(II) chelate compounds. There remains the possibility of catalysis on systems containing monodentate ligands. For the systems investigated, however, 1:1 Cu(II) complexes with monodentate reagents were not sufficiently stable to prevent precipitation at *p*H 7.

Steric Factors.—It has been shown previously[9] that the stability of a 1:1 Cu(II) chelate compound frequently is controlled by the tendency to disproportionate to the 2:1 chelate and copper hydroxide, as well as by its own intrinsic stability constant. Thus a 1:1 chelate with a high stability constant may be unstable in solution if the 2:1 chelate is also very stable. Since Cu(II) chelates are square planar, the substitution of alkyl groups in place of the amino hydrogen atoms would help to prevent this disproportionation reaction by steric repulsion between the substituents on two different moles of ligand, as is indicated by the formula shown below. This effect has been observed in the case of the N-



substituted ethylenediamines such as TMEN, DMEN, DIPY and *o*-PHEN. It is notable that all of these substances form soluble 1:1 Cu(II) chelates which do not disproportionate in aqueous solution at *p*H 7 and above, whereas the 1:1 Cu(II) chelate of ethylenediamine is not stable and is quickly converted to the 2:1 chelate with the precipitation of copper hydroxide. It is seen, therefore, that N-substitution of a 1,2-diamine is helpful in obtaining a stable aqueous catalytic chelate of Cu(II).

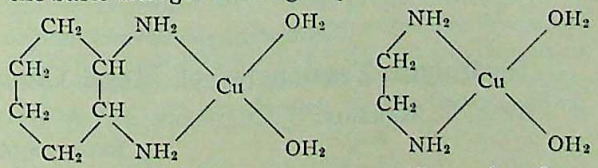
The influence of N-substitution on the specific catalytic activity of Cu(II)–ethylenediamine chelates cannot be determined unambiguously from the examples available since changes of structure also affect the stability of the metal chelate compound. The influence of stability on catalytic activity is discussed below.

Influence of Stability.—Although Wagner–Jauregg, *et al.*,[2] stated that stability of a Cu(II) chelate is not a significant factor in determining its catalytic activity, the evidence obtained in this research seems to indicate otherwise. While it is certain that many factors affect the catalytic activity of chelate compounds, the evidence in Table I seems to indicate that catalytic activity generally decreases with increasing stability of the metal chelate compound. This generalization is supported by a number of comparisons taken from the results of Table I.

1. In the series of 1:1 Cu(II) chelates formed by N-substituted ethylenediamines, the chelate stability constants decrease in the order: EN > DMEN > TMEN. The order of catalytic activity is seen to be exactly the reverse.

2. Although chelate stability constants are not available for monobipyridyl-Cu(II) and for mono-*o*-phenanthroline-Cu(II), the order of decreasing stability of these compounds and of the corresponding EN chelate may be deduced from the published stabilities of the chelates of other metal ions with these ligands to be: EN > *o*-PHEN > DIPY. It is seen that the order of increasing activity is the same: EN < *o*-PHEN[10] < DIPY.

3. Comparison of the Cu(II) chelates of the four diaminocyclohexenes and cyclohexanes with that of ethylenediamine shows no appreciable difference in catalytic activity, although it is known that the stability of the EN-Cu(II) chelate is 2 to 3 log *K* units lower than those formed from the cyclic diamines. A possible explanation of this anomaly is based on the fact that the two types of structures indicated below have equivalent electronic interaction (binding energy) between the Cu(II) ion and the basic nitrogen donor groups



The observed difference in stability, therefore, would be merely an entropy effect which depends on the initial and final states of the ligands in the formation of the metal chelate. Hence, the environment, or electronic condition of the Cu(II) ion, would be

the same in both cases, and the similarity of catalytic activity is not surprising.

In view of these correlations with stability, one would look for the least stable metal chelate compound in order to obtain maximum catalytic activity. There is a definite limit beyond which this concept cannot be pushed, however, which is defined by the stability necessary to keep the metal ion in solution. Thus the most active catalyst would be the aquo ion itself. Since the aquo ion cannot be obtained in sufficient concentration at a *p*H where the hydroxide ion concentration is also sufficient to carry out the reaction at a reasonable rate, it seems that an important function of the metal chelate compound is to maintain the metal ion at a reasonably high concentration (and activity) in aqueous solution.

Influence of Metal Ion on Catalytic Activity.—Measurements of the catalytic activities of a number of stable aqueous metal chelates of the Fe(III), La(III), Cr(III), Ti(IV) and Sn(IV) ions are listed in Table I. Not listed are a number of additional measurements made on chelates of other common metal ions such as Zn(II), Cd(II), Co(II), Fe(II), Ni(II) and Pb(II). None of the metal chelates, listed and unlisted, showed interesting catalytic activity. The Zn(II) ion was unique in that it was the only third row metal for which no active chelates were found.

On the other hand, a number of metal chelate compounds of oxo- metal ions such as ZrO(IV), UO_2(VI) and MoO_2(VI) showed very high catalytic activity toward the hydrolysis of Sarin, the most active being the ethylenediaminetetraacetato-zirconyl ion ($t_{1/2}$ = 2.2 min.), the dioxomolybdenum(VI) chelate of 3,5-disulfopyrocatechol (~7.0 min.), and the dioxouranium(VI) chelate of 3,6-disulfo-1,8-dihydroxynaphthalene (~3.5 min.), the numbers corresponding to the approximate half times of hydrolysis in the presence of a 0.0010 molar solution of the catalyst. The lack of information on the stabilities of these chelate compounds and the small number of examples of very active chelates make correlation of activity with properties of the ligand impossible. It is noted, however, that all of the active catalysts contain one or more oxo groups bound to the metal ion. Although these chelates are in some instances formed with ligands containing many donor groups, it is possible to state in all cases that oxo- or hydroxy-groups are also present. It seems probable that these basic groups must be involved in the observed catalysis by a push–pull mechanism analogous to that already proposed for the Cu(II) chelates.

Although the uranyl 5-sulfosalicylate chelate has been reported by Ryland, *et al.*,[3] to be catalytically active, studies of systems containing this chelate indicate that it is unstable in aqueous solution at *p*H 7.

General Conclusions.—The catalytic activities of metal chelate compounds listed in Table I are seen to increase with increasing *p*H and increasing concentration of the chelate. The measured rate constants increase with an increase in hydroxide ion and metal chelate concentrations, in accordance with the mechanisms suggested above. The rate constants do not increase with the first power of the concentration of these substances, and possible side reactions or equilibrium with inactive species is indicated. The authors are now engaged in an extensive study of these effects and hope to report their findings in a subsequent publication.

The list of rate constants of DFP hydrolysis in the presence of various metal chelates in Table III is restricted to some of the more active catalysts with interesting structures. The results for these compounds, together with the results reported by Wagner-Jauregg, *et al.*, and by Ryland, *et al.*,[3] indicate that the generalizations made above for the hydrolysis of Sarin also apply to DFP, although the latter compound is more slowly hydrolyzed by all reagents investigated.

As a result of the correlation in this paper of the catalytic activity of metal chelates with structure and other properties of the ligand, the following generalizations may be made concerning the factors which tend to increase catalysis of hydrolysis by a metal chelate compound: 1, the presence of oxo, hydroxy or aquo groups bound directly to the metal; 2, bidentate ligands in the case of Cu(II) (does not hold for metals of higher valence); 3, minimum stability of the metal chelate compound which will still prevent dissociation to the metal ion; 4, high concentration (hence high solubility) of the metal chelate; 5, high *p*H.

The most active catalysts found in this investigation in the order of decreasing activity are

For Sarin: Cu(II)TMEN > Cu(II)DMEN > ZrO(II) EDTA > Cu(II) DAP > UO_2(II) $(DNS)_2$ > Cu(II) DIPY > MoO_2(VI) PDS > Cu(II) N > Cu(II) 2-HEN > Cu(II) HEN > Cu(II) DIEN

For DFP: Cu(II) TMEN > Cu(II) DIPY > Cu(II) EN > Cu(II) DAP > Cu(II) HEN > Cu(II) 2-HEN > Cu(II) 2-HEN >>> Cu(II) DIEN

The tetramethylethylenediamine-Cu(II) chelate is the most active catalyst found up to the present time.

Hydrolytic Tendencies of Metal Chelate Compounds. I. Cu(II) Chelates[1]

BY A. E. MARTELL, S. CHABEREK, JR., R. C. COURTNEY, S. WESTERBACK AND H. HYYTIAINEN

RECEIVED MARCH 4, 1957

The hydrolysis of 1:1 chelates of copper with thirty ligands has been studied potentiometrically with a view to determining relative tendencies to form hydroxy complexes. Most of the bidentate chelate compounds investigated were found to undergo hydrolysis in a limited *p*H range, with *pK* values of 7.5 ± 0.3. The number of donor groups in the ligand was found to be more important than stability in determining hydrolytic tendencies. In certain cases the existence of a highly stable 2:1 chelate resulted in disproportionation of the 1:1 chelate with simultaneous precipitation of half of the metal in the form of its hydroxide.

June 20, 1957

Because of the interest in these laboratories in the study of incompletely coördinated metal chelate compounds as catalysts and as enzyme models, it was considered desirable to first investigate the behavior of copper chelates containing one or more uncoördinated positions on the metal ion. A search of the literature reveals very little information on this type of compound. Recently the monohydroxyl complex of dipyridyl-Cu(II) has been reported by Wagner-Jauregg, *et al.*,[2] while the equilibria involving this compound as well as the hydroxides of *o*-phenanthroline-Cu(II) and of ethylenediamine-Cu(II) have been measured quantitatively by Ryland, *et al.*[3]

Experimental

The experimental method consisted of potentiometric titration of the chelating agent in the absence of, and in the presence of, the metal ions being investigated.

Apparatus and Procedure.—A Beckman Model G *p*H meter with extension electrodes was used to record the hydrogen ion concentration. Titrations were carried out in a 200-ml. eight-neck flask designed to accommodate a mercury seal stirrer, microburet delivery tube, nitrogen inlet and outlet tubes, and glass and calomel electrodes. Measurements were made at a temperature of 25 ± 0.1° unless otherwise noted. The ionic strength was maintained relatively constant with a medium containing 0.10 *M* potassium nitrate and relatively low concentrations of ligand and metal ion. Carbonate-free potassium hydroxide prepared by the method of Schwarzenbach and Biedermann[4] was used as a titrant in all cases. In order to prevent absorption of atmospheric carbon dioxide, presaturated nitrogen was bubbled through the experimental solution during the course of the titrations. In all cases reported, titration data were obtained for solutions containing equimolar concentrations of ligand or metal ion.

When thermal equilibrium had been attained, *p*H readings were taken after the addition of small increments of 0.10 *M* potassium hydroxide until the *p*H reached values of 10.5–11.0. The *p*H meter-glass electrode-calomel electrode system was calibrated against standard acetate buffer to determine hydrogen ion concentrations.

Materials.—A solution of reagent grade copper(II) nitrate was standardized by titration with standard Na_2EDTA reagent with murexide as an indicator in ammoniacal solution.[5] Samples of ethylenediaminetetraacetic acid, N-hydroxyethylethylenediaminetriacetic acid, N,N′-dihydroxyethylethylenediaminediacetic acid, N-hydroxyethyliminodiacetic acid, nitrilotriacetic acid, aspartic acid, N-hydroxyethylaspartic acid and N-aminoethylaspartic acid were obtained through the courtesy of Versenes, Inc., Framingham, Massachusetts. Samples of N-hydroxyethylethylenediamine, N,N′-dihydroxyethylethylenediamine, diethylenetriamine and triethylenetetramine were obtained from Carbide and Carbon Chemical Co., purified by fractional distillation, and converted to the corresponding hydrochlorides. Ethylenediamine, 5-sulfosalicylic acid and 1,8-dihydroxynaphthalene-3,6-disodium sulfonate were purchased from Eastman Kodak Co. The ethylenediamine was dried over potassium hydroxide, redistilled and isolated as the dihydrochloride. Pyrocatechol-3,5-disodium sulfonate was purchased from LaMotte Chemical Products Corp., Baltimore, Maryland. The 1,3-diaminopropane was obtained from the Sharples Chemical Company while the dipicolinic acid (pyridine-2,6-dicarboxylic acid) was donated by Dr. Stanley Chaberek of the Dow Chemical Co., Framingham, Massachusetts. Samples of the dihydrochlorides of N,N′-dimethylethylenediamine and N,N,N′,N′-tetramethylethylenediamine were prepared and recrystallized by conventional methods. The hydrochlorides of *cis*- and *trans*-1,2-diaminocyclohexane and the corresponding cyclohexene derivative were prepared by the stereospecific method described by Craven.[6] N,N′-Dihydroxyethylethylenediaminediacetic acid (HEDDA) was prepared by cation exchange from a solution of the sodium salt in accordance with the method described by Chaberek and Martell[7] for the corresponding monohydroxyethyl compound (HEDTA). Standardization of the aqueous solutions of the above chelating agents was effected by means of potentiometric titration with either standard carbonate-free potassium hydroxide or hydrochloric acid.

Results

The potentiometric data obtained on the metal chelates outlined above are summarized in Table I. The symbols used to describe the formulas of the metal chelates in Table I involve the notation $H_mA(OH)_i$ for the ligand and the formula $(MAO_j(OH)_{i-j}[OH]_k)^{n-m-j-k}$ for the chelates formed by combination of one mole of ligand with one gram ion of the metal ion M^{+n}. The potentiometric titration curves of the various copper chelate systems investigated are reproduced in Figs. 1 and 2.

Discussion

Potentiometric Titration Curves.—Potentiometric measurements of stabilities of some of the Cu(II) chelates investigated as well as of their hydrolytic tendencies, are indicated in Figs. 1 and 2. Of the compounds listed in Table I, titration curves of metal chelates which have been investigated previously for hydrolytic tendencies have been omitted. Thus potentiometric measurements of the Cu(II) complex of EDTA, as well as those of HEDTA, HIMDA, ASPA, EN, DAP, DIEN, and TRIEN, have been described in sufficient detail by the investigators referred to in Table I.

For the ligands containing four or more strong coördinating groups, there is a single strong inflection in the 1:1 Cu(II) chelate titration curve corresponding to the neutralization of all the displaceable protons (four or less) of the ligand. This behavior is characteristic of EDTA, HEDTA, 2-HEDDA, TRIEN and DIEN. The titration curves of these compounds showed no evidence for the further coördination of the metal with hydroxyl groups derived from the solvent.

Ligands having hydroxyethyl groups in positions favorable for coördination constitute a special case in view of the weak coördinating tendencies of this group. In cases where the number of strong coordinating groups was too small to satisfy the requirements of the Cu(II) ion (*i.e.*, less than four), a step in the titration curve usually is observed. This is true of HASPA (Fig. 1), HEN and 2-HEN (Fig. 2) as well as HIMDA and HxG, titration curves of which have been given previously.[12,13] For these ligands, it is believed that the hydroxyethyl group is coördinated with the Cu(II) ion in view of the enhanced stability of the chelate compound over the one formed by the corresponding

[a] Chaberek and Martell[8] report 8.5 at 30°. [b] Ackermann, *et al.*,[9] report log K_{CuEN} = 10.72 at 25°. [c] K is formation constant of normal chelate. [d] K_a is acid dissociation constant of normal chelate.

ligand in the absence of the hydroxyethyl group. The additional step in the titration curve would then be due to the dissociation of a proton from the hydroxyethyl group as shown by I → II. This reaction has no counterpart in the uncoördinated ligand, due to the very weak acidity of hydroxyethyl groups. Since it is not possible to give the stability constant of compound II in terms of the metal ion and ligand, the only other alternative, followed in Table I, is to give a stability constant for I and pK values for the subsequent dissociation steps.

The qualitative comparisons possible in the titration curves of ASPA and HASPA, given in Fig. 1, serve to illustrate the principles involved. The greater *p*H decrease of HASPA on coördination with Cu(II) ion (observed best between a = 1

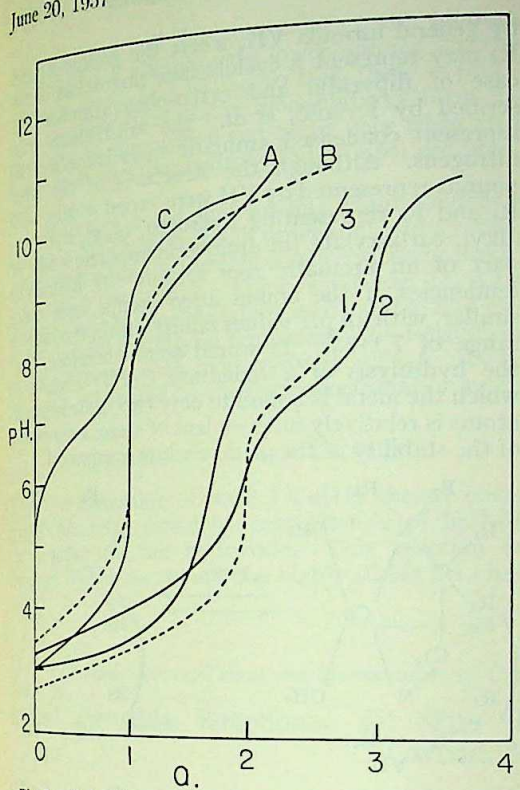

Fig 1.—Potentiometric titration of aspartic acid derivatives in the presence of (indicated by numbers) and in the absence of (indicated by letters) an equivalent molar amount of Cu(II) salt: HASPA, ASPA and AEASPA indicated by A, B, C, and 1, 2 and 3, respectively.

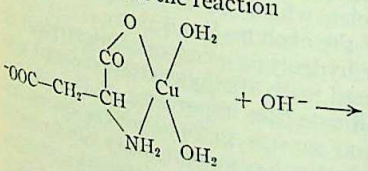
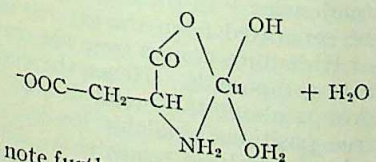
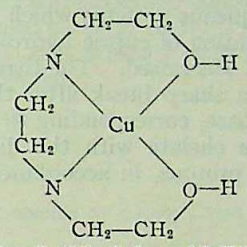
and $a = 2$) is an indication of the greater stability of the Cu-HASPA chelate, even though one would expect the reverse since HASPA is the more acidic ligand. This seems to indicate the participation of the hydroxyethyl group as a weak coördinating partner. For this reason the buffer region in the Cu(II)-HASPA curve is believed to correspond to a reaction similar to that illustrated above. Such a reaction is not possible with the Cu(II) aspartate, and the analogous buffer region must correspond to the dissociation of a coördinated water molecule in accordance with the reaction





It is interesting to note further that the more stable chelate (that of HASPA) shows the lower acidity of the proton attached to a coördinated oxygen. This may be due in part to the greater basicity of oxygen bound to alkyl groups over oxygen in water.

The question of participation of hydroxyalkyl groups in chelation of a metal ion has been considered by a number of investigators[10,13,19,20] with the weight of evidence in favor of direct coördination of the metal ion by the hydroxyalkyl groups. Thus for all of the Cu(II) chelates illustrated in Fig. 2, the coördination of the hydroxyalkyl group is believed to take place when such groups are present, in spite of the similarities of the buffer regions between $a = 2$ and $a = 3$. In the case of HASPA (Fig. 1) and HEN (Fig. 2), it should be pointed out that the hydroxy chelates and the alkoxy chelates would be tautomeric and that the product may actually be an equilibrium mixture of the two. It is noted that a similar interpretation cannot apply to the dihydroxyethyl derivative (III) without implying the displacement of a hydroxyalkyl group, which seems unlikely.



III. Cu(II) chelate of 2-HEN

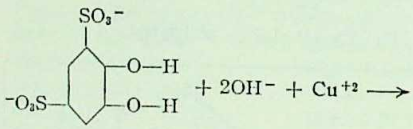
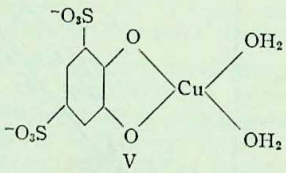
The titration curves of *cis*- and *trans*-1,2-diaminocyclohexane and *cis*- and *trans*-1,2-diaminocyclohexene indicate that the Cu(II) chelates are very similar to those of ethylenediamine, with somewhat enhanced stability of the normal chelate, but with little difference in the buffer regions resulting from hydroxy chelate formation. The synthesis and properties of these diamines and of their metal chelates will be given in a subsequent publication.[21]

The potentiometric titrations and related properties of the Cu(II) chelates of glycylglycine and of glycylglycylglycine are being reported elsewhere.[18]

A number of bidentate chelates of Cu(II) with only oxygen donors were also investigated. Thus far only tiron (PDS) and chromotropic salt (DNS) gave stable aqueous systems which did not result in the precipitation of cupric hydroxide as the *p*H of the solution was raised. The titration curve for PDS showed a sharp break after the addition of two moles of base, corresponding to the formation of a bidentate chelate with the displacement of both phenolic protons, in accordance with the reaction

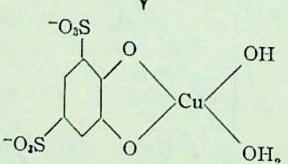


IV



V

↓ +OH-



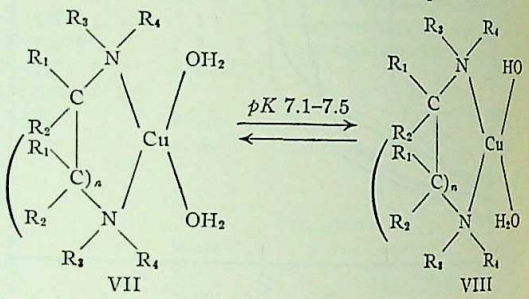
VI

A second step, requiring a third mole of base probably involves the formation of a hydroxy chelate according to the reaction given above.

The titration curve of the 1:1 Cu(II)-DNA chelate is not as clear-cut since there is only a long sloping buffer region in which three moles of base is required per mole of metal ion or ligand. It is probable that the compounds formed are analogous to those indicated above for tiron.

Among the bidentate ligands containing only oxygen donors, which failed to prevent precipitation of the metal at a 1:1 ratio of ligand to metal ion, may be mentioned 5-sulfosalicyclic acid and sodium pyrophosphate.

The majority of the Cu(II) complexes which were found to form soluble hydroxy chelate compounds are diamines with the structure indicated by general formula VII, where the groups R_1 and R_2 may represent a cyclohexane ring or, as in the case of dipyridyl and ortho-phenanthroline described by Ryland, *et al.*,[3] the substituents may represent condensed aromatic rings including the nitrogens. Although the structures of the compounds represented by VII were varied widely, with R_3 and R_4 representing hydrogen, alkyl, hydroxyalkyl, carboxylate (in aminoethylaspartic acid), or part of an aromatic ring system, the hydrolytic tendencies of the bound aquo groups were quite similar, with all *pK* values falling within the narrow range of 7.1–7.5. It would seem, therefore, that the hydrolysis of a bidentate Cu(II) chelate in which the metal is bound to only two basic nitrogen atoms is relatively independent of steric factors and of the stability of the metal chelate compound.



VII VIII

Thus the stabilities of ethylenediamine-Cu(II) and of tetramethylethylenediamine-Cu(II) differ widely, but their hydrolytic tendencies are almost identical. This is also true of the chelates formed from the mono- and dihydroxyethylethylenediamines.

The relative lack of influence of steric factors on the hydrolysis of substituted alkylenediamine-Cu(II) chelates is evidenced by the similarities between such widely different compounds as the Cu(II) chelates of dipyridyl, *o*-phenanthroline, ethylenediamine, and the *cis*- and *trans*-1,2-cyclohexanediamines. A number of Cu(II) chelates with oxygen donors or with oxygen and nitrogen donors show similar hydrolytic tendencies. Thus the Cu(II) chelates of tiron (PDS) and of chromotropic salt (DNS) and of aspartic acid have hydrolytic tendencies which do not differ appreciably from those of the chelates listed above.

The higher hydrolytic constants of the tridentate chelates formed with diethylenetriamine and glycylglycine indicate the importance of the number of bound aquo groups in determining hydrolytic tendencies. In these compounds this effect cannot be separated from the greater electronic influence of tridentate donors over the corresponding bidentate compounds. Hence the distribution of donor groups about the metal as well as the number of free positions available for hydrolysis may determine hydrolytic tendencies. Although one might be tempted to correlate the tendency of Cu(II) chelates toward hydrolysis with the asymmetry of the electronic field about the metal ion, the relative tendencies of stable tridentate and bidentate metal chelates can apparently be explained on much simpler grounds—the greater electron donor effect of the tridentate ligand on the remaining bound

water molecule and the consequent greater binding of protons (or alternatively lower affinity for the hydroxyl ion). In addition to this, there is probably a stabilization of the monohydroxy form by hydrogen bonding which can occur only when two water molecules (or hydroxylkyl groups) are present.

It is further noted that an important tendency in the Cu(II) chelates which prevents hydroxy chelate formation is the formation of a relatively stable 2:1 chelate compound. Thus, while the 1:1 Cu-(II)-ethylenediamine chelate is quite stable and exhibits normal hydrolytic tendencies, the formation of the corresponding monohydroxy chelate above *p*H 7.0 is prevented by the disproportionation reaction

$$2CuA(OH) \longrightarrow CuA_2 + Cu(OH)_2$$

Thus the formation of the 2:1 Cu(II) chelate compound is accompanied by precipitation of half of the copper as the hydroxide. This reaction is favored by the formation of a highly stable 2:1 chelate compound, with the result that the disproportionation reaction of the type given above results in a favorable free energy decrease. Such reactions are prevented in the hydroxyethylethylenediamines by higher stability of the 1:1 chelate as the result of participation of the weak ethanol donors in chelate formation. Disproportionation reactions are also prevented in the N-alkylated ethylenediamines through lowering of the stability of the 2:1 chelate compound as the result of steric repulsions between the alkyl groups.

On the basis of the behavior of the Cu(II) chelates listed in Table I, therefore, the factors favoring the formation of soluble hydroxy chelates are: 1, the formation of a sufficiently stable bidentate chelate to prevent precipitation of the Cu(II) as hydroxide; 2, high stability of the 1:1 chelate over the corresponding compound in which the ratio of ligand to metal ion is 2:1; 3, the absence of more than two strongly coördinating donor groups on the ligand.

Diacyl Peroxide Reactions. II. The Reaction of δ-Phenylvaleryl Peroxide with Carbon Tetrachloride

BY DELOS F. DETAR AND CLAUS WEIS[1]

RECEIVED AUGUST 30, 1956

A quantitative study has been made of the products of the thermal decomposition of δ-phenylvaleryl peroxide in carbon tetrachloride over a more than six hundred-fold variation in peroxide concentration and at two temperatures. The product yields are almost independent of concentration and of temperature. It is reasonably certain that induced decomposition of the peroxide is insignificant at concentrations below 0.02 *M* and of only very minor importance even at about 0.6 *M*. It appears that more than 55% of the radicals derived from the peroxide undergo geminate reaction. The results show that under certain conditions aliphatic diacyl peroxides can be used as reliable sources of free alkyl radicals in solution.

The present paper describes a detailed study of the products of the thermal decomposition of δ-phenylvaleryl peroxide in carbon tetrachloride. It is a continuation of work described in the first paper in the series,[2] and is part of a research program directed toward a study of elementary free radical processes in solution.

The decomposition of δ-phenylvaleryl peroxide in carbon tetrachloride was carried out over a range of concentrations from about 0.001 *M* to about 0.6 *M*, a more than 600-fold variation. Two temperatures were used, 55 and 77°. At the higher temperature the analyses of products accounted for 98 ± 1% of the phenylbutyl groups and for 97.5 ± 0.3% of the carboxyl groups. The solvent fragment balance was not quite so good in that the number of CCl_3 groups found in hexachloroethane did not usually agree very well with the number of Cl groups found in 4-phenyl-1-chlorobutane. It is possible that hexachloroethane was lost in the removal of the last traces of the solvent. Enough experiments were carried out to permit a valid estimate of the accuracy and reliability of the results. The details are presented in Tables I and II; a brief examination of the products of the decomposition of the peroxide in the absence of solvent is summarized in Table III.

Except for minor differences, the results are similar to, but more precise than, those reported in the previous paper.[2] One difference is that the phosgene previously reported as a reaction product has been reduced to a negligible factor by a more effective removal of oxygen in the runs at 77° (reported in Table I). The phosgene apparently arises from reaction of trichloromethyl radicals with oxygen.

Phosgene was evolved in small amounts from the 55° runs during distillation of the carbon tetrachloride through the fractionating column. Since free phosgene previously had been removed by sweeping the reaction mixture with nitrogen, it must be surmised that some unstable product was liberating the phosgene. The trichloromethyl ester of δ-phenylvaleric acid is possibly the phosgene precursor. Its decomposition would also yield δ-phenylvalerol chloride. The increased amount of δ-phenylvaleric acid found in these runs could be accounted for by this hypothesis. However, another potential phosgene source is hexachlorodimethyl peroxide from reaction of trichloromethyl radicals

[a] Entries are moles of product per mole of peroxide. The exothermic reaction goes out of control at higher temperatures.

with oxygen. In either event the amount involved was small.

The analysis of products formed in the absence of solvent was carried out as previously described for the benzene runs. It was not considered worthwhile to spend the time needed to perfect the analytical techniques for these runs; the error limits are somewhat larger than reported in Tables I and II, those for 1-phenylbutane, for 4-phenyl-1-butene and for tetralin may be fairly large.

The most striking feature of the results is the insensitivity of the product yields to the peroxide concentration and to the reaction temperature. The constancy is so pronounced that it is feasible to summarize many of the data in the form of averages as is done in the final columns of the tables. The deviations from the averages are generally only a few per cent. relative.

These results are strong evidence for the absence of induced decomposition, the usual types of which would lead to the ester, δ-phenylbutyl δ-phenylvalerate, or to the dimer, 1,8-diphenyloctane.[3] Since the yields of these particular products are invariant even for the reaction in absence of solvent, they cannot be produced by an induced chain mechanism. Products that might be expected from induced decomposition of the peroxide by trichloromethyl radicals are $RCCl_3$ or $RCOOCl_3$, in which R is a phenylbutyl group. However, no appreciable amount of these products was present, certainly not enough to account for more than a very few per cent. of induced decomposition. Furthermore kinetic studies[4] show that the reaction is quite accurately first order, and that the rate of disappearance of the peroxide is insensitive to oxygen.[5] The increase in initial rate with increase in peroxide concentrations can be accommodated by an estimated 5% of induced decomposition at an initial peroxide concentration of 0.1 *M*. These results all show that little induced decomposition takes place with δ-phenylvaleryl peroxide at low concentrations in carbon tetrachloride. It is thus possible in considering the reaction mechanism to eliminate the very large number of elementary steps that involve free radical attack on the peroxide.

The reaction products can be accounted for by means of the following series of elementary reactions, and there is some evidence to indicate that nearly all of these steps are occurring.

$$(RCOO)_2 \longrightarrow [2RCOO\cdot] \quad (1)$$

$$\longrightarrow [RCOO\cdot + R\cdot] + CO_2 \quad (2)$$

$$\longrightarrow [2R\cdot] + 2CO_2 \quad (3)$$

$$[2R\cdot] \longrightarrow 2R\cdot \quad (4)$$

$$\longrightarrow R{-}R \quad (5)$$

$$\longrightarrow C_6H_5(CH_2)_3CH_3 + C_6H_5(CH_2)_2CH{=}CH_2 \quad (6)$$

$$[RCOO\cdot + R\cdot] \longrightarrow R\cdot + RCOO\cdot \quad (7)$$

$$\longrightarrow RCOOR \quad (8)$$

$$\longrightarrow RCOOH + C_6H_5(CH_2)_2CH{=}CH_2 \quad (9)$$

$$[2RCOO\cdot] \longrightarrow 2RCOO\cdot \quad (10)$$

$$\longrightarrow (RCOO)_2 \quad (11)$$

$$RCOO\cdot \longrightarrow R\cdot + CO_2 \quad (12)$$

$$R\cdot + CCl_4 \longrightarrow RCl + \cdot CCl_3 \quad (13)$$

$$CCl_3\cdot + C_6H_5(CH_2)_2CH{=}CH_2 \longrightarrow C_6H_5(CH_2)_2\dot{C}HCH_2CCl_3 \quad (14)$$

$$\mathrm{I}$$

$$CCl_4 + \mathrm{I} \longrightarrow C_6H_5(CH_2)_2CHClCH_2CCl_3 + CCl_3\cdot \quad (15)$$

$$2CCl_3\cdot \longrightarrow C_2Cl_6 \quad (16)$$

Radicals capable of geminate reaction[6,7] in a solvent "cage" are shown in brackets as indicated in eq. 5, 6, 8, 9 and 11. Equations 4, 7 and 10 represent escape of the radical partners from the "cage," and eq. 12–16 represent reactions of the resulting "free" radicals. The principal evidence for the geminate reactions in this particular case is the absence of $C_6H_5(CH_2)_4CCl_3$, the cross termination product from phenylbutyl radicals and trichloromethyl radicals.[2,7] The geminate products are 1,8-diphenyloctane (eq. 5), δ-phenylbutyl δ-phenylvalerate (eq. 8) and δ-phenylvaleric acid (eq. 9). The 1,1,1,3-tetrachloro-5-phenylpentane is also a geminate product in the sense that all of the 4-phenyl-1-butene (eq. 9) is converted to the tetrachloro compound under the reaction conditions. The non-geminate products are 4-phenyl-1-chlorobutane and hexachloroethane. 1-Phenylbutane is absent.[2] In the 77° runs the yield of δ-phenylvaleric acid is nearly large enough to admit the formation of all of the 4-phenyl-1-butene by eq. 9. There is no excess of the acid, and therefore any δ-phenylvaleryloxy free radicals produced by eq. 7 and 10 must lead to 4-phenyl-1-chlorobutane and carbon dioxide either by eq. 12 and 13 or by formation of an unstable acyl hypochlorite which gives the same products: $RCOO\cdot + CCl_4 \rightarrow RCOOCl + \cdot CCl_3$; $RCOOCl \rightarrow RCl + CO_2$.

As an alternative to the geminate reaction hypothesis it has been suggested[8] that disproportionation products such as olefin and acid (*cf.*, eq. 9) are

formed by a rearrangement reaction. Ester may also presumably be formed by rearrangement. If there is only a single product to be explained by a rearrangement reaction, then it is difficult to find a good criterion for distinguishing between a rearrangement process and a geminate radical process. In the present example, however, there are three sets of products to be explained by rearrangement reactions, by geminate radical reactions, or by other as yet not postulated processes. If the ester, the dimer, and the 1,1,1,3-tetrachloro-5-phenylpentane are all ascribed to rearrangement reactions, then this is an example of the possible but remarkable circumstance of a compound undergoing three concurrent rearrangement reactions plus a free radical cleavage all at rather comparable rates. It is still more remarkable to have four such reactions with nearly identical temperature coefficients, yet the yields of the "rearrangement" reactions are indeed temperature independent over a more than 20° range. The geminate radical reaction hypothesis requires fewer coincidences: for reactions as fast as geminate combination, the temperature coefficients should be negligible. To attempt to select one product as arising by a rearrangement reaction and to ascribe the rest of the products to geminate radical reactions is wholly arbitrary. It is for these reasons that the rearrangement reactions have not been included in the mechanistic scheme.

The geminate products account for 59% of the peroxide at 77° and 55% at 55°; these yields are just significantly different at the 95% level in the statistical sense, but the difference is so small that they may be considered to be essentially the same from the chemical point of view. The only important direct free radical product is 4-phenyl-1-chlorobutane. Since induced decomposition reactions do not interfere under the present conditions, these results show that it is possible to find conditions under which aliphatic diacyl peroxides are a reliable source of free alkyl radicals in solution.

In eq. 1–3 it is postulated that the peroxide decomposition occurs by some combination of reactions involving cleavage of one, two or three bonds simultaneously in the initial step. With reasonable assumptions it is possible to account for the products on the hypothesis that reactions 2 and 3 are much faster than reaction 1, but the presence of ester and of acid exclude the occurrence of reaction 3 as the only cleavage. On the other hand if only reaction 1 can occur, then the decarboxylation reaction, eq. 12, must be able to compete with geminate radical reactions in order to give the products. This problem has been discussed previously,[9] but further work is clearly required before a decision is possible.

Experimental

The identification of the reaction products and the experimental procedure for carrying out the reaction has already been described.[2] The present runs were carried out with refinements of detail as in the better removal of oxygen.

In the quantitative determination of products, the solvent was removed using a 12 × 300 mm. column packed with glass helices. The residual 40–60 ml. of solution was then extracted with three 10-ml. portions of ice-cold 2 *N* potassium hydroxide solution, then with water, with dilute hydrochloric acid, and again with water. After drying over sodium sulfate, the carbon tetrachloride was removed through a small column, and the residue was quantitatively transferred to a small Claisen flask. At this point it contained about 5 ml. of CCl_4. In the subsequent distillation the receiver was cooled in Dry Ice, and the system was backed by traps. The oil-bath temperature was raised gradually to just under 130°, and two fractions were collected: distillate (b.p. up to 70° at 3 mm.) and residue. The distillate, containing hexachloroethane and 4-phenyl-1-chlorobutane, was analyzed by an infrared spectrophotometric procedure and the residue was analyzed by a combination utilizing chromatographic separation of the ester and infrared spectrophotometric analysis of the non-ester fraction. The carbon tetrachloride distilled into the traps.

Known mixtures of the reaction products were dissolved in 300 ml. of carbon tetrachloride and subjected to the complete separation and analytical procedure; the results are summarized in Table IV.

TABLE IV

TEST OF ISOLATION AND ANALYTICAL PROCEDURE ON KNOWN MIXTURES

	Taken,[a] mg.	Found, mg.	Taken,[b] mg.	Found, mg.
C_2Cl_6	179	180	930	880
$C_6H_5(CH_2)_3CH_3$	0	0	365	394
$C_6H_5(CH_2)_4Cl$	811	859	1520	1410
$C_6H_5(CH_2)_3C_6H_5$	471	460	792	809
$C_6H_5(CH_2)_2CHClCH_2CCl_3$	177	173	446	429

$C_6H_5(CH_2)_4COOH$	208	211	210	210

[a] Receiver cooled in Dry Ice, preventing loss of 4-phenyl-1-chlorobutane. [b] Receiver cooled with ordinary ice.

The runs at 55° were carried out in sealed flasks of appropriate capacity. These flasks had a sealed-on head containing a gas inlet tube (sealed off during the runs), a filling tube of 12 mm. tubing, and a break-seal side tube attached to a ball joint. The carbon tetrachloride was refluxed while nitrogen was introduced through a tube extending into the filling tube. The flask was cooled to 40° and the peroxide introduced as a carbon tetrachloride solution. The filling tube was then sealed off so that the flask was completely sealed.

The flasks were placed in an oil-bath constructed from a 55-gal. drum and were maintained at 55.5–55.2° for the first 30 days, 55.2–54.8° for the next 30 days and 54.8–54.6° for the last 18 days. The flasks were then removed. At room temperature the pressure was less than atmospheric. The gas inlet was opened, the flask attached to the aniline bulb–cold trap–Ascarite tube train previously described, and the break-seal opened. A stream of nitrogen was passed through while the mixture was refluxed. Some phosgene was present in these runs. The isolation and analysis of the products was carried out as described.

Diacyl Peroxide Reactions. III. The Behavior of the Optically Active 3-Phenyl-2-propyl Free Radical[1]

BY DELOS F. DETAR AND CLAUS WEIS[2]

RECEIVED AUGUST 30, 1956

The thermal decomposition of (+)- and (−)β-phenylisobutyryl peroxide in carbon tetrachloride gives products analogous to those formed in the corresponding δ-phenylvaleryl peroxide reaction. Similar mechanisms can therefore be assumed. The 2-chloro-1-phenylpropane (accounting for 30–40% of the 1-phenyl-2-propyl groups) was optically inactive, and the alcohol portion of the ester, 1-phenyl-2-propyl β-phenylisobutyrate, showed about 75% retention of configuration. The formation of inactive alkyl chloride demonstrates the reaction of an alkyl (rather than of an acyloxy) radical with carbon tetrachloride. Since the ester probably arises from the geminate combination of a 1-phenyl-2-propyl radical and a β-phenylisobutyryloxy radical, the partial racemization of the alcohol portion indicates a very low activation energy for racemization of a free radical of the structure $R_1R_2R_3C\cdot$.

The possible existence of optically active free radicals $R_1R_2R_3C\cdot$ has been discussed for many years.[3] The problem has been a difficult one to study effectively since free radical reactions are complex even at best and since in many cases highly speculative reaction mechanisms have been assumed. In addition the preparation of intermediates which will give free radicals is fraught with some difficulty.

One of the first mechanistically sound approaches was that of Brown, Kharasch and Chao[4] who carried out the chlorination of (+)1-chloro-2-methylbutane and found that the 1,2-dichloro-2-methylbutane fraction was optically inactive. The interpretation of this result is somewhat uncertain inasmuch as the dichloro compound has not been prepared in optically active form and the magnitude of its rotation is therefore not known. If the rotation should be appreciable, the chlorination experiment shows that the 2-(1-chloro-2-methylbutyl) radical racemizes faster than it reacts with chlorine. If the rotation should prove to be very small, then the experiment is inconclusive.

The isolation in 70% yields of similar mixtures of *meso* and *dl-sym*-dimethyldiisobutylsuccinonitrile from both *meso*- and *dl*-2,2′-azo-bis-2,4-dimethylvaleronitrile has been cited[5] as evidence for the existence of free and of planar aliphatic free radicals. This evidence is of uncertain value. If there is no geminate ("cage") reaction so that all radicals are free, then the *dl*-azonitrile and the *meso*-azonitrile will give rise to similar members of *d*- and *l*-radicals. Combination of these in statistical fashion will give identical mixtures of *dl*- and of *meso*- products even if the radicals are optically stable. On the other hand the argument would have some merit if all of the product were produced in geminate reaction, for then *dl*-azonitrile should give only *dl*-product and *meso*-azonitrile *meso*-product if the radicals were stable. Such products might predominate even from planar radicals since radicals may be unable to achieve random orientation before undergoing geminate combination. The authors isolated the crossed dimer product from the decomposition of a mixture of 2,2′-azobisisobutyronitrile and 1,1′-azobis-1-cyclopentanenitrile thus showing that some of the radicals are free in these reactions. Further interpretation of this type of experiment would require precise product analyses and an independent estimate of the amount of geminate reaction.[6]

The decarbonylation of (−)methylethylisobutylacetaldehyde with *t*-butyl peroxide is reported to give inactive 2,4-dimethylhexane due to racemization of the methylethylisobutylmethyl free radical prior to its abstraction of the aldehyde hydrogen atom.[7]

Recently two reports have appeared of the use of optically active diacyl peroxides to produce optically active free radicals.[8] Kharasch, Kuderna and Nudenberg carried out the decomposition of (+)α-methylbutyryl peroxide in benzotrichloride. The ester, *sec*-butyl α-methylbutyrate, was isolated in 30–40% yield. Both the acid portion and the *sec*-butyl alcohol portion were optically active; the rotation of the alcohol indicated some racemization, the configuration being retained. No other products were reported. The interpretation of this result requires information about the mechanism of ester formation. The occurrence of induced peroxide decomposition leading to ester would be a possible complication needing investigation.

Greene[8] attempted to prepare the peroxide of optically active α-phenylpropionic acid, but the peroxide decomposed so rapidly that preparation and decomposition had to be carried out simultaneously. This was done in the presence of ether or without solvent. The careful product analysis showed a 20–35% yield of the α-phenylethyl ester of α-phenylpropionic acid and 5–8% yield of 2,3-diphenylbutane. The alcohol portion of the ester was optically active with retention of configuration and with about 20–50% racemization. The diphenylbutane was a mixture of *dl*- and *meso*-products, perhaps altogether two-thirds racemized. These products were attributed either to the formation of free radi-

cals which rapidly underwent geminate combination or else to a rearrangement reaction. The former alternative was preferred by Greene on the grounds that a rearrangement reaction should be stereospecific. The relative insensitivity of product ratios to reaction procedure was cited as evidence that induced decomposition was not important.

α-Phenylpropionic acid is not entirely satisfactory as a tool for investigation of the optical stability of free radicals for the following reasons: (1) It has not been possible to isolate the peroxide because of its great lability. On this account the interpretation of the results must of necessity be speculative. (2) Since this is a substituted phenylacetic acid, the possibility of ionic decomposition paths for the peroxide requires a careful evaluation that was not feasible.[9] (3) If formation of ester and hydrocarbon dimer occur by geminate reactions as appears likely, then the optical stability of an isolated free radical has not been investigated.

It was therefore our objective to carry out a diacyl peroxide decomposition which would correlate with the detailed studies of the δ-phenylvaleryl peroxide reaction[1] and which would involve a nongeminate reaction of an optically active free radical of the type

$$R^{*}\cdot + CCl_4 \longrightarrow RCl + \cdot CCl_3$$

The choice of diacyl peroxide imposed certain restrictions if mechanistically conclusive results were to be obtained. The peroxides of the convenient and extensively studied α-substituted arylacetic acids suffer from the twin disadvantage of being especially unstable and of being subject to heterolytic as well as homolytic cleavage.[9] The possible occurrence of heterolytic cleavage renders the details of the over-all results somewhat less certain with these peroxides than with other types. α-Methylbutyryl peroxide is satisfactory except for the experimental inconvenience of the low boiling points of the products. Other dialkyl-substituted acetic acids also could be used.

β-Phenylisobutyryl peroxide appears to be one of the best possibilities for the study of optically active radicals. The relative configurations of the key compounds are known, and the rotations are about twice as great as in the α-methylbutyric acid series. Furthermore there is a possibility that the peroxide can be obtained in crystalline form, although this was not achieved in the present work. Since β-phenylisobutyryl peroxide is closely related to the previously studied δ-phenylvaleryl peroxide,[1] it should be possible to evaluate the details of the reaction mechanism with reasonable certainty.

β-Phenylisobutyric acid has been resolved by several workers.[10,11] The maximum reported rotation is $\alpha^{24}D$ +21.6 and $[\alpha]^{21}D$ +17.9 (in ethanol). 1-Phenyl-2-propanol has $\alpha^{14}D$ 27.3°(l = 1),[11] and 1-phenyl-2-chloropropane of unreported optical purity had $[\alpha]_{5461}$ 25°(no solvent).[11] Kenyon, Phillips and Pittman[11] have related the configurations in this series by an unambiguous method: those compounds with the same sign of rotation have the same configuration.

β-Phenylisobutyryl peroxide undergoes decomposition in carbon tetrachloride with a half-life of about an hour at 40°.[12] It is therefore much less stable than δ-phenylvaleryl peroxide, and was not obtained in pure form except in one run that decomposed prematurely on attempted storage at 0°. It was noted that explosive decomposition of this peroxide did not destroy the container; the brisance seems to be low. Very few secondary peroxides have been reported; hexahydrobenzoyl peroxide is one example, and it appears to be relatively unstable.[13] The secondary α-phenylpropionyl peroxide is much less stable than phenylacetyl peroxide.[8] Incidentally phenylacetyl peroxide itself has a half-life of only about seven hours at 0° in toluene.[9] The preliminary study of the kinetics of the decomposition of β-phenylisobutyryl peroxide in carbon tetrachloride shows that the amount of induced decomposition is small.

The samples of (+)β-phenylisobutyryl peroxide used in the present study were about 60–70% pure; the principal impurities seem to have been solvent and possibly ester, 1-phenyl-2-propyl β-phenylisobutyrate. The optical purity of the (+)peroxide present in the samples was estimated as 42% by reducing a portion back to β-phenylisobutyric acid.

The products of the decomposition of a dilute solution of the peroxide in carbon tetrachloride are summarized in Table I. While the yields of many of the products are only approximations, it is clear that there is a great deal of similarity between this reaction and that of δ-phenylvaleryl peroxide previously reported.[1] In particular it seems reasonably certain that none of the 1-phenyl-2-chloropropane nor of the 1-phenyl-2-propyl β-phenylisobutyrate is derived from induced decomposition of the peroxide.

The 2-chloro-1-phenylpropane was formed in nearly the same yield as was 1-chloro-4-phenylbutane from δ-phenylvaleryl peroxide.[1] This 2-chloro-1-phenylpropane was optically inactive ($\alpha^{25}D$ 0.02 ± 0.02°, pure liquid, l = 1). If the rotation of the pure isomer for the D-line is estimated as 20° ($[\alpha]_{5461}$ 25),[11] then the rotation expected if no racemization had occurred would have been 8°. The racemization reaction is therefore 200 or more times faster than the chlorine abstraction reaction.

The free acid isolated from the reaction mixture had a rotation experimentally the same as that of the acid resulting from reduction of the peroxide. Since this acid is fairly stable toward racemization, such a result is expected. The ester, 1-phenyl-2-propyl β-phenylisobutyrate, was also active. The acid fraction obtained on hydrolysis had the same rotation as observed for the other acid samples. The alcohol portion was also optically active, the OH group being in the position previously occupied by the carboxyl function. However, the alcohol had a somewhat lower optical purity than the acid fractions, indicating some 20–26% of racemization during its formation.

TABLE I

THE THERMAL DECOMPOSITION OF (+)- AND (−)β-PHENYLISOBUTYRYL PEROXIDE IN CARBON TETRACHLORIDE[a]

Products	Yield[b]	Rotation	% Opt. purity	Yield[b]	Rotation	% Opt. purity
	1.41			1.60		
CO_2	0.2[c]					
C_2Cl_6	.6[c]	0	0	0.8[c]	0	0
$C_6H_5CH_2CHClCH_3$	.04	+7.4[d]	41	.08	−7.3	41
$C_6H_5CH_2CH(CH_3)COOH$	.15[e]	0	0	.07[e]	....	..
$(C_6H_5C_3H_6CCl_3)$[e]	.6[c]	+9.6[f]	..	.8[e,g]	−9.5[f]	..
Ester	...	+7.8[d]	44	...	−8.5[f]	46
Acid from ester	...	+8.6[f]	31[h]	...	−9.6[d]	35[i]
Alcohol from ester						
Starting Material						
$[C_6H_5CH_2CH(CH_3)COO]_2$, mmoles	(83.6)[j]	+7.5[d,k]	42	(59.4)[l]	(−)	..

[a] Reaction in 5 l. of CCl_4 at 60–77°; the amount of peroxide used is given at the bottom of the table. [b] Moles per mole of peroxide. [c] Approximate figure. [d] $[\alpha]^{20}D$ in ethanol. [e] The identity of this compound has not been established. [f] $\alpha^{20}D$ (l = 1, no solvent). [g] This figure is much too large and indicates presence of ester as impurity in the (−)peroxide used. [h] 31/42 or 74% retention. [i] 35/44 or 80% retention. [j] Based on 37.95-g. sample of 71.8% pure peroxide. [k] This applies to the β-phenylisobutyric acid obtained from reduction of the peroxide. [l] Based on 30-g. sample of 64.5% pure peroxide.

Although ester may have been present as an impurity in the (−)peroxide before decomposition in carbon tetrachloride, there does not seem to be any reason to suppose that ester arose from a source other than peroxide decomposition, though some of the decomposition may have taken place in a solvent medium other than carbon tetrachloride. The infrared curve of the (+)peroxide showed that ester was not present as an impurity in this sample.

Discussion

The fact that *dl*-1-phenyl-2-chloropropane is formed in the reaction of active β-phenylisobutyryl peroxide with carbon tetrachloride makes it possible to eliminate decarboxylative substitution as the mechanism of formation of the alkyl chloride. Such a reaction

$$RCOO\cdot + CCl_4 \longrightarrow RCl + CO_2 + \cdot CCl_3 \quad (1)$$

should be stereospecific irrespective of whether it occurs by inversion or by retention of configuration. This leaves halogen abstraction by the alkyl radical as the only route (eq. 2). The reasoning is as follows

$$R\cdot + CCl_4 \longrightarrow RCl + \cdot CCl_3 \quad (2)$$

The only potential direct precursors of RCl are the alkyl radical, the acyloxy radical or the peroxide. The peroxide is ruled out on the basis that induced decomposition is at most a minor process, and since the acyloxy radical has been eliminated, only the alkyl radical remains. There is at present no evidence to require consideration of less direct mechanisms.

The decarboxylative substitution step was proposed by Edwards and Mayo to explain an apparent discrepancy in the reactivity of alkyl radicals.[14] Edwards and Mayo developed a method for evaluating the relative reactivities of various solvents toward hydrogen abstraction by methyl radicals. A careful determination was made of the methane–methyl chloride ratio obtained in the decomposition of acetyl peroxide in solvent mixtures that had carbon tetrachloride as one component. It was possible to compare

$$CH_3\cdot + S_1H \longrightarrow CH_4 + S_1\cdot \quad (3)$$

$$CH_3\cdot + CCl_4 \longrightarrow CH_3Cl + \cdot CCl_3 \quad (4)$$

the reactivity of each solvent in the hydrogen abstraction reaction (eq. 3) with the reactivity of carbon tetrachloride in the chlorine abstraction (eq. 4). This led to a series of relative reactivities of methyl radicals with S_1H, S_2H, etc. The order of reactivities found was so different from the order obtained for other alkyl radicals (in polymerization systems) that it seemed advisable to speculate that the acetyl peroxide reaction involved decarboxylative substitution by acetoxyl radicals (eq. 1) rather than the expected methyl radical reactions. Since publication of this work, accurate estimates have become available for the rates of methyl radical reactions in the gas phase.[15] It has been shown that the methyl radical reactivities obtained in solution by Edwards and Mayo correlate very well with the gas phase values.[16] The main reason for postulating decarboxylative substitution has thus evolved instead into a reason for preferring the methyl radical reaction hypothesis.

There is now direct experimental evidence against decarboxylative substitution for three types of radicals: $CH_3COO\cdot$, $R_2CHCOO\cdot$ and $ArCOO\cdot$. The aryl group studied was the optically active 2-(2′-methyl-6′-nitrophenyl)-phenyl group.[17] The optically active peroxide reacted with carbon tetrachloride to give low yields of 2-chloro-2′-methyl-6′-nitrobiphenyl with partial racemization.

Since direct alkyl radical and aryl radical halogen abstraction has been demonstrated for three very different types of radicals, the method of Edwards and Mayo can be expected to be of great significance for obtaining relative radical reactivities.

In considering the optical properties of a free radical such as the 1-phenyl-2-propyl radical the extreme possibilities appear to be either a planar symmetrical structure or else a pyramidal structure with an optical stability of the same order as the structurally similar amine, methylbenzylamine. The activation energy for inversion of an amine is not known accurately, but estimates range around 5 kcal.[18] The activation energy for racemization should therefore be in the approximate range of 0 to 10 kcal. A reasonable estimate of the activation energy of the chlorine abstraction step (eq. 2) is 12 kcal., on the assumption that chlorine abstraction and hydrogen abstraction (*cf.* eq. 3 and 4) have similar activation energies.[15] Since an activation energy for halogen abstraction that is about 3 kcal. greater than that for racemization will lead to the observed complete racemization, the formation of racemic 1-phenyl-2-chloropropane is not unexpected.

Further information can be obtained from a consideration of the ester, 1-phenyl-2-propyl β-phenylisobutyrate. In the present investigations induced peroxide decomposition can be excluded as a source of ester. Two possibilities remain: (1) a rearrangement process involving loss of carbon dioxide and (2) a radical combination reaction (eq. 5). Since rearrangement reactions are usually

$$RCOO\cdot + R\cdot \longrightarrow RCOOR \qquad (5)$$

stereospecific and since there seems to be no reason for anticipating more than one rearrangement path for the peroxide, it appears that at least some of the ester must have been formed by a non-rearrangement process in order to account for the partial racemization of the alcohol portion.

Evidence has been presented that all of the ester is formed by a geminate radical combination reaction,[1,19] rather than by rearrangements. In this case the racemization of the 1-phenyl-2-propyl radical is competing with a radical combination reaction and the activation energy for racemization would be of the order of 2 kcal. It is even possible that a planar free radical could give an optically active ester providing that random rotational orientation of the radical is slow compared to the geminate combination. While "asymmetric induction" could be invoked, it is unlikely that the configuration of the acyloxy radical would have much effect in a radical combination reaction.

Experimental

***dl*-β-Phenylisobutyric Acid.**[20]—To a solution of 24 g. of sodium in 410 ml. of absolute ethanol was added 174 g. of commercial diethyl methylmalonate. This was followed by dropwise addition of benzyl chloride during a period of two hours at a reaction temperature of 40°. After removal of the ethanol by distillation, the diethyl benzylmethylmalonate was extracted with ether, and after washing and drying was finally distilled, b.p. 127–133° at 1.5 mm.; yield 62 and 66% in two runs.

The ester (174 g.) was hydrolyzed by refluxing it with a solution of 110 g. of potassium hydroxide in 300 ml. of water and 120 ml. of methanol. After removal of the methanol, the benzylmethylmalonic acid was precipitated with acid and, after drying, recrystallized from a benzene–hexane mixture to give 130 g. (95%) of colorless crystals, m.p. 136–138°. This was raised to 138–139.5° after recrystallization; the reported m.p. is 135°.[20c] In precipitating the benzylmethylmalonic acid it is necessary to add the solution of the salt to a solution of hydrochloric acid since the reverse procedure leads to precipitation of the insoluble monopotassium salt.

The acid was decarboxylated in 90-g. portions at a temperature of 190–210°, and the resulting β-phenylisobutyric acid purified by distillation; b.p. 118–122° at 1 mm.

Resolution of β-Phenylisobutyric Acid.[10]—To a solution of 500 g. of quinine in 650 ml. of hot ethanol was added 250 g. of *dl*-β-phenylisobutyric acid. The solution was cooled to 30° and seeded with the pure *d*-salt (obtained from a previous small scale run). The crystallization was allowed to proceed at room temperature for 24 hours and at 5° for another 24 hours. Filtration gave 265 g. of dry salt, $[\alpha]^{20}D$ +110° (*c* 0.0203 g./cc., in ethanol). Three additional crops totaling 167 g. and having the same or slightly higher rotation were obtained by partial evaporation of the solvent and re-seeding. It is worth notice that the rotation of the quinine salt remained essentially constant even though the acid was not completely resolved.[10]

To 450 ml. of 10 *N* sulfuric acid was added 398 g. of the recrystallized *d*-salt. The liquid (+)β-phenylisobutyric acid was extracted with ether, washed, dried and distilled; yield 96%; $\alpha^{20}D$ +13.73° (*l* = 1), $[\alpha]^{20}D$ +11.5° (*c* 0.0327, ethanol, *l* = 2); reported $\alpha^{24}D$ +21.6° (no solvent),[11] $[\alpha]^{21}D$ + 17.87° (in ethanol[11]).

The (−)acid was obtained from the residue resulting from evaporation of the mother liquors to dryness, b.p. 123–124° at 1.5 mm.; $[\alpha]^{20}D$ −11.2° (*c* 0.0245, ethanol, *l* = 2).[21]

The *p*-bromophenacyl ester of the (+)acid was obtained in 0.83-g. yield from 0.4 g. of acid and 0.71 g. of *p*-bromophenacyl bromide; m.p. 54.5–56°; $[\alpha]^{21}D$ +23.8° (*c* 0.0136, ethanol, *l* = 2).

Anal. Calcd. for $C_{18}H_{17}BrO_3$: C, 59.8; H, 4.7; Br, 22.1. Found: C, 59.7, H, 5.0; Br, 22.0.

(+)- and (−)β-Phenylisobutyryl Chloride.[10,11]—A mixture of 85 g. of (+)β-phenylisobutyric acid, $[\alpha]^{20}D$ +19.7° (*l* = 2) and 110 g. of purified thionyl chloride was warmed on the water-bath for 70 min. and then distilled; b.p. 72–73° at 1 mm.; yield 92.5 g.; $\alpha^{20}D$ + 22° (*l* = 2, no solvent); reported $[\alpha]D$ +26.3°. The (−)acid chloride was prepared similarly, b.p. 110° at 1.5 mm., $\alpha^{20}D$ −25.2° (*l* = 2, no solvent).

(+)- and (−)β-Phenylisobutyryl Peroxide.—This peroxide proved to be much less stable than δ-phenylvaleryl peroxide. A number of samples decomposed spontaneously even when kept in the refrigerator, although the peroxide can be preserved at Dry Ice temperatures. It is more stable in carbon tetrachloride than in ether.

To a stirred mixture of 70 g. of ice, 70 g. of water, 10.5 g. of sodium peroxide and 50 ml. of pentane was added slowly a solution of 12 g. of (+)β-phenylisobutyryl chloride in 80 ml. of pentane. The temperature was maintained at 2–2.5° during the addition (15 min.) and for an additional half hour. The pentane layer was separated, washed, dried over sodium sulfate, and the solvent removed under reduced pressure. The resulting viscous oil had a peroxide titer corresponding to 74.8%. Carbon tetrachloride was added and removed under reduced pressure at −10 to 0°, and the titer then corresponded to 71.8% of peroxide. It is possible that solvent is still present. The ester peak at 5.77 μ was negligible in the spectra of a carbon tetrachloride solution.

The rotation was obtained in carbon tetrachloride solution for a 40-g. peroxide sample obtained by combining two preparations; $[\alpha]^{20}D$ + 69° (*l* = 2); 0.425 g. of peroxide of 71.8% purity corresponds to a concn. of 0.305 g. of peroxide in 15 ml. of carbon tetrachloride.

The (−)peroxide was similarly prepared from 40 g. of the (−)acid chloride and 34 g. of sodium peroxide to give a

sample containing 64.5% of (−)β-phenylisobutyryl peroxide.

A 0.7-g. sample of the above (+)β-phenylisobutyryl peroxide was reduced to the acid by treatment with 0.75 g. of potassium iodide and 3 ml. of water in 50 ml. of acetone. Sulfur dioxide was passed in to reduce the iodine, the acetone was evaporated, the oil treated with sodium carbonate and extracted with ether to remove neutral materials. The acid was recovered from the alkaline solution, the ether evaporated, and the residue kept *in vacuo* over phosphorus pentoxide for 24 hours; $[\alpha]^{20}D + 7.5°$ (*c* 0.0234, ethanol, *l* = 2), or 67% of that of the starting acid.

dl-1-Phenyl-2-propanol.[22]—Commercial phenylacetone was reduced in 96% yield with a suspension of lithium aluminum hydride in ether; b.p. 64–65° at 1 mm.; phenylurethan, m.p. 89.5–91° from hexane.

dl-1-Phenyl-2-chloropropane.—A solution of 50 g. of 1-phenyl-2-propanol in 100 ml. of benzene was added in dropwise fashion to a solution of 50 g. of purified thionyl chloride in 70 ml. of benzene maintained at gentle reflux. The solution was then warmed on a water-bath for another hour, poured into water, washed thoroughly, dried and distilled; b.p. 83–85° at 12 mm., yield 76%; reported b.p. 205–207°.[23]

dl-1-Phenyl-2-propyl β-Phenylisobutyrate.—This was prepared by direct esterification at 110° for 3 hours in the presence of sulfuric acid; b.p. 142–144° at 1 mm., $n^{25}D$ 1.5264, yield 87%.

Anal. Calcd. for $C_{19}H_{22}O_2$: C, 80.8; H, 7.86. Found: C, 80.7; H, 7.9.

Decomposition of (+)β-Phenylisobutyryl Peroxide in Carbon Tetrachloride.—In a 5-l. flask with sealed-on reflux condenser and gas inlet tube was placed 5 l. of repurified carbon tetrachloride. About 50 ml. of this was distilled through the drained condenser while a stream of high purity nitrogen was passed in. The nitrogen stream was continued while the temperature was reduced to 20–25°. A 37.95-g. portion of the combined sample of (+)β-phenylisobutyryl peroxide described above (purity 71.8%, equivalent to 27.3 g. (0.0836 mole) of pure peroxide) was added, the temperature raised to 65–70° over a period of one hour and maintained there for four hours and then refluxed overnight. The carbon dioxide yield was 5.191 g. (1.41 mole per mole of "pure" peroxide). No phosgene was produced.

The solvent was removed through a column until the volume was reduced to 50 ml. Extraction with alkali gave 0.670 g. of (+)β-phenylisobutyric acid, $[\alpha]^{20}D + 7.4°$ (*c* 0.0874, ethanol, *l* = 1) (0.037 mole per mole peroxide). The remainder of the solvent was removed with a small column and the residue fractionated through a small Vigreux column to give (1) 4.74 g. (mostly hexachloroethane), b.p. 60–66° at 12 mm.; (2) 3.25 g. of a hexachloroethane–2-chloro-1-phenylpropane mixture, b.p. 66–68° at 12 mm.; (3) 5.90 g. of 2-chloro-1-phenylpropane, b.p. 81–90° at 10 mm., and a residue of 17.70 g. of yellow oil. The hexachloroethane (3.25 g.) was frozen out of the first two fractions, and the remaining liquids redistilled to give 7.65 g. of 2-chloro-1-phenylpropane (0.59 mole per mole of peroxide). This had a $\alpha^{20}D$ +0.52°, but the infrared curve had some small peaks not present in 2-chloro-1-phenylpropane. After passage through a column of F-20 alumina, the extra peaks were no longer present and the rotation was nearly zero; $\alpha^{20}D$ +0.03 ± 0.01 (18 D.F.).

There was some evidence for the presence of allylbenzene in that the contents of the Dry Ice traps from the first vacuum distillation contained allylbenzene peaks in addition to those of CCl_4 and C_2Cl_6.

Since the residue showed incipient signs of decomposition on attempted distillation, it was instead purified by chromatography on a 17 × 550 mm. column of F-20 alumina (grade 1) using hexane as eluent. From 11.40 g. there was obtained 3.02 g. of pure 1-phenyl-2-propyl β-phenylisobutyrate and a larger less pure fraction. This impure remainder was rechromatographed. There was ultimately obtained 9.42 g. of ester and 1.58 g. of a chlorine-containing oil; the original 17.70 g. of residue therefore contained 15.2 g. of ester, (0.64 mole per mole "pure" peroxide) and 2.5 g. of chlorine-containing oil (0.15 mole per mole peroxide assuming it is $RCCl_3$), $[\alpha]^{20}D$ 0°.

Redistillation of the ester gave a fraction, b.p. 143–145° at 1 mm., $n^{25}D$ 1.5264, $\alpha^{20}D$ 9.65° (*l* = 1, no solvent), $[\alpha]^{20}D$ 15.1° (*c*, 0.046, ethanol, *l* = 1); the infrared curve matched that of the *dl*-ester. Hydrolysis of the ester at room temperature gave an acid (2.86 g.) with an infrared curve identical with that of β-phenylisobutyric acid; $[\alpha]^{20}D$ +7.8° (*c* 0.068, ethanol, *l* = 1) and an alcohol, b.p. 70–71° at 2 mm. (2.7 g.), $n^{25}D$ 1.5192, $\alpha^{20}D$ +8.55 (*l* = 1, no solvent); the infrared curve of the alcohol was identical with that of the *dl*-1-phenyl-2-propanol.

Decomposition of (−)β-Phenylisobutyryl Peroxide in Carbon Tetrachloride.—A 30-g. sample of the peroxide containing 64.5% or 19.35 g. (0.0594 mole) of pure peroxide was added to 5 l. of carbon tetrachloride prepared as described for the other run. The solution, initially at 25–30°, was heated at reflux overnight, and 4.168 g. of carbon dioxide was evolved (1.60 moles per mole of peroxide). From the solution there was obtained 1.62 g. of (−)β-phenylisobutyric acid, $[\alpha]^{20}D$ −7.3° in ethanol (0.084 mole per mole of peroxide); 7.85 g. of 2-chloro-1-phenylpropane, b.p. 90–91° at 15 mm., $n^{25}D$ 1.5152, and after passage through F-20 alumina the infrared curve was identical with that of an authentic sample, $\alpha^{20}D$ 0.00° (*l* = 1, no solvent) (0.85 mole per mole of peroxide); 13.30 g. of 1-phenyl-2-propyl β-phenylisobutyrate $\alpha^{20}D$ −9.50° (*l* = 1, no solvent), b.p. 150–151° at 1 mm., $n^{25}D$ 1.5266 (0.80 mole per mole of peroxide); and 0.87 g. of a chlorine-containing fraction. Saponification of the ester gave 4.7 g. of (−)β-phenylisobutyric acid, $[\alpha]^{20}D$ −8.5° in ethanol and 4.3 g. of 1-phenyl-2-propanol, b.p. 67–68° at 1 mm., $n^{25}D$ 1.5192, $\alpha^{20}D$ −9.55° (*l* = 1, no solvent). It is possible that ester was present as an impurity in the peroxide.

Metal Protein Interactions in Buffer Solutions.[1] I. An Electrophoretic Study of the Interaction of Copper, Zinc, Cadmium and Cobalt Ions with Native and Modified Bovine Serum Albumins

BY HIRA LAL AND M. S. NARASINGA RAO[2]

RECEIVED DECEMBER 10, 1956

General concepts governing the interpretation of metal–protein interactions in buffer solutions have been outlined. It has been shown that the binding data should be supplemented by mobility measurements if the interactions are to be treated as a competition between the metal and hydrogen ions for combining with a given set of sites on the protein molecule. The existing data for the binding of cupric and cobaltous ions by bovine serum albumin in an acetate buffer of *p*H 6.5 and ionic strength 0.20, together with the corresponding mobility data reported in the present communication, have been analyzed. The intrinsic constant for the association of cobaltous ion with the carboxyl groups of serum albumin remained constant over the entire binding range, and had a low value characteristic of metal–acetate complexes. The constant for the association of cupric ion with the imidazole groups of serum albumin, however, tended to decrease with the number of bound metal ions, due, possibly, to an increased interaction, in the higher binding region, with the free carboxyl groups of the protein.

The interaction of zinc ion with human serum albumin has been studied by Gurd and Goodman[3] in unbuffered solutions. These authors have shown that the binding data could be interpreted in terms of a competition between the metal and hydrogen ions for reaction with the same sites, *viz.*, the imidazole groups of the protein molecule. The difficulties associated with the measurement and interpretation of such a competition in buffered solutions have been pointed out by Scatchard.[4] Most measurements of the interaction of small ions with proteins have however been made in buffered solutions. It is therefore of interest to attempt an interpretation of binding data obtained in buffer solutions in terms of a competition phenomenon.

A competition between metal and hydrogen ions entails that the metal ions can combine only with the basic (unprotonated) functional groups. The uptake of metal ion will however shift the hydrogen ion equilibria in the direction of the basic (unprotonated) form of the functional groups. The hydrogen ion release, thus occasioned, results, in unbuffered systems, in a decrease in *p*H.[3] For metal–protein interactions in buffer solutions, however, the relevant quantities may be derived from the electrophoretic mobility data provided allowance is made, as in unbuffered systems, for the binding of anions by the protein.

The electrophoretic behavior of metal–protein systems has not, as far as we are aware, been reported so far.[5] Such a study of the interaction of cupric, zinc, cadmium and cobaltous ions with bovine serum albumin in an acetate buffer of *p*H 6.5, ionic strength 0.20 is presented in the present communication.

Experimental

Native Bovine Serum Albumin (NBSA).—Crystallized bovine serum albumin was an Armour product, Lot No. M 66909. A polarographic examination did not indicate any detectable amount of metallic impurities. It was electrophoretically homogeneous in an acetate buffer of *p*H 6.5 and ionic strength 0.20, and had a mobility of -3.12×10^{-5} cm.^{2}/volt/sec., corresponding to a net charge of approximately −16 (electron units) calculated on the basis of a 0.2×10^{-5} cm.^{2}/volt/sec. change in mobility per unit change in charge.[6]

Esterified Bovine Serum Albumin (EBSA).—Serum albumin was esterified according to the method of Fraenkel-Conrat and Olcott.[7] The ester was analyzed for its methoxy groups[8] and showed that all the free carboxyl groups of the albumin molecule had been esterified. The material was electrophoretically homogeneous and had a mobility of 6.02×10^{-5} cm.^{2}/volt/sec. (acetate buffer, *p*H 6.5, ionic strength 0.20) corresponding to a net charge of +30 units. It would appear from the mobility of EBSA as compared to that of NBSA that only 46 carboxyl groups of the albumin molecule had been esterified as against the value of 100 obtained from titration data.[9] This discrepancy has been attributed by Saroff, *et al.*,[10] to a splitting of the esterified derivative into two nearly equal halves. It is our opinion, however, that the discrepancy may possibly be due to an increased uptake of buffer anions by the highly positively charged esterified derivative (see Discussion).

Acetylated Bovine Serum Albumin (ABSA).—Serum albumin was acetylated by the method of Fraenkel-Conrat, *et al.*,[11] using acetic anhydride as the acetylating agent. Acetic anhydride is specific for the free α- and ε-amino groups.[12] It may be assumed, therefore, that other functional groups, such as the imidazolium and guanidinium, are not affected. The acetylated derivative was analyzed for its free amino groups by the Van Slyke nitrogen estimation as modified by Baddiley, *et al.*,[13] indicating 83% acetylation of the free amino groups of the albumin molecule.

The acetylated derivative was found to be electrophoretically inhomogeneous in an acetate buffer of *p*H 6.5 and ionic strength 0.20 (Fig. 2A). Two components were observed: a slow one, constituting about 60% of the total, had a mobility of -7.60×10^{-5} cm.^{2}/volt/sec., and a fast one, constituting the rest, had a mobility of -8.60×10^{-5} cm.^{2}/volt/sec. The mobility computed from the first moment of the gradient curve had a value of -7.87×10^{-5} cm.^{2}/volt/sec., corresponding to a net charge of about −39 units.

Solutions.—All studies, unless otherwise stated, were made in an acetate buffer of *p*H 6.5 and ionic strength 0.20. 1% protein solutions were used. Solutions of the protein

were prepared by direct weighing, corrections being made for its moisture content.[14]

Electrophoresis.—Mobility measurements were made at 0.5° in a Tiselius electrophoresis apparatus (Perkin–Elmer Model 38[15]) using Longsworth's scanning system. A 2-ml. cell was used. The boundaries were formed between the protein and buffer solutions to which suitable additions of metal ion, corresponding to the metal distribution in equilibrium-dialyzed systems,[1,16–18] had previously been made. Standard procedure for the formation of boundaries was employed. After thermostating the cell assembly for three hours, the boundaries were brought into view and their positions photographed. The positions of the boundaries were also photographed at regular intervals during the electrophoresis run. The runs were usually made from 1–3 hours depending on the nature of the protein. Mobilities were calculated from the displacements in the descending boundary. Only those runs in which the boundary displacement was a linear function of time (at constant current) were used for the evaluation of mobilities.

The current passing through the cell was estimated to within ±0.1% from the potential difference developed across a standard resistance placed in series with the cell. The conductivity of protein solutions was measured at 0° with a Leeds and Northrup conductivity bridge using a conductivity cell of 0.5-ml. capacity (cell constant 12.6). The boundary displacements were measured from the schlieren patterns with a travelling microscope. In the systems involving non-homogeneous proteins, such as the acetylated serum albumin, the schlieren patterns were enlarged and the boundary displacements measured from the first moment of the entire gradient curve.

Analar cupric chloride and cupric acetate, and Merck zinc sulfate, zinc acetate, cadmium acetate and cobalt chloride were used as the source of metal ions.

Results

Metal–NBSA Systems.—The mobility increment $\Delta\mu$ ($= \mu_{PAi} - \mu_P$) is plotted in Fig. 1A as a function of $\bar{\nu}$, the number of metal ions bound per protein molecule. It may be noticed that the slope of the curves represented in Fig. 1A is positive for the system Co–NBSA and decreases in the order: Co–NBSA → Cd–NBSA → Zn–NBSA. The corresponding slope for the system Cu–NBSA, however, shows a negative slope—a result which is contrary to what should be expected from the uptake of a metal ion by the protein. As the metal uptake increases, however, the mobility of the protein is affected in a manner depending upon the nature of the metal ion bound. Thus the mobility of serum albumin tends toward a steady value as more and more cobalt ions are bound. This is in contrast to the behavior of Cd–NBSA and Zn–NBSA systems in which the mobility increases more and more as the value of $\bar{\nu}$ is increased, the effect being more pronounced in the former than in the latter. The mobility of the system Cu–NBSA passes through a minimum at $\bar{\nu} \simeq 2$.

Metal–ABSA Systems.—The $\Delta\mu$ *vs.* $\bar{\nu}$ curves for the metal–ABSA systems are shown in Fig. 1B.

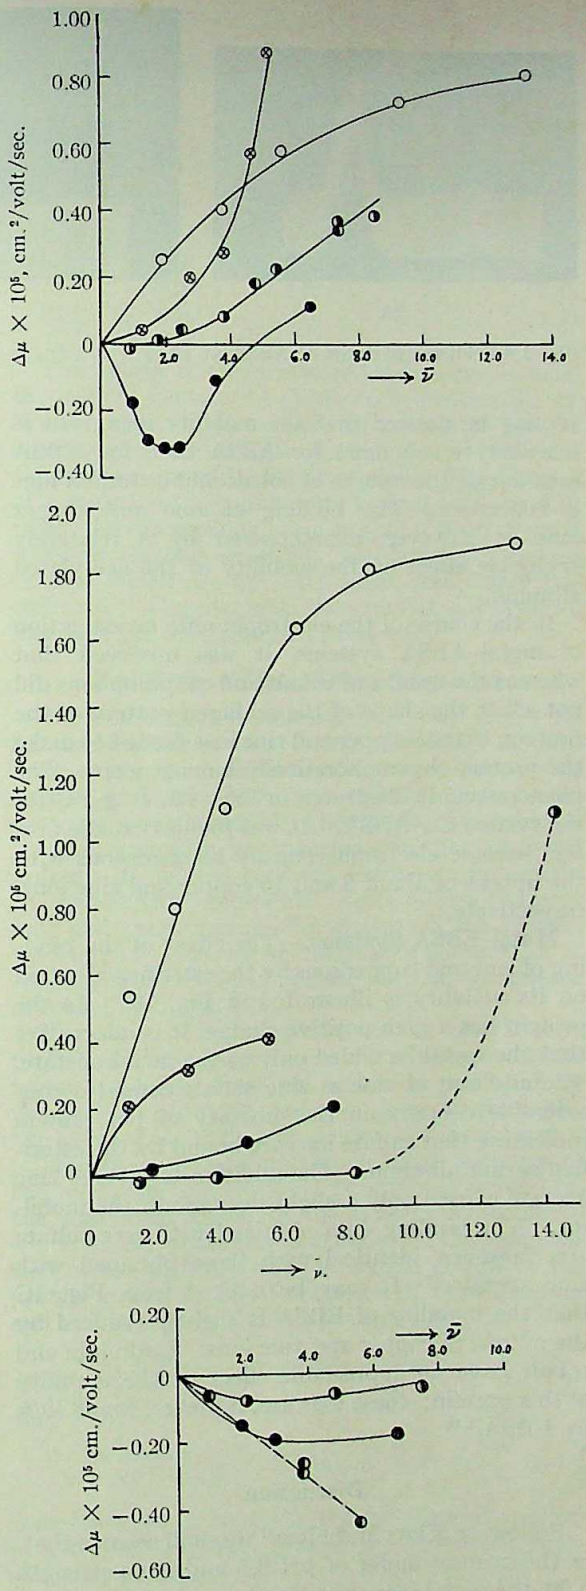

Fig. 1.—The effect of the binding of metal ions on the electrophoretic mobility of bovine serum albumins (0°, acetate buffer, *p*H 6.5, ionic strength 0.20): A, NBSA; B, ABSA; C, EBSA; —⊙—, Co^{++} as $CoCl_2$; —⊗—, Cd^{++} as $Cd(CH_3COO)_2$; —◑—, Zn^{++} as $Zn(CH_3COO)_2$; —◐—, Zn^{++} as $ZnSO_4$; —●— Cu^{++} as $Cu(CH_3COO)_2$.

(14) Stock solutions containing 2% protein in the acetate buffer medium were stored in a cold room maintained at 0°. The solutions containing EBSA, however, tended to hydrolyze on prolonged storage. This tendency toward hydrolysis was suppressed by storing the stock solution in a deep freeze.

(17) I. M. Klotz and H. A. Fiess, *J. Phys. Colloid Chem.*, **55**, 102 (1951).

(18) In line with the molecular weight of NBSA assumed for the titration data of ref. 9, the binding data of ref. 1, 16 and 17 were recalculated on the basis of a molecular weight of 65000 for NBSA instead of 66000 for ABSA and EBSA.

2A 2B 2C

Fig. 2.—Schlieren patterns of ABSA at (A) $\bar{\nu} = 0$, (B) $\bar{\nu} = 2$, (C) $\bar{\nu} = 8$ (0°, acetate buffer, *p*H 6.5, ionic strength 0.20)

It may be noticed that the mobility increment is relatively much more for ABSA than for NBSA in so far as the uptake of cobalt and cadmium ions is concerned. The binding of zinc and copper ions is, however, characterized by a relatively negligible effect on the mobility of the acetylated albumin.

In the course of the electrophoretic investigation of metal–ABSA systems, it was observed that whereas the uptake of cobalt and cadmium ions did not affect the shape of the schlieren pattern of the protein, that of copper and zinc ions tended to make the protein electrophoretically homogeneous. The phenomenon is illustrated in Figs. 2A, B and C for the system Cu–ABSA. It was found that the protein became electrophoretically homogeneous with the uptake of about 8 and 15 copper and zinc ions, respectively.

Metal–EBSA Systems.—The effect of the binding of zinc and copper ions by the esterified albumin on its mobility is illustrated in Fig. 1C. As the protein has a high positive charge, it is imperative that the metal be added only as the metal acetate. The addition of zinc as zinc sulfate caused a considerable decrease in the mobility of the protein indicating that sulfate ions are bound by the esterified serum albumin. The addition of zinc as zinc acetate caused only a slight decrease in the mobility. The binding data obtained with zinc sulfate are, however, identical with those obtained with zinc acetate.[16] It may be noticed from Fig. 1C that the mobility of EBSA is slightly reduced by the uptake of copper and zinc ions. Cadmium and cobalt have no appreciable effect on the mobility of this protein; these ions are, however, *bound little* by EBSA.[1,16]

Discussion

Following Klotz and Fiess[17] we shall assume that, in the acetate buffer of *p*H 6.5 and ionic strength 0.20, the metal ions exist largely as the MAc^+ complex ion and that this complex ion participates in the binding process. This assumption shall be tacitly adhered to in the following discussion. If the binding process were to involve the simple addition of MAc^+ ions, the charge on the protein would be a linear function of $\bar{\nu}$. Consequently, the slope of $\Delta\mu$ *vs.* $\bar{\nu}$ curves should be of the order of 0.2×10^{-5} cm.^{2}/volt/sec. An examination of Fig. 1, however, reveals that this simple state of affairs does not in fact exist and that the behavior of the metal–protein systems investigated depends in a rather complex manner on the nature of the metal ion and of the protein. It seems to us, therefore, that a proper evaluation of the electrophoretic mobility data must entail a definition of (i) the functional groups of the serum albumin molecule in terms of their equilibria in the acetate buffer of *p*H 6.5 and ionic strength 0.20, and (ii) the extent to which these equilibria are influenced by the uptake of MAc^+ ions.

Equilibria in Serum Albumin Solutions

Equilibria Involving Hydrogen Ions.—The dissociation of functional groups in a given set of sites may be represented by the equilibrium equation[9]

$$\frac{n_A}{n_B} = (H^+)k^0_H e^{-2\omega z^0_P} \qquad (1)$$

where n_A and n_B are the number of a given set of functional groups in the acid and basic forms, respectively, (H^+) the activity of hydrogen ions, k^0_H the proton affinity constant for the functional group, z^0_P the charge on the protein molecule and ω the familiar function of ionic strength. The hydrogen ion equilibria in bovine serum albumin solutions have been investigated by Tanford, Swanson and Shore.[9] It may be concluded from their data that the guanidinium, sulfhydryl, phenolic, α- and ϵ-amino groups, in view of their high proton affinities, are present in the acid form at *p*H 6.5, and are not available for binding metal ions. We are therefore interested only in the hydrogen ion equilibria involving imidazole and carboxyl groups of the protein molecule. It follows from eq. 1 that, of the 100 carboxyl groups of the protein molecule, 99.2 are dissociated in NBSA and 97.8 in ABSA. Similarly it may be shown that, of the 16 imidazole groups in the albumin molecule, 10 exist in the neutral (basic) form in EBSA, 2.5 in NBSA and only 0.9 in ABSA. The intrinsic proton affinity constant was assumed to be $\log k^0_H = 4.05$ for the carboxyl groups, and $\log k^0_H = 6.90$ for the imidazole groups, the function ω was given a value of 0.024,

NBSA (pH 4.71)	22	58	16	96	82	+14	0	14	1.71

being 80% of the calculated value in a medium of ionic strength 0.20.[9]

Binding of Acetate Ions.—The interaction of proteins with anions may be assumed to occur at the charged cationic functional groups of the proteins. The equilibrium may be represented by the equation

$$\frac{n_{Ac}}{n_c - n_{Ac}} = (Ac^-)k^0_{Ac}e^{2\omega z^0_p} \qquad (2)$$

where n_c is the total number of charged cationic groups, n_{Ac} the number of acetate ions bound per protein molecule, (Ac^-) the activity of free acetate ions at equilibrium (assumed 0.20) and k^0_{Ac} the intrinsic association constant for the binding of the acetate ion by the protein.

No quantitative work on the binding of acetate ions by serum albumin has been reported so far. A reasonably accurate evaluation of this interaction may, however, be made from considerations of electroneutrality. The charge balance in serum albumin solutions in the acetate buffer indicates that if the albumin molecule were not to bind the acetate ion it should have a net charge of +86, −5.7 and −50.8 for EBSA, NBSA and ABSA, respectively (see Table I, column 6). These values differ markedly from those obtained from mobility measurements. It is therefore reasonable to assume that the acetate ion is bound to the extent of 56 and 10.3 acetate ions per mole of EBSA and NBSA, respectively (Table I, column 8). With the values of n_c, n_{Ac} and z^0_p given in the table, and with ω = 0.024, we may evaluate k^0_{Ac} from eq. 2. These values are also given in the table (column 9).

A fair estimate of the ability of bovine serum albumin to bind the acetate ion may also be obtained from the results of Longsworth and Jacobsen[6] who have reported the isoelectric pH of bovine serum albumin in 0.1 acetate solution to be 4.71. From the charge balance at pH 4.71, the number of acetate ions bound per mole of protein comes to 14 (Table I). The value of k^0_{Ac} as calculated from eq. 2 will then be 1.71, in good agreement with the values given in column 9 (Table I).

In what follows we have assumed that the intrinsic association constant governing the binding of acetate ion by bovine serum albumin has a value of 1.33 for NBSA and 2.21 for EBSA. As we are interested essentially in the change in acetate binding consequent on the uptake of metal ions by the protein, the dual value used for k^0_{Ac} may not be particularly objectional.

The ability of the acetylated derivative to bind the acetate ion may be shown to be practically nil. We are thus led to expect this protein to have a charge of −50.8 as against the value of −39 obtained from mobility measurements. The binding of acetate ions, even if it were to occur, will tend to make the discrepancy even larger. This protein is however electrophoretically non-homogeneous for reasons which are not at present completely understood. The charge on the acetylated derivative has therefore been assumed to be −39.

Equilibria in Metal–Protein Systems

The equilibrium conditions in bovine serum albumin solutions in an acetate buffer of pH 6.5 and ionic strength 0.20 have been discussed above. We shall now examine how these equilibria may be expected to be influenced by the uptake of metal ions. A tacit assumption has been made in that the metal uptake, as stated earlier, involves the singly charged MAc^+ complex ion. The binding of $\bar{\nu}$ metal ions will then increase the charge on the protein by $\bar{\nu}$ units. This will tend to favor the uptake of the negatively charged acetate ion and the release of bound hydrogen ion.

The effect of metal uptake on the acetate ion–protein equilibria may be evaluated from eq. 2, the factor z^0_p being now, by definition, replaced by ($z^0_p + \bar{\nu}$). With k^0_{Ac} and n_c as given in the table, the value of n_{Ac} may be evaluated as a function of $\bar{\nu}$.

The effect of metal uptake on the dissociation of the imidazole and carboxyl groups will depend on the functional group of the protein molecule to which the metal ion may be bound. If the combination occurs with the basic imidazole groups of the protein molecule, the dissociation of the imidazole and carboxyl groups will be governed by

$$\frac{n_{Hlm}}{16 - \bar{\nu} - n_{Hlm}} = (H^+)k^0_{Hlm}e^{-2\omega(z^0_p + \bar{\nu})} \qquad (3a)$$

and

$$\frac{n_{COOH}}{100 - n_{COOH}} = (H^+)k^0_{COOH}e^{-2\omega(z^0_p + \bar{\nu})} \qquad (4a)$$

respectively. If, however, the metal uptake occurs at the basic carboxyl groups, we have the corresponding equations

$$\frac{n_{Hlm}}{16 - n_{Hlm}} = (H^+)k^0_{Hlm}e^{-2\omega(z^0_p + \bar{\nu})} \qquad (3b)$$

and

$$\frac{n_{COOH}}{100 - \nu - n_{COOH}} = (H^+)k^0_{COOH}e^{-2\omega(z^0_p + \bar{\nu})} \qquad (4b)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

In the above equations, n_{HIm} represents the number of acid imidazole groups and n_{COOH} that of the acid carboxyl groups per protein molecule, k^0_{HIm} the intrinsic proton affinity constant for the imidazole group and k^0_{COOH} that for the carboxyl group.

The net increment, Δz_p, in the charge on the protein molecule consequent on the binding of metal ions may be represented as

$$\Delta z_p = \bar{\nu} - \Delta n_{Ac} + \Delta n_{HIm} + \Delta n_{COOH} \qquad (5)$$

The expected net increment in charge on the protein molecule, thus calculated, is plotted in Fig. 3 as a function of the number of metal ions, $\bar{\nu}$, bound

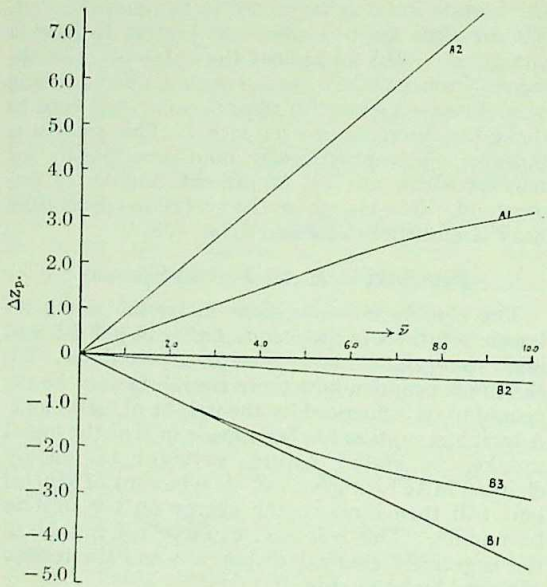

Fig. 3.—Calculated Δz_p *vs.* $\bar{\nu}$ curves, assuming interaction at: (A) carboxyl sites; (B) imidazole sites (25°, acetate buffer, *p*H 6.5, ionic strength 0.20); A1, B1, NBSA; A2, B2, ABSA; B3, EBSA.

per protein molecule. It may be immediately noticed from Fig. 3 that the electrophoretic mobility data may give useful information as to the nature of the functional group of the protein molecule with which a metal ion may react and the manner in which this interaction may be influenced by successive additions of metal ion.

A comparison of the experimental mobility data (Fig. 1A, B and C) with Fig. 3 reveals the following interesting features of the interaction process.

(i) The electrophoretic mobility data point distinctly to the conclusion that the cobaltous ion is bound essentially at the free carboxyl groups of the albumin molecule, thus supporting the conclusions derived earlier from equilibrium dialysis and optical absorption studies.[1]

(ii) The electrophoretic mobility data for the systems: copper–NBSA and copper–ABSA are characterized by the binding of the metal ions at the imidazole groups followed by an increasing participation of the carboxyl groups of the protein molecule in the interaction process after a few metal ions are bound by the protein. This participation of the carboxyl groups in the interaction process appears to increase in the direction: copper → zinc → cadmium, so much so that the mobility behavior of systems involving cadmium, especially of the system cadmium–ABSA, resembles that of the corresponding systems involving cobalt ions.

Calculation of Intrinsic Association Constants.—The calculations made in the preceding section have been shown to give useful qualitative information as to the nature of the interaction of bovine serum albumin with metal ions. These calculations, however, merely give the trend in which the equilibrium may be expected to move depending on whether the interaction involves the imidazole or the carboxyl groups of the albumin molecule. For a quantitative determination of intrinsic constants, however, we must analyze the equilibrium state as experimentally obtained. As there is little doubt that the interaction of cobaltous ion involves only the free carboxyl groups of the protein molecule, we shall in this section deal only with the equilibria involving bovine serum albumin and its derivatives on the one hand and copper, zinc and cadmium ions on the other. If the metal ion is bound at the basic imidazole groups, we have the equilibrium equation

$$\frac{\bar{\nu}}{16 - \bar{\nu} - n_{HIm}} = (A)k^0_{MIm}e^{-2\omega z_p} \qquad (6)$$

For the corresponding equilibrium between imidazole groups and hydrogen ion we have

$$\frac{n_{HIm}}{16 - \bar{\nu} - n_{HIm}} = (H^+)k^0_{HIm}e^{-2\omega z_p} \qquad (7)$$

In the above equations, (A) represents the activity of free metal ions in equilibrium with the metal–protein complex, z_p the charge on the metal–protein complex, and k^0_{MIm} an intrinsic constant representing the association of the metal ion with the imidazole group of the protein molecule. Combining eq. 6 and 7, we have

$$k^0_{MIm} = k^0_{HIm} \times \frac{\bar{\nu}}{n_{HIm}} \times \frac{(H^+)}{(A)} \qquad (8)$$

Assuming that interaction process involves the binding of MAc^+ ion at the imidazole sites of the albumin molecule and that all the imidazole sites are equivalent, k^0_{MIm} may be expected to be independent of $\bar{\nu}$, and have a value in reasonably good agreement with the first association constant of the metal ion with imidazole alone.

In eq. 8, $\bar{\nu}$ and (A) are known from separate equilibrium dialysis data[1,16,17] and k^0_{HIm} from the titration data of Tanford, Swanson and Shore referred to earlier.[9] The buffer medium of *p*H 6.5 fixes the value of (H^+). For an evaluation of k^0_{MIm}, we thus require to know the value of n_{HIm} at equilibrium at each stage of interaction process. The values of n_{HIm} at $\bar{\nu} = 0$ for the three protein solutions have already been listed (Table I). The increment, Δn_{HIm}, associated with the reaction of metal ion with the imidazole groups of the protein molecule can be calculated from eq. 5. In eq. 5, Δz_p is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

known from the electrophoretic mobility data; the values of n_{Ac}[19] and n_{COOH} (and hence Δn_{Ac} and Δn_{COOH}) at each stage of the interaction process may be evaluated from the following equations, respectively.

$$\frac{n_{Ac}}{n_c - n_{Ac}} = (Ac^-)k^0_{Ac}e^{2\omega z_p} \qquad (9)$$

$$\frac{n_{COOH}}{100 - n_{COOH}} = (H^+)k^0_{COOH}e^{-2\omega z_p} \qquad (10)$$

It would thus seem that the data for the binding of metal ions by bovine serum albumin together with the corresponding electrophoretic mobility data may be employed usefully to follow the course of the interaction process.

Data of Klotz and Fiess.—Klotz and Fiess[17] have studied the binding of cupric ion by bovine serum albumin at 25° in an acetate buffer of *p*H 6.5, ionic strength 0.20. We shall examine their data in detail in order to illustrate the concepts on which the binding data in buffer solutions may be analyzed. Taking electrostatic interaction into account, it can be shown that, for a set of n equivalent sites[20]

$$\frac{\bar{\nu}}{A}e^{-2\omega\Delta z_p} = kn - k\bar{\nu} \qquad (11)$$

where k is an intrinsic association constant uncorrected for the charge on the protein molecule. It is obvious from the electrophoretic mobility data presented in this paper that Δz_p (and hence the electrostatic interaction correction factor) is a complex function of $\bar{\nu}$. A plot of $(\bar{\nu}/A)e^{-2\omega\Delta z_p}$ *vs.* $\bar{\nu}$ should, however, give a straight line with the intercepts kn and n. Such a plot for the binding data obtained by Klotz and Fiess combined with the corresponding electrostatic interaction correction, as experimentally obtained from the mobility data presented in this paper, is given in Fig. 4.

It is immediately obvious from Fig. 4 that even when electrostatic interaction is taken into account the binding of copper ions by bovine serum albumin cannot be explained on a single value of n equivalent sites. The intercept kn ($=k_1$, the first association constant) can however be determined easily, and has a value of 3.8×10^5. For an evaluation of k, we require to know the value of n, the number of sites available for reaction with the first metal ion.

In view of the shape of the curve in Fig. 4, it is rather difficult to evaluate the intercept n by extrapolation. Fiess and Klotz[21] have indeed pointed out that this intercept may have a value of 20–100. The extrapolated value for n, even if extrapolation could be made precisely, should not however be used for the evaluation of the intrinsic association constant. Assuming that the interaction involves

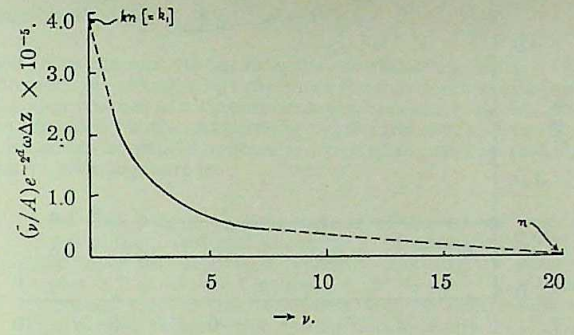

Fig. 4.—The interaction of cupric ion with NBSA (from the data of Klotz and Fiess): 25°, acetate buffer, *p*H 6.5, ionic strength 0.20.

the imidazole groups, it is reasonable to expect that it is only the unprotonated imidazole groups which are available for reaction with metal ions, and furthermore, that their value, as shown in the preceding sections, increases with $\bar{\nu}$. n is therefore dependent on the number of metal ions bound to the imidazole sites of the protein molecule. We may thus define

$$n = 16 - n_{Hlm} = n^3[1 + f\bar{\nu}] \qquad (12)$$

where n^0 is the number of basic imidazole groups present on the protein molecule at $\bar{\nu} = 0$, and f is a function governing the rate of change of n with $\bar{\nu}$. Substituting for n in eq. 11, we then have

$$\frac{\nu}{A}e^{-2\omega\Delta z_p} = kn^0 - [1 - n^0f]k\bar{\nu} \qquad (13)$$

It is obvious from eq. 13 that the intercept on the ordinate in Fig. 4 represents kn^0. With a value of 2.5 for n ($n^0_{Hlm} = 13.5$ at $\bar{\nu} = 0$, see Table I, column 3), and correcting for electrostatic effect due to the charge on the protein, the intrinsic association constant can be evaluated. A value of log $k^0 = 4.86$ was thus obtained.[22]

Assuming that the copper ion is bound at the imidazole sites of the albumin molecule, the in-

(19) As the metal uptake has been assumed to occur at the imidazole groups, the value for n_c, the number of charged cationic centers on the protein molecule, may be expected to depend on $\bar{\nu}$. Assuming that an imidazole group whether covered by metal ion or by hydrogen ion acts as a cationic center, the increase, Δn_c, in the number of cationic centers over the values given in Table I (column 4) may be expected to be $\bar{\nu} + \Delta n_{Hlm}$. For systems involving NBSA, Δn_c was assumed to be zero as the uptake of a metal ion may be expected to cause a nearly equivalent proton release from the imidazole sites of NBSA (assumptions concerning the value of n_c are not critical in their effect on the final value of n_{Hlm}). For systems involving EBSA, however, the values given for n_c are critical and must be accurately known; in these systems, Δn_c was assumed to be 0.6 $\bar{\nu}$ as, on an average, 0.4 proton may be expected to be released for every metal ion bound to EBSA. These estimates, necessarily approximate, were based on eq. 3a.

(21) H. A. Fiess and I. M. Klotz, THIS JOURNAL, **74**, 887 (1952).

(22) The intrinsic constant (log $k^0_{Culm} = 4.86$) is much larger than the first association constant for the interaction of cupric ion with imidazole alone (log $k_1 = 4.3$[23] at 25°). In this connection it is of interest to note that the value of the intrinsic constant for the association of zinc ion with human serum albumin (ref. 3, log $k^0_{Znlm} = 2.82$ at 0°) needs to be revised in view of the recent titration data of Tanford, Swanson and Shore (ref. 9). Assuming that the intrinsic proton affinity constants of the imidazole groups in NBSA and HSA are identical (see Discussion in ref. 9), it is obvious in view of eq. 5 in ref. 3 that the intrinsic association constant for the interaction of zinc ion with HSA as reported by Gurd and Goodman should be upgraded by 0.8 logarithmic units to give log $k^0_{Znlm} = 3.62$. A comparison of this revised value with the first association constant for the interaction of zinc ion with imidazole alone (log $k_1 = 2.8$[23] at 0°) reveals a similar trend to the one observed in the corresponding systems involving cupric ion.

trinsic association constant was evaluated as a function of $\bar{\nu}$ (eq. 8). The relevant log k^0 *vs.* $\bar{\nu}$ plot is given in Fig. 5A. It may be noticed that k^0 decreases with $\bar{\nu}$—a fact which may be attributed, among others, to an increasing participation of the free carboxyl groups of the albumin in the interaction process as more and more metal ions are bound by the protein. The matter shall be discussed further in a later communication.

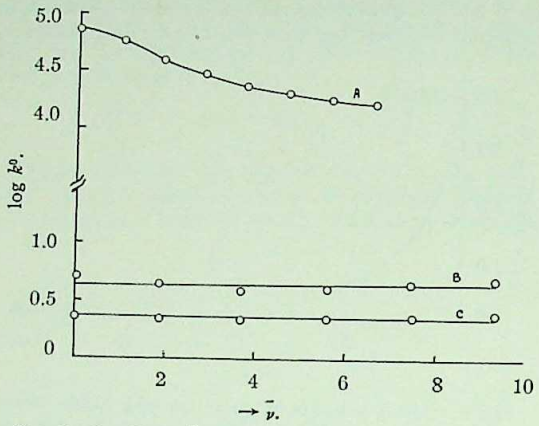

Fig. 5.—log k^0 *vs.* $\bar{\nu}$ curves: A, system copper–NBSA (from the binding data of Klotz and Fiess); B, system cobalt–NBSA (Rao and Lal); C, system cobalt–ABSA (Rao and Lal).

The Data of Rao and Lal.—The interaction of native and modified bovine serum albumins with the cobaltous ion in an acetate buffer of *p*H 6.5, ionic strength 0.20, has been studied by Rao and Lal.[1] There is conclusive evidence to show that the cobaltous ion is bound at the three carboxyl groups of the albumin molecule. Assuming that all the 100 carboxyl groups are in the basic form (see Table I, column 5), the value of the intrinsic association constant, k^0, evaluated from the first association constant, k_1, was found to be 5.1 for NBSA and 2.3 for ABSA. The intrinsic association constant remained independent of the number of cobaltous ions bound by the proteins (Figs. 5B and C). The low value of the intrinsic association constant together with the fact that it is independent of $\bar{\nu}$ point conclusively to the interaction of the cobaltous ion with the free carboxyl groups of the serum albumin molecule.

In the present work, we have outlined the general concepts governing the interpretation of metal-protein interactions in buffer solutions. A full treatment of our data for the binding of metal ions by bovine serum albumins and its modified derivatives shall be presented in a separate communication.

The Mechanisms of Permanganate Oxidation. III. The Oxidation of Benzhydrol

BY ROSS STEWART

RECEIVED NOVEMBER 23, 1956

The permanganate oxidation of benzhydrol has been studied in an attempt to elucidate the reaction mechanism. The reaction kinetics, the existence of hydroxyl ion catalysis, the presence of a positive salt effect and the sign and magnitude of the entropy of activation all indicate that the rate-controlling step consists of a reaction between benzhydrylate ion and permanganate ion. The existence of an isotope effect (6.6:1) obtained for the oxidation of benzhydrol-α-*d*, and the fact that when potassium permanganate-O^{18} is used as the oxidant no excess oxygen-18 appears in the product, suggest that the reaction occurs by hydride ion transfer from benzhydrylate ion to permanganate ion.

Introduction

The previous papers in this series dealt with the permanganate oxidations of aromatic aldehydes[1] and formate ion[2] and demonstrated further the manifold character of permanganate ion as an oxidant.

The presently available evidence indicates that permanganate oxidizes each of the following groups or compounds by a distinctive reaction path: C=C,[3,4] ArCHO,[1] RCHO and R_2CO,[5] $-CH_3$,[6] $-HCO_2^-$[2] and $(CO_2H)_2$.[7]

Such versatility[8] is even more impressive when one considers that a change in reaction conditions can cause a change in mechanism as has been shown in the case of the permanganate oxidation of benzaldehyde.[1] The present study was undertaken to determine the mechanism of the reaction of this reagent with alcohols. It deals with the behavior of permanganate toward a typical secondary alcohol, benzhydrol, $(C_6H_5)_2CHOH$, which was chosen because of the stability of its oxidation product, benzophenone, to further attack.

Previous work on the reaction of alcohols with permanganate in acid media has been reported. Merz, Stafford and Waters showed that isopropyl alcohol in acid solution is oxidized by an induced process which probably involves Mn^{+4}.[9] Cullis and Ladbury have made a comprehensive study of reaction conditions for the acid permanganate oxidation of aromatic compounds including benzyl alcohol and 1-phenylethanol,[10] but the reaction mechanism remains obscure.

Experimental

Reagents.—Benzhydrol was crystallized from carbon tetrachloride to constant m.p. 64–65°. Benzhydrol-α-*d* was prepared as follows. Benzophenone (3.6 g., 0.02 mole) was dissolved in 30 ml. of dry ether and added dropwise to lithium aluminum deuteride (0.44 g., 0.01 mole) dissolved in 20 ml. of ether. The mixture was refluxed for ten minutes, cooled and poured on to a mixture of one ml. of concentrated sulfuric acid and about 20 g. of crushed ice. The ether layer was separated, washed, dried and evaporated to give 2.7 g. of white crystals, m.p. 63–64°. The benzhydrol-α-*d* used in the rate experiments was recrystallized from carbon tetrachloride to constant m.p. 64–65°. The infrared spectrum of the labeled alcohol showed a shift in the carbon–hydrogen stretching peak from 3.52 to 4.71 μ. The isotopic purity was shown to be high by the complete absence of a band at 3.52 μ in the benzhydrol-α-*d*.

Potassium permanganate-O^{18} and potassium manganate were obtained as previously described.[1]

Kinetic Method.—Two procedures, titration and measurement of light absorption, were used to follow the disappearance of permanganate and hence to determine the reaction rate.

In the first method an aqueous solution of benzhydrol, approximately 0.002 *M*, was obtained by dissolving a weighed amount of benzhydrol in hot distilled water which had been boiled to remove dissolved gases and making the solution up to the mark in a volumetric flask. In a typical experiment, 20 ml. of this solution, 10 ml. of 0.2 *M* carbonate-free potassium hydroxide and 18 ml. of boiled distilled water were brought to reaction temperature in a vessel immersed in a constant temperature bath controlled to ±0.04°. Two ml. of a standard solution of potassium permanganate was added to start the reaction, the progress of which was followed by titrating five-ml. aliquots iodometrically, essentially as described previously.[1] A slow flow of nitrogen through the system was maintained during the reaction.

Since most of the investigation dealt with the basic *p*H region where the permanganate oxidation of benzhydrol was fast and the manganate oxidation was shown to be slow, the reaction studied involved a valence change for manganese from +7 to +6. A very accurate titration is required if the points on the rate plot are to be precise since the titration measures the total oxidizing power of all manganese species above valence two. Reasonably good precision was obtained on most of the rate plots; nevertheless, there is a considerable scatter of points in Fig. 3, for example.

As a check on the titration method the disappearance of permanganate was also followed spectrophotometrically. The reaction mixture was made up essentially as in the previous method. After addition of the permanganate the solution was shaken and a portion of it transferred quickly to an absorption cell and placed in the cell compartment of a Beckmann spectrophotometer, model DU. Thermospacers kept the sample at a constant temperature and even when measurements were made at temperatures ten degrees above room temperature, no difficulty was experienced. In this case a drop in temperature of about one fifth of a degree in transferring the sample to the cell was observed. The temperature rose to that of the thermostat within a short time, however, and the rate constants were calculated from those points obtained after thermal equilibrium had been attained. Measurements of the light absorption were made at 522 and 426 mμ, the former wave length corresponding mainly to absorption by permanganate and the latter mainly to absorption by manganate. From the known values of the extinction coefficients of the two ions at these two wave lengths[11] the following equation was derived, where *D* stands for optical density.

$$[MnO_4^-] = D_{522} - 0.282D_{426}$$

In most of the rate experiments which were followed using this method, benzhydrol was present in considerable excess and the concentration of MnO_4^- need not be obtained in any specific units since only log $[MnO_4^-]$ is used in the calculations. The values of $[MnO_4^-]$ obtained by the use of the above equation are quite arbitrary.

The light absorption method for determining the rate is subject to the following disadvantages. For very slow permanganate oxidations some manganate is likely to be reduced to MnO_2 which can cause light scattering and may introduce errors in the estimate of the permanganate concentration. It is assumed, too, that no other light absorbing species are formed as the reaction proceeds (see Results and Discussion). The fact that the two methods gave rate constants in good agreement with each other indicates that the results obtained are reliable.

Oxidation with Potassium Permanganate-O^{18}.—A typical experiment was conducted as follows. Benzhydrol (0.45 g.) was dissolved in 860 ml. of hot, previously boiled, distilled water and, when the solution had cooled to 30°, 45 ml. of 0.2 *N* potassium hydroxide was added. Labeled potassium permanganate (1.55 g., onefold excess) was dissolved in 30 ml. of water and added to the reaction solution. After four minutes 30 ml. of 10% sodium bisulfite and one ml. of concentrated sulfuric acid were added to quench the reaction. The solution was immediately extracted with 30 ml. of petroleum ether which was washed, dried over anhydrous sodium sulfate and poured through a column of 3 g. of alumina. The column was eluted with three 15-ml. samples of petroleum ether and one sample of ether. The first two petroleum ether fractions yielded 0.25 g. of pure benzophenone, m.p. 49°. The third and fourth fractions contained small amounts of benzophenone, and the ether eluate contained about 0.06 g. of unreacted benzhydrol. The original reaction solution after the petroleum ether extraction was further extracted with 100 ml. of benzene and this, in turn, yielded about 0.11 g. of a mixture of benzophenone and benzhydrol, m.p. 46–54°.

Benzhydrol-O^{18}.—Benzhydryl chloride readily was prepared by shaking 14 g. of benzhydrol with 80 ml. of concentrated hydrochloric acid for 0.5 hr. Extraction with ligroin followed by distillation at reduced pressure yielded 12 g. of benzhydryl chloride, m.p. 18–19°, b.p. 100–102° at 0.3 mm. A solution of 5 g. of benzhydryl chloride, 6 ml. of dry pyridine and 1 ml. of H_2O^{18} (about 1.4 atom % O^{18}) was allowed to stand overnight and then heated for 2 hr. on the steam-bath. The liquid was distilled off under reduced pressure and the residual white solid was extracted with ether. Evaporation of the ether yielded 3.0 g. of white crystals which were recrystallized from carbon tetrachloride–ligroin. Repeated recrystallizations from this solvent did not raise the m.p. above 62–63°. One gram of ordinary benzhydrol was added to 2.5 g. of the labeled material and the whole dissolved in hot ether. Addition of petroleum ether produced 2.1 g. of crystals of benzhydrol which melted at 64–65° and gave no m.p. depression when mixed with an authentic sample.

Oxidation of Benzhydrol-O^{18}.—The same general procedure was used here as for the oxidation with potassium permanganate-O^{18} except that in one experiment the reaction was quenched with sodium bisulfite only. The unreacted benzhydrol which was recovered in this experiment was submitted to oxygen-18 analysis to determine whether or not any exchange of oxygen with solvent had occurred prior to reaction.

Results and Discussion

Kinetics.—The benzhydrol–permanganate reaction is strongly base catalyzed as can be seen from the results shown in Fig. 1.[12]

(12) Except for the few experiments required to establish the fact that the reaction is slow in neutral or acid solution, the only work done in these regions was an experiment to determine the effect of added manganous ion on the rate, a device which has been used to determine whether or not the oxidizing agent is some manganese species of intermediate valence. Addition of enough manganous sulfate to make the solution 0.00024 *M* in Mn^{++} compared to a permanganate concentration of 0.0013 *M*, caused a drop in the bimolecular rate constant k_2 from 0.48 to 0.32 in 0.18 *M* H_2SO_4, indicating that ions of intermediate valence produced by the manganous–permanganate reaction are not the active oxidizing species even in acid solution.

In all rate experiments in which equivalent quantities of benzhydrol and permanganate were used and in which hydroxyl ion was in excess the reaction was found to be second order in agreement with the rate law

$$\frac{-d\,[MnO_4^-]}{dt} = k_2[MnO_4^-][(C_6H_5)_2CHOH]$$

For those points in Fig. 1 below *p*H 12 the benzhydrol–permanganate ratio was kept at 3:2 since any manganate or hypomanganate formed in the process undergoes disproportionation to MnO_2 and MnO_4^-. This initial ratio of 3:2 ensures a constant ratio of the two reactants as the oxidation proceeds. The second-order rate constants were obtained using the expression

$$k_2 = \frac{1}{t[\text{benzhydrol}]_0} \times \frac{V_0 - V_t}{V_t - 2/5V_0} \qquad (1)$$

where V is the volume of thiosulfate required in the iodometric titration.[1] In sufficiently basic solution, however, the manganate formed does not disproportionate. Since it was shown that manganate reacts with benzhydrol at about one fortieth of the rate of permanganate in 0.1 *M* KOH solution, the manganate accumulates as the reaction proceeds and the reaction in basic solution, which was the one studied in detail, becomes

$$(C_6H_5)_2CHOH + 2MnO_4^- + 2OH^- \longrightarrow (C_6H_5)_2C{=}O + 2MnO_4^{=} + H_2O$$

To preserve a constant benzhydrol–permanganate ratio as the reaction proceeds a 1:2 initial ratio is required. It can be shown that in this case the rate constant is given by the expression

$$k_2 = \frac{1}{t[\text{benzhydrol}]_0} \times \frac{V_0 - V_t}{V_t - 4/5V_0} \qquad (2)$$

Linear relations were obtained when t was plotted against $V_0 - V_t/V_t - 4/5V_0$ showing the reaction to be second order but not proving it to be first order in each reactant. For this reason experiments were performed in which there was an initial benzhydrol–permanganate molar ratio of 1:1 and 1:4. It can be shown that when the initial molar concentrations of benzhydrol and permanganate are the same (two equivalents of benzhydrol to one of permanganate) relation (3) holds

$$k_2 = \frac{4.61}{y_0 t} \log \frac{V_t - 3/5V_0}{V_t - 4/5V_0} \qquad (3)$$

and that when the ratio of the initial concentration of benzhydrol to permanganate is 1:4 this expression holds

$$k_2 = \frac{-2.30}{y_0 t} \log \frac{V_t - 9/10V_0}{V_t - 4/5V_0} \qquad (4)$$

Equation 3 can be derived as (let $x = [MnO_4^-]$ and $y = [\text{benzhydrol}]$)

$$\frac{-dx}{dt} = k_2xy$$

if $x_0 = y_0$, $y = 1/2y_0 + 1/2x$

$$-1/2k_2t = \int \frac{dx}{(y_0x + x^2)}$$

$$= -\frac{1}{y_0} \ln \left(\frac{y_0 + x}{x}\right)$$

now $x = A[V_t - 4(V_0 - V_t)]$, where A is a con-

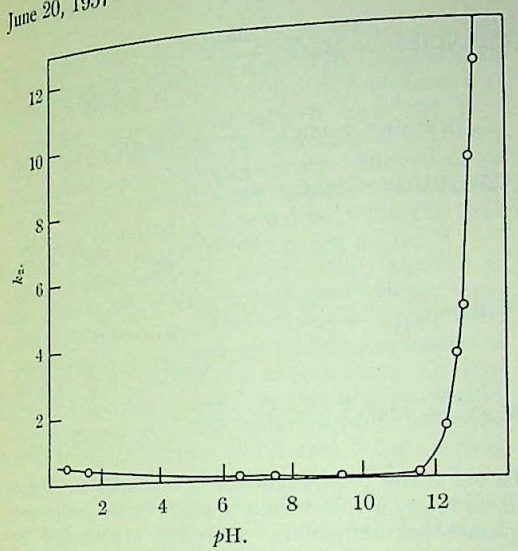

Fig. 1.—Effect of variation in pH on the bimolecular rate constant, k_2, for the permanganate–benzhydrol reaction; $T = 25°$.

stant, provided the only oxidizing species of manganese in solution are MnO_4^- and $MnO_4^{=}$.

$$\therefore 1/2k_2t = \frac{1}{y_0} \ln \frac{V_t - 3/5V_0}{V_t - 4/5V_0}$$

and

$$k_2 = \frac{4.61}{y_0 t} \log \frac{V_t - 3/5V_0}{V_t - 4/5V_0}$$

Equation 4 follows from a similar argument.

Good straight line relations were obtained for these two cases when t was plotted against the logarithmic function and the rate constants listed in Table I show that the reaction is indeed first order in MnO_4^- and first order in benzhydrol. Also listed in Table I are values for the rate constant obtained using benzhydrol in excess. These values were obtained from spectrophotometric experiments and the kinetics were, as expected, pseudo unimolecular.

TABLE I

RATE CONSTANTS FOR THE BENZHYDROL–PERMANGANATE REACTION FOR VARIOUS INITIAL CONCENTRATION OF REACTANTS

$(C_6H_5)_2CHOH$ × 10⁴, mole l.⁻¹	MnO_4^- × 10⁴, mole l.⁻¹	OH^-, mole l.⁻¹	Ionic strength	k_2, l. mole⁻¹ sec.⁻¹	Method
15.6	15.6	0.020	0.040	1.52[a]	Titration
7.80	15.6	.020	.040	1.54[b]	Titration
3.90	15.6	.020	.040	1.55[c]	Titration
7.80	15.6	.022	.040	1.79[b]	Titration
13.0	2.1	.022	.024	1.75[d]	Spectral
6.50	2.1	.022	.024	1.84[d]	Spectral

[a] Calculated using equation 3. [b] Calculated using equation 2. [c] Calculated using equation 4. [d] Calculated using the relation $k_2 = (2.30 \log x)/y_0't$ where $x = [MnO_4^-]$ and y_0' = mean concentration of benzhydrol over range studied.

Hydroxyl Ion Catalysis and Salt Effect.—The reaction rate was shown, too, to be directly proportional to the hydroxyl ion concentration (Fig. 2). A likely role for hydroxyl ion in the reaction would be to produce the anion of benzhydrol which, in turn, might undergo a rate-determining reaction with permanganate. This possibility can be further investigated by determining the effect of a change in ionic strength on the rate, since two anions would be reacting in the slow step. Unfortunately, a certain minimum hydroxyl ion concentration is required to ensure that the reaction one is studying is, indeed, the hydroxyl ion catalyzed one. This places the ionic strength in a region where the Brönsted–Debye–Hückel relation is not expected to hold. Harty and Rollefson[13] have recently had some success with a treatment for ionic reactions in more concentrated solution which involves plotting log k against a parameter which depends on both the ionic strength and the particular salt added. Using their value for the parameter when potassium sulfate is the added salt, as in the present case, one obtains the curve shown in Fig. 3. Although the precision of the results shown in this plot is not impressive (for reasons discussed in the Experimental section) the results do support the idea that the slow step is between two ions of like, single, charge. The over-all reaction may then be expressed as

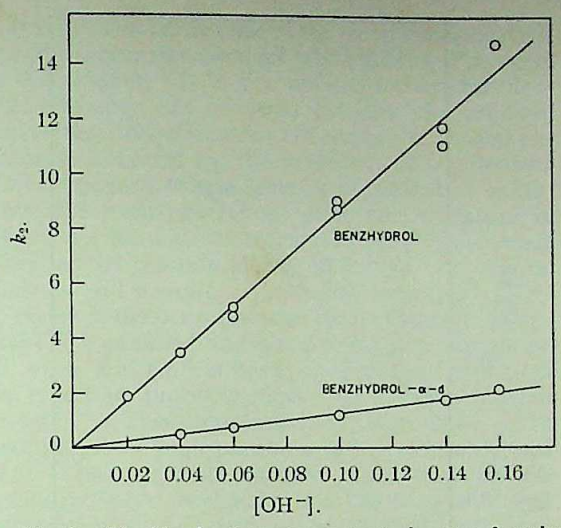

Fig. 2.—The bimolecular rate constant, k_2, as a function of the hydroxyl ion concentration for the permanganate oxidation of benzhydrol and benzhydrol-α-d; $T = 25.0°$.

$$(C_6H_5)_2CHOH + OH^- \overset{K}{\rightleftharpoons} (C_6H_5)_2CHO^- + H_2O$$

$$MnO_4^- + (C_6H_5)_2CHO^- \xrightarrow{k} \text{products}$$

The rate law which corresponds to this mechanism is

$$\frac{-d[MnO_4^-]}{dt} = k[MnO_4^-][(C_6H_5)_2CHO^-]$$

$$= kK[MnO_4^-][(C_6H_5)_2CHOH][OH^-]/[H_2O]$$

$$\therefore k_2 = kK[OH^-]/[H_2O]$$

These equations are in agreement with the observed kinetics.

Thermodynamic Functions.—A plot of log k/T against $1/T$ shows a satisfactory linear relation but leads to the rather low value for $\Delta H^{\ddagger}$ of 5.7 kcal. mole^{-1} and the rather high negative value for $\Delta S^{\ddagger}$

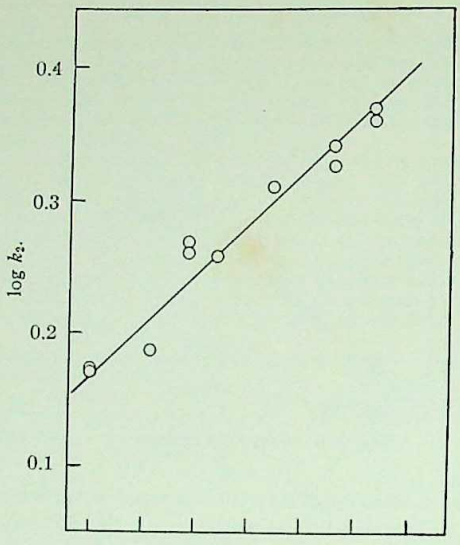

Fig. 3.—Log k_2 plotted against the parameter, $1/(3.26 + 1/\sqrt{u})$ for the permanganate–benzhydrol reaction; $T = 25.0°$.

of −38.4 e.u. It should be pointed out that these are composite values which include the thermodynamic parameters for the ionization step as well as for the rate-controlling step. The entropy of activation for the rate-controlling step must, in fact, be a much smaller negative quantity than the value of −38.4 e.u. calculated here since the equilibrium concentration of benzhydrylate ion is probably quite small in the solutions used in this work. In view of this the measured entropy of activation is not unreasonable since reactions between univalent anions in aqueous solution normally have activation entropies of the order of −20 e.u.[14]

Mechanism of the Rate-controlling Step.—If it is assumed that the first step in the reaction is the ionization of benzhydrol, then the following mechanisms for the rate-controlling step can be considered, each of which agrees with the observed kinetics.[15]

$$(C_6H_5)_2CHO^- + MnO_4^- \xrightarrow{\text{slow}} (C_6H_5)_2CHO\cdot + MnO_4^{=} \quad (5a)$$

$$(C_6H_5)_2CHO\cdot + MnO_4^- \xrightarrow{\text{fast}} (C_6H_5)_2C{=}O + MnO_4^{=} + H^+ \quad (5b)$$

$$(C_6H_5)_2CHO^- + MnO_4^- \xrightarrow{\text{slow}} (C_6H_5)_2C{=}O + HMnO_4^- \quad (6a)$$

$$HMnO_4^- + MnO_4^- \xrightarrow{\text{fast}} 2MnO_4^{=} + H^+ \quad (6b)$$

$$(C_6H_5)_2CHO^- + MnO_4^- \xrightarrow{\text{slow}} (C_6H_5C(OH)O^-) + MnO_3^- \quad (7a)$$

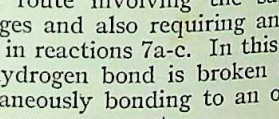
$$(C_6H_5)_2C(OH)O^- \underset{\text{fast}}{\rightleftharpoons} (C_6H_5)_2C(O^-)OH \xrightarrow{\text{fast}} (C_6H_5)_2C{=}O + OH^- \quad (7b)$$

$$MnO_4^- + MnO_3^- + 2OH^- \xrightarrow{\text{fast}} 2MnO_4^{=} + H_2O \quad (7c)$$

In eq. 5 the permanganate is acting as an electron abstractor, a role which it plays in the rapid manganate–permanganate exchange reaction.[16] Symons has suggested, with reference to permanganate oxidations, that direct electron exchange between negative oxy-ions may be facilitated by their size and ease of polarization.[17] This mechanism was shown to be incorrect by establishing the fact there is an isotope effect when the hydrogen on the α-carbon atom is replaced by deuterium. The ratio, k_H/k_D, the ratio of the slopes of the lines in Fig. 2, is 6.6:1 showing clearly that the rate controlling step involves the scission of the carbon-hydrogen bond.[18]

Reaction 6a is simply a transfer of hydride ion from benzhydrylate ion to permanganate producing Mn(V).[19] A species of this valence is believed to be the intermediate in the benzaldehyde–permanganate reaction,[1] and it has recently been shown that hypomanganate ion, Mn(V), is very rapidly oxidized by permanganate in basic solution.[20] Further, the kinetics of the homogeneous reaction between permanganate and molecular hydrogen have been interpreted in terms of a two electron or hydride transfer to permanganate to form Mn(V).[21]

A possible route involving the same over-all valence changes and also requiring an isotope effect is shown in reactions 7a-c. In this mechanism the carbon–hydrogen bond is broken by the two atoms simultaneously bonding to an oxygen atom donated by the permanganate.



This mechanism warrants consideration since the oxidation of formate ion which resembles the reac-

(14) The Arrhenius activation energy reported by L. M. Hill and F. C. Tompkins, *Trans. Roy. Soc. S. Africa*, **30**, 59 (1943), for the permanganate–formate reaction is 11.8 kcal. mole^{-1}. The value of $\Delta S^{\ddagger}$ which corresponds to this value is −22.7 e.u.

(15) A reaction such as the following involving hydroxyl radicals would require the rate to decrease with time because of the accumulation of manganate in the system.

$$MnO_4^- + OH^- \rightleftharpoons MnO_4^{=} + \cdot OH$$
$$(C_6H_5)_2CHOH + \cdot OH \longrightarrow (C_6H_5)_2COH + H_2O$$
$$(C_6H_5)_2COH + MnO_4^- \longrightarrow \text{products}$$

If the hydroxyl radicals were involved in a chain reaction or if the first step above was irreversible, one would not expect the kinetics to be first order in each of benzhydrol, permanganate and hydroxyl ion as was observed here.

(16) J. C. Sheppard and A. C. Wahl, THIS JOURNAL, **76**, 5133 (1953).

(18) K. B. Wiberg, *Chem. Revs.*, **55**, 713 (1955).

(19) An equivalent reaction can be written in which the benzhydrylate ion gives up two electrons to MnO_4^- to produce $MnO_4^{=}$ and simultaneously gives up a proton to a water molecule present in the solvation sphere. Since $MnO_4^{=}$ is probably a fairly basic species, it does not seem unreasonable to picture the electron pair plus proton being transferred simultaneously to the same site, *i.e.*, a hydride ion transfer.

tion studied here in many respects[22] may occur partly by just such a process since it has been shown that a considerable fraction of the oxygen found in the product, carbonate, is derived from the permanganate. In addition, the reaction of carbene, CH_2, with carbon–hydrogen bonds is believed to go through a similar transition state since the methylene group is found to be inserted between the previously bonded carbon and hydrogen atoms.[23]

To determine whether the hydride transfer *to* permanganate or the oxygen transfer *from* permanganate is occurring, benzhydrol was oxidized with $KMnO_4^{18}$ under conditions resembling as closely as possible those for the kinetic experiments. It was anticipated that the product, benzophenone, would exchange oxygen with the water in basic solution since ketones are known to do this,[24] but it was hoped that complete equilibration would not take place in the short reaction times used. The results of the oxidation of both benzhydrol with $KMnO_4^{18}$ and benzhydrol-O^{18} with $KMnO_4$ are shown in Table II.

TABLE II

OXYGEN-18 ANALYSIS OF BENZOPHENONE AND BENZHYDROL[a]

Sample	Source	Atom % O^{18} in CO_2 from sample[b]	Atom % O^{18} in excess in sample[b]
Tank CO_2		0.204	...
$(C_6H_5)_2C{=}O$	$(C_6H_5)_2CHOH$ + $KMnO_4^{18}$	.200	...
		.206	...
		.205	...
$(C_6H_5)_2CHOH$	$(C_6H_5)_2CHCl$ + H_2O^{18}	.558	0.708
		.557	.706

		.249	.090
$(C_6H_5)_2CHOH$[c]	$(C_6H_5)_2CHO^{18}H$ + $KMnO_4$	.254	.100
		.552	.696
		.552	.696

[a] See Acknowledgment. [b] CO from sample was oxidized to CO_2 and the O^{18} content determined mass-spectrometrically. If y = %O^{18} in CO_2, the atom %O^{18} in excess in the sample = $2(y - 0.204)$. [c] Recovered after the reaction.

(22) The permanganate oxidations of benzhydrol and formate ion resemble one another in the following respects: the size of the isotope effect, the sign and magnitude of the entropy of activation, the fact that the reaction in each case involves an anion, benzhydrylate ion and formate ion. In addition, the reaction of manganate with both formate ion and benzhydrol is slow.

(23) P. S. Skell and R. C. Woodworth, THIS JOURNAL, **78**, 4496 (1956).

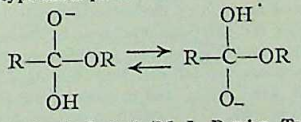
(24) M. Cole, *Chem. Revs.*, **51**, 286 (1952).

It is apparent that none of the permanganate oxygen appears in the product when $KMnO_4^{18}$ is used as the oxidant. It is also apparent that considerable exchange has occurred between the product and water, since the excess O^{18} content of the benzophenone obtained by the oxidation of benzhydrol-O^{18} is reduced to one-seventh of its initial value. That the exchange occurs after the oxidation is shown by the fact that the benzhydrol recovered after partial reaction shows no loss of O^{18}. Since there is still a quite definite concentration of O^{18} in excess in the benzophenone formed when benzhydrol-O^{18} is oxidized and since there is no excess at all when $KMnO_4^{18}$ is used, one can conclude that the reaction probably does not involve oxygen transfer.[25] This conclusion is warranted only because of the high precision of the O^{18} analytical data. Thus, the route shown in reactions 6a and 6b is the probable mechanism for the base-catalyzed permanganate oxidation of benzhydrol and may, indeed, be the general course of permanganate–alcohol reactions in basic media.

Acknowledgments.—The author is grateful to Drs. K. B. Wiberg and J. Halpern for helpful discussions and to Mr. Klaus Saegebarth of the University of Washington for the O^{18} analytical data which appear in Table II. Certain of the experimental results reported herein were obtained by the author in the Chemistry Laboratories of the Canadian Services College, Royal Roads, B. C.

VANCOUVER 8, CANADA

(25) Two other factors should be mentioned which might conceivably account for the absence of an excess of O^{18} in the benzophenone even though the mechanism shown in eq. 7a be correct. First, although permanganate by itself exchanges oxygen only slowly with water in neutral and basic solution, the exchange is more rapid in the presence of manganate (M. C. R. Symons, *J. Chem. Soc.*, 3676 (1954).) Since a onefold excess of permanganate was used in the tracer experiments and since the reaction time was short, this effect is not believed to be serious. Second, if the reaction shown on the left in eq. 7c is not a rapid equilibrium, the hydroxyl ion lost would be the one containing the excess of O^{18}. Since the equilibrium involves proton addition to an oxygen anion, it is believed that this would be a much faster reaction than the splitting of the oxygen–carbon bond to produce the products. An analogous situation exists for the case of ester hydrolysis where Bender has shown that rapid equilibration of the following type takes place



before the OR group is eliminated (M. L. Bender, THIS JOURNAL, **73**, 1626 (1951)).

π-Complexes of the Transition Metals. I. Hein's Polyaromatic Chromium Compounds[1,2]

BY HAROLD H. ZEISS[3] AND MINORU TSUTSUI[3]

RECEIVED NOVEMBER 29, 1956

The essential steps of Hein's methods for the preparation of polyphenylchromium compounds have been reproduced. The products of the chemical reduction of these compounds have led to a reformulation of their structures in terms of a bis-arene cation. This biconoidal structure is then discussed with respect to the formerly anomalous behavior reported for these complexes and the new chemistry which may now evolve.

Sidgwick's brief summary of the phenylchromium compounds[4a] provided the impetus for this introductory study of the transition metal complexes. The new experimental facts relating to the anomalous behavior and properties exhibited by these compounds and the concept of a new and fertile borderland of π-complexes between organic and inorganic molecules are now reported.

Repetition of the steps employed by Hein and his co-workers[4] in preparing the key compounds of the series, "pentaphenylchromium hydroxide" I, "tetraphenylchromium" iodide II and "triphenylchromium" iodide III, afforded these compounds, corresponding to their previous descriptions albeit in very small amounts. The basic reaction, formulated by Hein as (1), gave the amorphous, hygroscopic and impure "pentaphenylchromium bromide" which, with alcoholic potassium hydroxide (2), gave rise to "pentaphenylchromium hydroxide," which crystallized in the form of golden orange plates from water–chloroform mixture.

$$5C_6H_5MgBr + 4CrCl_3 \longrightarrow$$
$$\text{"}(C_6H_5)_5CrBr\text{"} + CrCl_2 + MgBr_2 + MgCl_2 \text{ (Hein)} \quad (1)$$

$$\text{"Raw bromide"} + KOH \longrightarrow$$
$$\text{"}(C_6H_5)_5CrOH\cdot 4H_2O\text{"} + KBr \quad (2)$$

$$\text{"}(C_6H_5)_5CrOH\text{"} + KI \longrightarrow$$
$$\text{"}(C_6H_5)_4CrI\text{"} + C_6H_5OH + KOH \quad (3)$$

The aqueous mother liquor, after concentration and cooling, deposited crystalline, orange "pentaphenylchromium carbonate," formulated as "$[(C_6H_5)_5Cr]_2CO_3\cdot 6H_2O$." The mother liquor resulting from this step consisted of a strongly alkaline, sirupy, water-soluble black mass which deposited orange-yellow plates of "triphenylchromium" iodide III when treated with aqueous potassium iodide; while a suspension of I in a mixture of aqueous potassium iodide and chloroform was transformed into an orange oil which slowly crystallized and was eventually obtained as golden orange plates of "tetraphenylchromium" iodide II (reaction 3).

The first series of anomalies is apparent from the reaction scheme just presented. Phenylmagnesium bromide is recognized to be a reducing agent but not one of oxidation. The separation of tetra-, penta- and hexavalent chromium compounds from the same solution (no free iodine formed) is unaccountable. The production of tetravalent II with the liberation of phenol by potassium iodide from pentavalent I is scarcely conceivable, and this difficulty is compounded by the fact that over 50 salts were prepared by Hein, *et al.*,[4] from I with organic and inorganic anions, of which upwards of 40 were formulated as *tetraphenyl*chromium derivatives. The remainder were written as pentaphenylchromium salts containing varying amounts of solvent of crystallization.

The second set of anomalies recognized at the time consisted of the uniform light absorption properties of these polyphenylchromium compounds. They were found to have similar color in the visible range (orange to yellow) and to exhibit similar chromium band absorption near 350 mμ in the ultraviolet region. In the only previous independent work on the Hein compounds Klemm and Neuber[5] measured the magnetic susceptibilities of representatives of each "valence class" and found them all to possess one free electron, *i.e.*, paramagnetic to the extent of 1.72 ± 5% Bohr magnetons. These authors suggested, therefore, that all of Hein's compounds were in the same valence state and that this state was probably Cr^V. We have confirmed this magnetic property also with our sample of II.[6] Unquestionably these observations cast serious doubt on the formulation of 5, 4 and 3 phenyl groups attached covalently to chromium.

The difficulties attending the synthesis of the polyphenylchromium compounds by the Hein procedure induced us to attack the structural problem imposed by degradation methods. At this stage

(1) The subject matter of this paper was presented in 1954, Abstr., 126th Meeting, Amer. Chem. Soc., p. 29-0, Sept., 1954, and also submitted to THIS JOURNAL as a preliminary Communication. The paper, however, was rejected by the referees chiefly on the grounds of insufficient evidence for our (with Professor L. Onsager) proposal of the π-complexed biconoidal structure. In 1955 a portion of our results was published in abbreviated form, *Yale Sci. Mag.*, **29**, 14 (1955); *Angew. Chem.*, **67**, 282 (1955); and in more complete form by F. A. Cotton, *Chem. Revs.*, **55**, 551 (1955). A series of lectures on this subject were also presented during June-July, 1955, at Heidelberg, Tübingen, Munich and Zürich, *Handbook, XIVth International Congress of Pure and Applied Chemistry*, p. 262. We have been informed (private discussion with Dr. E. O. Fischer) that the preparation of bis-benzenechromium from benzene, E. O. Fischer and W. Hafner, *Z. Naturforsch.*, **10b**, 665 (1955), was first realized after the above dates. This chronology is given here in an attempt to reduce the confusion which has arisen and is not to be construed as a detraction from the elegant method of preparation and structural proofs devised by Dr. Fischer and his colleagues.

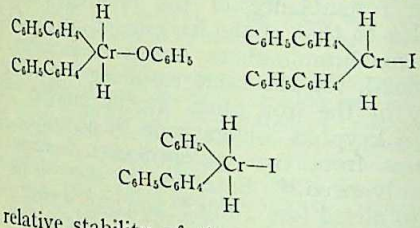
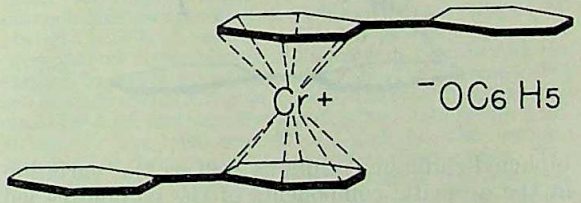
it was discovered that biphenylmercury was reduced smoothly in ether to benzene by lithium aluminum hydride without formation of biphenyl.[7] A similar reduction of "pentaphenylchromium bromide" demonstrated its grossly impure nature, for the organic product consisted of benzene, biphenyl, terphenyl and higher boiling polyphenyls. Reductions of I, II and III were next performed on a semi-quantitative basis owing to the small amounts of these substances available. "Tetraphenylchromium" iodide II on reduction gave biphenyl as the *sole* organic product and this in the amount of *two* mole equivalents. The degradation of "triphenylchromium" iodide III gave *both* benzene and biphenyl, each estimated to be present in a 1:1 mole ratio. Finally, "pentaphenylchromium hydroxide" I was reduced to a mixture of biphenyl and *phenol*, the molar ratio of which amounted to 2:1. Failure to detect benzene spectroscopically either from the hydride reduction of I or II clearly rendered the Hein formulation inadmissible. Also, the reappearance of phenol as a product from I, as it was in the reaction of I with potassium iodide, compelled the conclusion that I is a phenoxide rather than an hydroxide.

The pentavalent structures suggested by Klemm and Neuber[5] were next considered in the light of the new evidence. Rationalization of these structures with the experimental facts led to the following hydride structures for I, II and III. However,

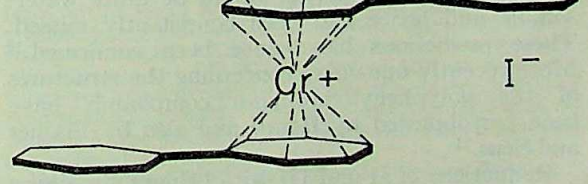


the relative stability of these compounds toward water, dilute acid and base, not being a typical property of metal–hydride bonds, invited considerable scepticism; and so an isotopic reduction method for testing the Klemm–Neuber structures was devised. A sample of II was reduced with lithium aluminum hydride and then hydrolyzed with deuterium oxide. As previously found, no benzene was formed; but the biphenyl was collected and burned to carbon dioxide and water. This water was reduced with zinc to hydrogen which was observed to be free of deuterium in the mass spectrometer.[8] This result of course eliminated a reduction mechanism which involved a displacement of biphenyl anion by aluminum hydride from chromium. But when II was reduced with lithium aluminum deuteride, the biphenyl produced contained 5.0 D% or one atom of deuterium per molecule of II or 2 molecules of biphenyl. It was supposed that the Klemm–Neuber structure for II would lead to biphenyl containing 10 D% or one atom of deuterium per molecule of biphenyl if reductive attack occurred on carbon as the previous experiment indicated. Deuteride reduction of III gave biphenyl containing 6.7 (6.55) D%,[9] or two-thirds of the amount predicted for the Klemm–Neuber structure. The benzene deuterium content was not determined. A sample of reagent biphenyl was subjected to the action of lithium aluminum deuteride in ether under the same conditions of time and temperature without becoming deuterated. While these isotopic results did not unequivocally dispose of the hydride structures, they did render them most unlikely.

In the course of a number of discussions which ensued after the results of the lithium aluminum hydride reductions became known, Professor L. Onsager proposed the bis-aromatic structure for II as shown below. It was reasoned that the chromium atom, atomic number 24, requiring 12 electrons to fill its 4s, 3d and 4p shells to reach the stable krypton level, could do so by the donation of 6 π-electrons each from two aromatic rings, thus becoming a bis-aromatic-chromium[0] complex of considerable stability. It was recalled too that Hein in his early work had reduced both I and II



I



II

electrolytically in liquid ammonia to, strangely enough, the *same* compound, formulated as "*tetraphenylchromium*." Also, III could be reduced, both electrolytically and by sodium metal in the same solvent, to "*triphenylchromium*." The corresponding cation, therefore, would arise by the loss of one electron, leaving the chromium atom with one unpaired electron and therefore paramagnetic. At the outset we were reluctant to believe that aromatic π-electrons could be donated in this manner and that the loss of resonance energy accompanying this process would be offset by the stability associated with the inert-gas configuration achieved. However, the weight of the

(7) In footnote 2, p. 569, of reference 4b there is a statement of misconception of the purpose of this experiment. It was meant to show that of the polyphenylchromium compounds possessed chromium–phenyl covalent bonds, such as exist in biphenylmercury and as suggested by Hein, then benzene would be produced by this ionic reduction and biphenyl could not arise by a free radical process. The importance of this observation, therefore, lay in testing the Hein formulation and not in determining others. The fact that the experiment showed the absence of biphenyl groups in biphenylmercury was gratuitous.

(8) We wish to express our appreciation for the assistance given us by Mr. J. Graff of the Department of Biochemistry, and by Dr. J. H. Wang, Department of Chemistry, Yale University, in the mass determinations and spectrometric determinations.

(9) The figure given here in parentheses was obtained several weeks after the first result with the remaining portion of biphenyl.

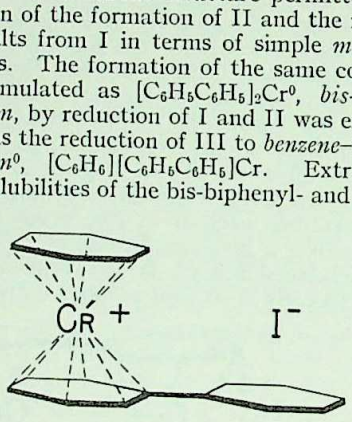
evidence became compelling. Reformulating I in terms of the bis-arene structure permitted an explanation of the formation of II and the numerous other salts from I in terms of simple *metathetical* reactions. The formation of the same compound, now formulated as $[C_6H_5C_6H_5]_2Cr^0$, *bis-biphenyl-chromium*, by reduction of I and II was explicable, as well as the reduction of III to *benzene–biphenyl–chromium*^{0}, $[C_6H_6][C_6H_5C_6H_5]Cr$. Extrapolation of the solubilities of the bis-biphenyl- and benzene-



III

biphenyl-chromium^I salts as well as the variation in the aromatic components of the complexes led to the prediction that the bis-benzene-chromium^I cation had also been formed in the course of the Grignard reaction, that it would be quite water-soluble and hence had been consistently missed. These predictions have since been confirmed.[10] More recently our views concerning the structures of the polyphenyl-chromium compounds have been corroborated by Hein[11] and also by Fischer and Seus.[11]

Reductions of II and III with lithium aluminum deuteride gave biphenyl in each case containing one-half and two-thirds of the deuterium, respectively, expected from a displacement by aluminum deuteride on carbon in the hydride structures. If, however, the assumption is made that the aromatic rings of the bis-arene structures for II and III are equivalent in reactivity and that the attack of one deuteride ion on any one aromatic ring is sufficient to cause the reductive collapse of the complex, then the fractional results are understandable on a statistical basis. Thus, a random collision with any of the four phenyl groups of II by a deuteride ion collapses the complex with expulsion of a non-deuterated biphenyl molecule and the formation of one monodeutero-biphenyl molecule per molecule of II with evolution of hydrogen. Since only biphenyl was measured for deuterium from the reduction of III, random distribution of deuterium by indiscriminate deuteride reduction at either benzene or biphenyl sites in the complex introduces deuterium two out of three effective reactions in biphenyl, or 6.7 D% in biphenyl. In terms of a nucleophilic displacement mechanism, this interpretation requires of course a 100% isotope effect as well as reliance on the deuterium analyses.[9] However, as long as the reactions of odd-electron, aromatic complexes are incompletely explored, an unforeseen reaction seems not as significant as an unexpected inhibition.

The resemblance of the bis-arene-chromium^I complex to that of the ferricinium ion, and of the bis-arene-chromium^0 to ferrocene, is more than superficial, for the same reasoning regarding the ability of the iron atom, atomic number 26, to reach a krypton configuration by accepting 10 π-electrons from two cyclopentadienyl anions has been advanced.[12] Extension of these considerations to nickel (see Table I) and its 8 π-electron requirement for a stable krypton configuration permits the prediction of the eventual capture of cyclobutadiene in a complex such as bis-cyclobutadiene-nickel^0 or its cation.[1] Longuet-Higgins and Orgel[13] have now applied the molecular orbital theory to the possible existence of such a complex with favorable results. More broadly, this new concept of transition metal complexes may be expected to lead to significant advances in the theory of catalysis.

Experimental[14]

"Pentaphenylchromium Bromide."[15]—Phenylmagnesium bromide solution prepared from 25 g. of magnesium, 150 g. of bromobenzene and 200 ml. of ether was treated with 40 g. of anhydrous chromium trichloride[16] according to Hein from which *ca.* 12 g. of orange-brown resinous solid was obtained from the chloroform layer. In only 3 out of over 50 runs did we obtain "raw bromide" from which "pentaphenylchromium hydroxide" could be prepared. We attribute these failures to our subsequent care in excluding oxygen from the Grignard flasks (no phenol formed). Many varia-

tions of time, temperature, reagent concentrations, added reactants and chromium trichloride purity were tried without success. In one run out of 3 using chromyl chloride in place of the trichloride, we obtained "raw bromide" of the "correct" composition.

"Pentaphenylchromium Hydroxide."[15]—The "raw bromide" (27 g.) was transformed into the "hydroxide" in ethanol with potassium hydroxide (7 g.), which was crystallized from water as large, deep orange plates, 2 g. These crystals were very hygroscopic and lost water of hydration when dried *in vacuo* over Drierite. Their color changed too to a deep olive-gray, m.p. 102–104°, as described by Hein. In water the orange color of the crystals returned and they absorbed at 248 and 345 mμ in the ultraviolet region in 95% ethanol.

"Tetraphenylchromium" Iodide.[16]—A solution of 0.05 g. of "pentaphenylchromium hydroxide" in chloroform was shaken with 1 ml. of a saturated solution of potassium iodide in water, and the chloroform solution was then washed with water. Petroleum ether was now added to the chloroform solution to incipient turbidity, and the mixture was then put aside in the cold. The orange-yellow flakes of "tetraphenylchromium" iodide (0.005 g.) which had crystallized were separated by centrifugation and washed thrice with ether, m.p. 160–165°. These were crystallized from chloroform as orange-red plates containing solvent of crystallization and this chloroform was removed by heating at 55° *in vacuo* for 7 hr. The pure iodide, m.p. 177–178°, was yellow-orange in color and absorbed at 250 and 342 mμ (log ε 4.01 and 3.39, resp., 0.0001 *M* in ethanol).

Anal. Calcd. for $C_{24}H_{20}ICr$: C, 59.13; H, 4.52; I, 26.07; Cr, 10.68. Found: C, 58.82; H, 4.46; I, 26.13; Cr, 10.58.

The *density* of the iodide was determined by suspending the solid in a mixed solution of iodobenzene and carbon tetrachloride: 1.6170 (16°). Its *molecular weight* was determined cryoscopically using *m*-dinitrobenzene as solvent and was found to be 482 (487) in dilute solution, *i.e.*, 0.00233 g. of iodide in 0.04898 g. of solvent. This value was reproducible so long as solutions of comparable concentration were employed. However more concentrated solution gave erratic results as would be expected for ionic compounds.

"Triphenylchromium" Iodide.[17]—One hundred ml. of the water layer remaining after the filtration of "pentaphenylchromium hydroxide" described above was concentrated to 50 ml. by freeze-drying (Hein performed this concentration at 40–45° also *in vacuo*). After standing in the refrigerator for one week, this solution had deposited red prisms which were separated by centrifugation and recrystallized from ethanol, m.p. 117–119°, and corresponding to the compound designated by Hein as "*pentaphenylchromium carbonate*." Four ml. of the deep-red filtrate was evaporated to dryness under freeze-dry conditions, leaving 0.82 g. of a yellow-brown, brittle resin whose chromium analysis corresponded to a trihydrate of "*triphenylchromium*" *hydroxide*. A solution of 0.75 g. of this hydroxide in 30 ml. of chloroform and 15 ml. of water was shaken with 2 ml. of a saturated aqueous solution of potassium iodide, and the aqueous layer was then extracted thoroughly with chloroform. The combined chloroform extracts, now red in color, were washed with water, poured over Drierite, filtered and then brought to turbidity with petroleum ether. After standing one week in the cold, the solution had deposited a red solid which after four recrystallizations from chloroform with tetrahydrofuran gave orange-yellow plates, m.p. 110–112°, when dried *in vacuo* at 60° for 9 hr. This "triphenylchromium" iodide is considerably more soluble in water than "tetraphenylchromium" iodide and absorbs weakly at 270 mμ and strongly at 343 mμ in 95% ethanol.

Anal. Calcd. for $C_{18}H_{16}ICr$: Cr, 12.64. Found: Cr, 11.88.

Its molecular weight was found to be 430 (theory 411) by cryoscopic measurement in *m*-dinitrobenzene. Fifteen similar recrystallizations of the iodide raised the m.p. to 146–148°, but the infrared spectrum of the iodide remained essentially unchanged. Analysis and molecular weight of the iodide, m.p. 112°, indicated that it was a monohydrate, but this was not confirmed.

Anal. Calcd. for $C_{18}H_{16}ICr \cdot H_2O$: C, 50.5; H, 4.24; I, 29.6; Cr, 12.1. Found: C, 50.6; H, 4.05; I, 27.3; Cr, 11.9.

(17) F. Hein, *Ber.*, **54**, 2727 (1921).

$LiAlH_4$ Reduction of "Tetraphenylchromium" Iodide.—To a solution of 0.50 g. of lithium aluminum hydride in 50 ml. of ether previously distilled from $LiAlH_4$ was added 0.0102 g. of "tetraphenylchromium" iodide. Vigorous reaction occurred at the surface of the ether-insoluble iodide with evolution of gas, presumably hydrogen, and complete disappearance of the iodide within a few minutes. The solution became brown and, after standing for 4 hr. in the cold, it turned clear with the deposition of a white, amorphous precipitate. The cold reaction mixture was then hydrolyzed with 0.5 ml. of water, the ether layer was decanted and the precipitate was dissolved in dilute hydrochloric acid. The acid solution was extracted with ether, and the ether extracts were distilled in a simple distilling flask. The residue consisted of pure biphenyl whose identity was confirmed by its ultraviolet absorption, determined in ether and a 10-cm. cell path, to be at 248 mμ. The distilled ether likewise showed absorption at 248 mμ and contained biphenyl in the amount of 0.0027 g. as determined from the optical density of the solution. A total of 0.0049 g. was thus determined, or 76% of the theoretical amount based on two molecules of biphenyl per mole of the iodide. Both the absence of benzene and amount of biphenyl produced in this reduction precluded a Klemm–Neuber formulation for the iodide such as bis-phenyl–biphenyl-chromium iodide.

$LiAlH_4$ Reduction of "Triphenylchromium" Iodide.—The iodide (0.2034 g.) was reduced in one l. of ether with 1.00 g. of $LiAlH_4$ by the general procedure just described. However, in this case the ethereal solution was distilled through a 12″ Vigreux column, for it was found that while ordinary distillation permitted co-distillation of biphenyl with the ether, the column perfectly inhibited this complication. The ether distillate was free, therefore, of biphenyl but was now found to contain benzene in the amount of 0.0010 g. by spectrophotometric determination. The residue from the distillation amounted to 0.0480 g. and was shown to be biphenyl both by sublimation and mixed m.p. and by ultraviolet absorption. Based on the benzene-biphenyl-chromium iodide structure these yields constitute 63% of biphenyl and 3% of benzene. The low recovery of benzene prompted us to determine the maximum efficiency of the method by treating a solution of 0.0135 g. of benzene in 585 ml. of ether with 0.150 g. of $LiAlH_4$, allowing the mixture to stand for 8 hr. and then hydrolyzing the solution with 1 ml. of water. The solids were filtered and the ether solution was distilled through the Vigreux column used above. The amount of benzene recovered as determined spectrophotometrically was 0.0041 g. or 31%. In a similar experiment freshly prepared biphenylmercury (0.0144 g.) was reduced with 0.080 g. of lithium aluminum hydride in 70 ml. of ether over a period of 4 hr. The solution was then hydrolyzed with a small amount of water and filtered, and the precipitate was dissolved in dilute hydrochloric acid and extracted with ether. The combined ether extracts were distilled through the 12″ Vigreux column, and the ether distillate was found to contain 0.0020 g. of benzene, or 32% of the theoretical amount. The small quantity of residue remaining in the distillation flask contained neither biphenyl nor biphenylmercury.

$LiAlH_4$ Reduction of "Pentaphenylchromium Bromide."—To a solution of 5.0000 g. of lithium aluminum hydride in 5 l. of ether was added 1.000 g. of "raw bromide" with evolution of gas. Shortly after the addition of the sample, it dissolved with a development of brown color in the ether solution. After 8 hr. in the refrigerator and occasional shaking, the solution became clear and yielded a white precipitate. This mixture was hydrolyzed with 20 ml. of water in the cold, the ether layer was decanted and the precipitate was dissolved in dilute hydrochloric acid and extracted with ether. The ether solutions were next distilled from an ordinary distilling flask, and the residue was separated into methanol-soluble (0.3108 g.) and insoluble (0.065 g.) fractions. A portion of the former fraction was first sublimed and then crystallized from methanol to give pure biphenyl, m.p. 68–69°, which melted undepressed with an authentic sample and which absorbed at 248 mμ in ether. The methanol-insoluble fraction was recrystallized from 95% ethanol as plates of *p*-biphenylbenzene, m.p. 210–212°, 0.007 g., melting undepressed with a reagent sample. The ether distillate now amounting to 4240 ml. was redistilled through the 12″ Vigreux column, leaving 0.3246 g. of biphenyl as residue. The ether distillate contained 0.0259 g. of benzene as determined spectroscopically.

$LiAlH_4$ Reduction of "Pentaphenylchromium Hydroxide."—The "hydroxide" (0.0031 g.) was reduced with 0.020 g. of $LiAlH_4$ in 40 ml. of ether according to the general procedure previously described in detail. The reaction mixture was hydrolyzed with 0.5 ml. of water after the solution had come clear with the formation of the white precipitate. This precipitate, after separation by filtration, was dissolved in 1 ml. of dilute hydrochloric acid. This solution was saturated with sodium chloride and then extracted with 20 ml. of ether. The ether extract was combined with the ether filtrate, this solution washed with 3% sodium hydroxide twice, and the resultant ether solution was then distilled through the Vigreux column. No benzene was detected in the distillate, but biphenyl was left as residue, 0.0010 g., or 47% of the theoretical amount based on the bis-biphenyl-chromium phenoxide formulation. The alkaline solution was acidified and extracted exhaustively with ether. This ether solution absorbed at 273 mμ and was estimated to contain 0.0003 g. of phenol, or 47% of the theoretical amount.

$LiAlD_4$ Reduction of "Tetraphenylchromium" Iodide.—A solution of 0.0945 g. of the iodide was reduced with 0.200 g. of lithium aluminum *hydride* in 500 ml. of ether for 7 hr. and then hydrolyzed with 2 g. of *deuterium oxide*. After handling this mixture as already described, the ether solution was distilled, and no benzene was detected in the distillate. Biphenyl, 0.0122 g., was obtained by sublimation of the residue, 0.0310 g. (52%) and contained 0.31 D%.[8]

In a completely similar experiment 0.0520 g. of the iodide was reduced with 0.1500 g. of lithium aluminum *deuteride* in 260 ml. of ether. This mixture was hydrolyzed with 1.5 g. of deuterium oxide. Again, no benzene was found in the ether distillate, and biphenyl, containing 5.0 D%,[8] was obtained, 0.0083 g. , by the sublimation of the residue, 0.021 g. (64%), from the distillation.

Biphenyl (100 mg.) was treated with 500 mg. of lithium aluminum *deuteride* in 500 ml. of ether and hydrolyzed with 2.0 ml. of water. The sublimed biphenyl product contained 0.00 D%.[8]

$LiAlD_4$ Reduction of "Triphenylchromium" Iodide.—This iodide (0.300 g.) was reduced with 0.900 g. of lithium aluminum *deuteride* (97.8%) in 1500 ml. of ether and the solution hydrolyzed with 5 ml. of deuterium oxide. The ether solutions from the work-up procedure were distilled through the Vigreux column leaving 0.0890 g. of residue (79%) which gave 0.0470 g. of sublimed biphenyl. The ether distillate contained 0.0162 g. of benzene by spectrophotometric analysis, or 28% of the theoretical amount based on the benzene-biphenyl-chromium iodide structure. The biphenyl obtained above contained 6.7 D%. In a duplicate run made two weeks later the content was found to be 6.55 D%.[8]

Infrared Absorption Spectra of *o*-Hydroxyazobenzene and its Metal Chelate Compounds

BY KEIHEI UENO

RECEIVED DECEMBER 17, 1956

The infrared absorption spectra of *o*-hydroxyazobenzene and its Cu, Ni and Co chelates are reported. Disappearance of the OH band in 3300 cm.$^{-1}$ region and the bathochromic shift of the carbonyl band in 1600 cm.$^{-1}$ region indicate the presence of a resonating system involving the azo linkage and the *o*-hydroxy group. The carbonyl band and the azo band shift to lower frequencies in the metal chelates, and the extent of shift is in the order of Cu > Ni > Co.

Introduction

In connection with an infrared absorption study of polyazobenzenes,[1] an investigation of a series of *o*-hydroxy azo compounds has been undertaken. In spite of the need for fundamental information on infrared absorption spectra of aromatic azo compounds, very little work has been reported in this field. It is the purpose of this investigation to study the infrared absorption spectra of *o*-hydroxyazobenzene, the simplest of the *o*-hydroxy aromatic azo compounds, and its Cu, Ni and Co chelates. The result of such a study should be of importance in connection with infrared analysis of *o*-hydroxy azo dyes of more complicated structures.

Experimental

Preparation of Samples.—*o*-Hydroxyazobenzene was prepared by coupling diazotized aniline with phenol according to the method of Bamberger[2] and was purified *via* copper chelate and recrystallized from ethanol (m.p. 82.5°).

The metal chelates were prepared by refluxing an ethanol solution of ligand and metal acetate for 10 minutes. After cooling, the metal chelates separated as needles, which were then recrystallized from ethanol. Although an attempt was made to prepare the cadmium chelate, only the ligand was recovered. The copper chelate was most easily prepared, while the nickel and cobalt complexes were prepared with increasing difficulty. The metal content of these chelate compounds was determined by complexometric titration after decomposing the samples with fuming nitric acid in a sealed tube,[3] and all the chelate compounds were found to contain 2 moles of ligand per mole of metal. The properties and the result of analyses are shown in Table I.

TABLE I

METAL CHELATES OF *o*-HYDROXYAZOBENZENE

Metal chelated	Color	Metal, % Calcd.[a]	Found
Cu(II)	Brown	14.80	14.55
Ni(II)	Dark green	13.81	14.02
Co(II)	Dark blue	13.87	14.11

[a] Metal contents were calculated from the formula $(C_{12}H_9ON_2)_2M$, where M represented the metal chelated.

Infrared Spectra.—A Perkin–Elmer model 21 double beam spectrophotometer equipped with sodium chloride optics was used for the determination of infrared spectra, and samples were run both as Nujol mulls and as potassium bromide disks. For all the samples, these procedures gave almost identical spectra.

Results and Discussion

The significant absorption bands of these compounds below 1700 cm.$^{-1}$ are shown in Table II, along with assignments to group vibrations where possible.

The only absorption band observed in the 3300 cm.$^{-1}$ region is one due to the characteristic aromatic C–H stretching vibration at 3030 cm.$^{-1}$. This band is stable in position as well as in intensity when one goes from the ligand to the metal che-

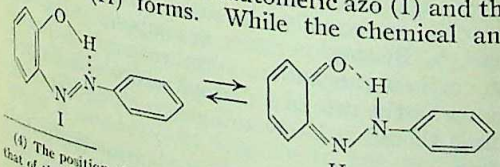
lates, indicating that it is due purely to the aromatic C–H stretching vibration.

It is striking that no other well-defined band can be found in and around the 3300 cm.$^{-1}$ region on the ligand, since an additional band due to O–H stretching vibration would be expected in this region, as is true of the corresponding *para* derivative, which has a strong band at 3150 cm.$^{-1}$.[4] The absorption due to O–H stretching vibration is known to shift to the lower frequency region and to decrease in intensity as the result of hydrogen bonding. Although a very weak band is found at around 2300 cm.$^{-1}$ on the ligand, it cannot be due to O–H bonding, because the corresponding band with increasing intensity is found on all metal chelates, in which no O–H bonding exists.

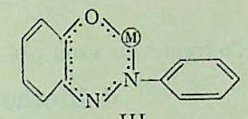
There have been many discussions on the structure of *o*-hydroxyazo compounds,[5] since the compounds can have the tautomeric azo (I) and the hydrazone (II) forms. While the chemical and



I II

absorption spectrophotometric evidence on the *o*-hydroxyazo compounds in solution favor the hydrazone structure,[6] it has been shown that *o*-hydroxyazobenzene appears in the azo form only, irrespective of the solvent.[7]

In accordance with these observations Hadzi[8] concluded, in his investigation on the *o*-hydroxyazo compounds, that the absorption band due to the O–H stretching vibration of *o*-hydroxyazobenzene was, owing to its intramolecular hydrogen bonding, too weak and too broad to be observed. A broad and rather strong band with a maximum at 1610 cm.$^{-1}$ is observed in the ligand, *i.e.*, *o*-hydroxyazobenzene, but is shifted to lower frequencies in its metal chelate compounds. This absorption probably is due to the C=O stretching vibration of the hydrogen bonded ring system as shown by the formula II. Although the free carbonyl band is expected at around 1700 cm.$^{-1}$, such a bathochromic shift is often observed in hydrogen-bonded ring systems.[9] In the metal chelates, this band is observed at around 1531–1540 cm.$^{-1}$, as the result of involvement of the C=O . . . linkage in the metal chelate ring as shown by formula III.



III

The shift of this band from the original position of the ligand probably is due to the increased mass of the metal attached to the oxygen atom relative to that of the proton and also due to the electronegativity of the metal ions.

Although no quantitative data are available on the stability of the metal chelates of *o*-hydroxyazobenzene, the ease of metal chelate formation and the stability order of metals[10] would indicate that the stability of the metal chelates of *o*-hydroxyazobenzene decreases in the order of Cu > Ni > Co. It may also be noted that the order of decreasing frequency of the band arising from the carbonyl linkage of the metal chelates is parallel to the order of decreasing stability.

Similar shifts of the carbonyl band by metal chelation also were reported for salicylaldehyde and its metal chelates.[9b] However, in these cases, the extent of shift was found to parallel the order of increasing stability of the salicylaldehyde metal chelates. It is not clear why the carbonyl band shifts with increasing stability in one case and with decreasing stability in other case. However, the results of this research indicate that the shift of carbonyl band by metal chelate formation does not result simply from a change of bond order but result from more complicated effects such as the mass of metal ions and the formation of π-orbitals in the

(4) The position of the band at 315 cm.$^{-1}$ is somewhat lower than that of the free O–H absorption band which appears at around 3500 cm.$^{-1}$. The details will be discussed elsewhere along with those of other polyazobenzenes.

chelate ring involving the d-orbitals of the metal ion.

Another considerable change of the spectra resulting from metal chelate formation is found in the bands at 1283 and 1272 cm.$^{-1}$. Although the 1283 cm.$^{-1}$ band appears as a shoulder on the main band at 1272 cm.$^{-1}$, both bands are rather strong and are missing in the metal chelates. Hadzi[8] assigned the band at 1272 cm.$^{-1}$ to the in-the-plane bending mode of the C–O–H group. The fact that the corresponding band is missing in the metal chelates supports this assignment, and either one of these two bands is possibly due to the C–O–H group of the ligand.

No conclusive assignment of absorptions due to the azo linkage has been reported in the literature. Le Fèvre[11] and his co-workers have investigated some 43 aromatic diazonium and azo compounds and found common absorption bands at around 1406 and 1577 cm.$^{-1}$. The main difficulty in the assignment of a frequency to the azo linkage is that the absorption frequency of N=N stretching vibration would overlap with other absorptions such as those of the aromatic ring which are usually of strong intensity.

Of the absorption bands due to the azo linkage, a band corresponding to 1405 cm.$^{-1}$ was found in the polyazobenzenes which we have investigated,[1] and it is believed that this band can be assigned to the azo linkage with certainty. For azobenzene and *o*-hydroxyazobenzene, this absorption band is found at 1395 and 1418 cm.$^{-1}$, respectively. For the metal chelate compounds of *o*-hydroxyazobenzene, this band shifts to lower frequencies as shown in the Table II. The extent of shift is again found to be parallel to the order of decreasing stability of metal chelate compounds.

Acknowledgment.—The author wishes to express his sincere appreciation to Prof. A. E. Martell of Clark University, Worcester, Mass., who so generously carried out the measurement of infrared spectra.

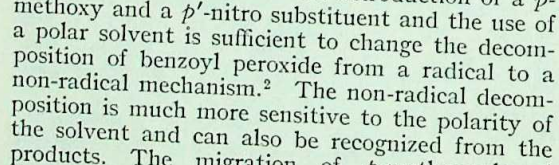
4-Methoxy-3′,5′-dinitrobenzoyl Peroxide[1]

BY JOHN E. LEFFLER AND CONSTANTINE C. PETROPOULOS

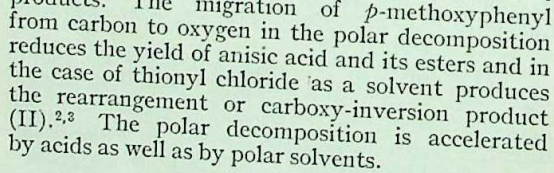
RECEIVED DECEMBER 20, 1956

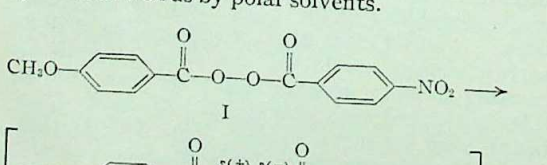
The decomposition of 4-methoxy-3′,5′-dinitrobenzoyl peroxide is accelerated by a shift to a more polar solvent, by acids, and by 1,3,5-trinitrobenzene. Its behavior is compared with that of other diacyl peroxides.

The combined effect of the introduction of a *p*-methoxy and a *p*′-nitro substituent and the use of a polar solvent is sufficient to change the decomposition of benzoyl peroxide from a radical to a non-radical mechanism.[2] The non-radical decomposition is much more sensitive to the polarity of the solvent and can also be recognized from the products. The migration of *p*-methoxyphenyl from carbon to oxygen in the polar decomposition reduces the yield of anisic acid and its esters and in the case of thionyl chloride as a solvent produces the rearrangement or carboxy-inversion product (II).[2,3] The polar decomposition is accelerated by acids as well as by polar solvents.



I





II

Similar experiments have now been done with 4-methoxy-3,′5′-dinitrobenzoyl peroxide. This peroxide is even more sensitive to solvent changes, but the reaction is less clean cut.

The Effects of Substituents and Solvents.—Table I summarizes the combined effects of the various substituents and solvents on the first-order rate constants for the peroxide decomposition; the results are remarkably different from those obtained with symmetrical peroxides. The effects of solvent changes or of symmetrical *meta* or *para* substitution on the rate of homolysis of benzoyl peroxide are usually less than one order of magnitude. For example in acetophenone at 80° the rate constants range from 1.46×10^{-3} min.$^{-1}$ for bis-(*p*-cyanobenzoyl) peroxide to 9.32×10^{-3} min.$^{-1}$ for bis-(*p*-methoxybenzoyl) peroxide.[4] In the solvents benzene, acetophenone, dioxane and styrene the first-order constants of a given benzoyl peroxide are usually the same within a factor of two.[4-6] Benzoyl peroxide decomposes at the same rate in benzene and in nitrobenzene.[7] A drastic change in the rate of a diaroyl peroxide decomposition is therefore likely to mean a change in mechanism.

In benzene the 4-methoxy-4′-nitro substitution

[a] K. Nozaki and P. D. Bartlett, This Journal, 68, 1686 (1946). [b] Estimated from E_{act} of reference (*a*). [c] Reference 2. [d] With 0.17 molar 1,3,5-trinitrobenzene added the rate constant is 1670 × 10^{-6} sec.$^{-1}$.

in the peroxide increases the rate by a factor of about 3 at 70°. The effect of substituents on the purely radical part of the rate can be estimated from data on symmetrically substituted benzoyl peroxides in dioxane[5] and in acetophenone,[4] except that there is undoubtedly some interaction of substituent and solvent effects even in the case of the radical reaction. Neglecting any perturbation by the difference in solvent, the 4-methoxy-4′-nitro substitution should decrease the purely radical decomposition rate somewhat. But the observed increase by a factor of three may not have any mechanistic significance since the reaction products in benzene are consistent with a purely radical decomposition. In nitrobenzene the same 4-methoxy-4′-nitro substituted peroxide decomposes about eight times as fast as in benzene. This might also be within the bounds of possible behavior for a radical reaction, but here the increase in rate is accompanied by a change in products suggesting an almost complete shift to the non-radical mechanism.[2]

The 4-methoxy-3′,5′-dinitro substitution has an even greater effect, producing a 23-fold acceleration in benzene at 51°. This is rather a large increase in rate for the radical reaction and suggests that this peroxide decomposes at least partly by a non-radical mechanism even in benzene. 4-Methoxy-3′,5′-dinitrobenzoyl peroxide decomposes in benzene without initiating the radical polymerization of styrene, although this might be due to the inhibitory effect of the dinitroaromatic compounds present. In nitrobenzene the 4-methoxy-3′,5′-dinitrobenzoyl peroxide decomposition at 51° is 94 times as fast as it is in benzene and about 2000 times as fast as the decomposition of benzoyl peroxide in benzene. Furthermore, 1,3,5-trinitrobenzene, a radical chain inhibitor, actually accelerates the reaction.

Acid Catalysis.—Figure 1 and Table II show the acceleration of the decomposition of 4-methoxy-3′,5′-dinitrobenzoyl peroxide by acids in benzene. The Brønsted plot of the catalysis in benzene (Fig. 1) is roughly linear with the expected exception of picric acid. Picrate ions (or ion pairs) are at a disadvantage relative to the un-ionized molecule because the latter should be more stabilized by π-complex formation with aromatic solvent molecules. Picric acid also has been observed to deviate from the Brønsted plot in the rearrangement of N-bromoacetanilide in benzene[8] and in the racemization of menthone in chlorobenzene.[9] In all three examples picric acid is less effective as a catalyst than would be predicted from its acid strength and by more than an order of magnitude. Our motive for including picric acid in the experiments is its well-known action as a radical inhibitor. However, we do not believe that the acid-

catalyzed reaction is a radical one or that the picric acid anomaly is explicable as a compensating shortening of radical chains.

Acetic acid also has been studied as a catalyst for the decomposition of 4-methoxy-3′,5′-dinitrobenzoyl peroxide in nitrobenzene, where it is found to be much more effective than in benzene. Apparently the degree of charge separation in the transition state for the acid-catalyzed reaction is even greater than it is for the uncatalyzed polar reaction. 1,3,5-Trinitrobenzene (0.17 molar) also accelerates the decomposition in nitrobenzene, probably by π-complex formation, a phenomenon in some ways analogous to catalysis by proton donors. Since the acceleration by trinitrobenzene was so large (more than a third of that produced by the same concentration of acetic acid), it is likely that the minor catalysis by picric acid in benzene is partly due to π-complexing rather than to the acidity of the picric acid. Trinitrobenzene inhibits the decomposition of benzoyl peroxide[7] and accelerates the decomposition of phenylacetyl peroxide.[10] The decomposition of phenylacetyl peroxide is also subject to catalysis by carboxylic acids while the decomposition of benzoyl peroxide is not.

Even though the available data are for different temperatures, it is of interest to compare the slopes of the Brønsted relationships for various peroxide decompositions. Sensitivity to acid catalysis seems to be in the order 4-methoxy-4′-nitrobenzoyl peroxide > phenylacetyl peroxide > 4-methoxy-3′,5′-dinitrobenzoyl peroxide. The first and third of these are of closely analogous structure, and it may be significant that the peroxide derived from the stronger nitro-substituted acid is the less sensitive to acid catalysis.[11]

The Products of the Decomposition of 4-Methoxy-3′,5′-dinitrobenzoyl Peroxide.—The products of the decomposition of 4-methoxy-3′,5′-dinitrobenzoyl peroxide in various solvents are reported in Table III as per cent. of the acyloxy groups surviving in the form of free acid or ester. As in the case of 4-methoxy-4′-nitrobenzoyl peroxide, there is less conservation of anisoyloxy groups in nitrobenzene than in benzene, but the yields of both anisic and dinitrobenzoic acids and esters are lower. The low recovery of the dinitrobenzoyloxy part of the peroxide may be due to the instability of the carboxy-inversion product.

The carboxy inversion product III could not be purified but is undoubtedly present in the reaction

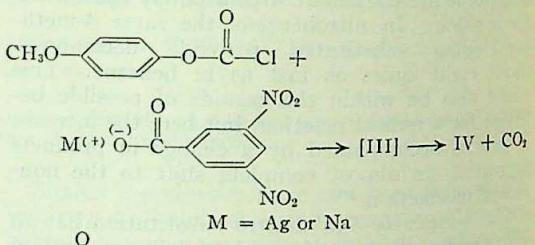
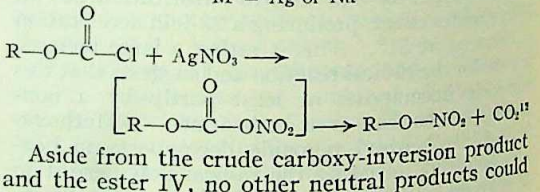
[a] Amount of 4-methoxyphenyl 3,5-dinitrobenzoate actually isolated. The other ester yields are yields of the acid after saponification of the neutral fraction.

mixtures from the polar solvents as is shown by the evolution of carbon dioxide and the formation of IV on recrystallization and by the formation of ethyl 3,5-dinitrobenzoate on treatment of the crude product with ethanol. The elimination of carbon dioxide also takes place in the attempted synthesis of III from anisyl chloroformate and salts of the dinitrobenzoic acid. An analogous reaction of chloroformate esters with silver nitrate gives similar results.[12]



M = Ag or Na



Aside from the crude carboxy-inversion product and the ester IV, no other neutral products could be isolated from the decomposition mixture.

Experimental

Preparation of 4-Methoxy-3′,5′-dinitrobenzoyl Peroxide.—To a freshly prepared solution of one gram of sodium in 40 ml. of absolute ethanol cooled to −20° is added dropwise, with stirring, a solution of 10 g. of anisoyl peroxide in 100 cc. of cold chloroform. After ten minutes of continued stirring and cooling in the Dry Ice–acetone bath, that bath is replaced with an ice-bath and the stirring continued for 20 minutes. The sodium peranisate is then extracted with two 60-ml. portions of cold water and the extract washed with 30 ml. of cold chloroform.

The aqueous peranisate solution is nearly neutralized with solid carbon dioxide pellets, and a concentrated solution of 7.6 g. of 3,5-dinitrobenzoyl chloride in dry acetone is added dropwise with stirring at 0°. Stirring is continued for 1 hr. The resulting precipitate is removed by filtration, washed with 10 ml. of 5% $NaHCO_3$ solution, dissolved in chloroform and filtered. After methanol is added to the chloroform solution, it is cooled in ice. The peroxide is obtained as white flaky crystals, wt. 4 g. after two recrystallizations, m.p. 97° with decomposition.

Anal. Peroxide assay, 96–97%. Calcd. for $C_{15}H_{10}O_9N_2$: C, 49.73; H, 2.78; N, 7.73. Found: C, 50.34; H, 2.94; N, 7.91.

Kinetics.—Solutions of the peroxide were degassed, sealed in ampules and placed in a constant temperature bath. The decomposition was stopped by cooling the ampules in Dry Ice–acetone, and aliquots were analyzed by the method of Nozaki[13] using a "dead-stop" end-point.[14] It was found necessary to use carbonated water in order to get good results (±0.2%) with thiosulfate from 0.001 to 0.005 *N*.

Product Analysis.—With the exception of anisyl 3,5-dinitrobenzoate and the crude carboxy inversion product, no neutral products were formed in sufficient quantity for isolation, although various chromatographic adsorbents were tried. The acid mixtures were removed by extraction with sodium bicarbonate and analyzed for anisic and 3,5-dinitrobenzoic acid by means of infrared bands at 1612 and 1350 cm.$^{-1}$. Control analyses indicate that the results are accurate to within 9% for the 3,5-dinitrobenzoic acid and 8% for the anisic acid. The mixture of acids is not readily separated by chromatography. Esters were estimated by saponification of the neutral fraction followed by infrared analysis of the resulting mixture of acids. Anisyl 3,5-dinitrobenzoate was identified by its melting point, mixed melting point and infrared spectrum.

The Carboxy-inversion Product III.—The neutral fraction of the decomposition products from the reaction in nitrobenzene gave a small amount of ethyl 3,5-dinitrobenzoate on treatment with ethanol, presumably because of the presence of III. The ester IV was isolated by crystallization of the decomposition products from the reaction in acetone and in benzene–picric acid, with the carboxy-inversion product as a likely precursor. The decomposition products from the reaction in thionyl chloride contained a substance of variable melting point (137–139 for one sample, 139–149 for another), evidently III in crude form. This crude product has an anhydride band at 1830 cm.$^{-1}$, absent in the spectrum of the ester IV. All attempts at recrystallizing the crude product gave only the ester IV. Warming the crude III in methanol evolved 70% of the theoretical amount of carbon dioxide; saponification gave 94% of the theoretical amount of *p*-methoxyphenol. Attempts at synthesizing III from anisyl chloroformate and the sodium or silver salt of 3,5-dinitrobenzoic acid also gave the ester IV.

Phosphorus(V) Acid Esters of Oximes

BY J. FORREST ALLEN[1]

RECEIVED JANUARY 12, 1957

Alkyl esters of trivalent phosphorus acids react with α-halonitro compounds to form alkyl halide and oxime esters of the corresponding pentavalent phosphorus acids.

The similarity in the chemical behavior of the nitro and carbonyl groups in certain reactions suggested that α-halonitroparaffins should react with esters of trivalent phosphorus acids to form products which are analogous to the vinyl esters of pentavalent phosphorus acids which have recently been reported from this Laboratory[2] and by several other groups. The reaction of triethyl phosphite with several representative halonitroparaffins has been studied and the reaction shown to proceed according to the equation

$$RR'XCNO_2 + 2(R''O)_3P \longrightarrow RR'C{=}NOP(O)(OR'')_2 + (R''O)_3PO + R''X$$

I

Ia, R = R′ = Cl; R″ = Et
Ib, R = R′ = Me; R″ = Et

Trimethyl phosphite and diethyl phenylphosphonite react in an analogous fashion, but triphenyl phosphite appears to react by a different mechanism. The ease with which the reaction takes place increases with the number of halogen atoms on the α-carbon atom and bromine compounds are more active than chlorine compounds. 1-Chloro-1-nitroethane and triethyl phosphite did not react at 50°, but 1,1-dichloro-1-nitroethane and triethyl phosphite reacted rapidly at 25°, and trichloronitromethane reacted violently with the phosphite at −40° producing smoke and flame unless carefully controlled. 2-Bromo-2-nitropropane reacted rapidly with the phosphite at 50°.

Arbuzov and co-workers[3] reported the reaction of triethyl phosphite with α-bromonitro compounds but were able to identify only triethyl phosphate and ethyl bromide. These investigators observed a two-stage reaction, the first occurring at or below ordinary temperatures and the second at about 90–100°. They found that nitromethane did not react with triethyl phosphite, indicating that the halogen atom plays an important role in the oxidation of the phosphite to the phosphate. The work reported in this paper indicates that the second reaction observed by the Russian workers was probably the Beckmann rearrangement of the primary reaction product I as reported recently by Kenner, Todd and Webb.[4] Kamai[5] treated trichloronitromethane with triethyl phosphite and tributyl phosphite and reported the corresponding dialkyl phosphorochloridates as the only identifiable products. The author has found that the reaction of two moles of triethyl phosphite with one mole of trichloronitromethane converts about 3 to 11% of the phosphite to the phosphorochloridate, about 50% to the phosphate and the remainder to Ia and other products. Ia has been obtained in yields of 32 to 63%. When

other halonitro compounds were treated with triethyl phosphite, the triethyl phosphate fraction was contaminated with a small amount of halogen compound, but this could not be identified as the phosphorochloridate. Since Ford-Moore and co-workers[6] have reported the preparation of dialkyl phosphorochloridates from phosgene and trialkyl phosphites, it seemed possible that Ia, a phosgene derivative, might also convert phosphite to phosphorochloridate. However, when equimolar quantities of triethyl phosphite and Ia were heated at 75–150°, ethyl chloride (100%) was evolved slowly but the reaction mixture did not contain diethyl phosphorochloridate.

The assignment of structure I to the reaction products is based upon the following evidence: (a) elemental analysis and physical properties, including strong infrared absorption at 6.1–6.3 μ, characteristic of the carbon–nitrogen double bond; (b) the independent synthesis of Ib from acetone oxime, aqueous sodium hydroxide and diethyl phosphorochloridate; and (c) the hydrolysis of Ib to acetone.

It also should be noted that structure I is analogous to the vinyl phosphate structure, and it seems likely that both reactions proceed by the same mechanism. However, the reaction of the nitro compounds is complicated by the oxidation–reduction, and it is not apparent whether the nitro compound is first reduced to the nitroso compound which reacts with additional phosphite or whether the nitro compound forms an intermediate with the phosphite which is then reduced by additional phosphite. That the first route is possible was shown by the synthesis of Ib from 2-chloro-2-nitrosopropane and triethyl phosphite. But since the over-all reaction is usually very rapid, the initial stage must also be rapid, and it might be expected that the addition of phosphite to a large excess of nitro compound would result in the formation of nitroso compound which would be evident from its characteristic intense blue color. In no instance has more than a trace of color appeared, and in most reactions no color has been observed.

The presence of a hydrogen atom on the alpha carbon atom of the oxime moiety of I (R or R′) lends instability to the molecule and no product of this type has been distilled. When heated to about 100° these products undergo a vigorous exothermic reaction as reported by Arbuzov and co-workers.[3] The crude product of the reaction between trimethyl phosphite and 1-bromo-1-nitropropane at 30–40° showed strong infrared absorption at 6.3 μ which is assumed to indicate that the product had structure I (R = H, R′ = Et, R″ = Me). The product of the reaction between triethyl phosphite and 2-bromo-2-nitropropane, Ib, when heated rapidly did not give the second-stage reaction below 175°. Although it is assumed that the second-stage reaction is a Beckmann rearrangement of the oxime ester, it is obvious that the reaction is accompanied by decomposition and most of the product is converted to a tar from which no pure product has been isolated.

Experimental

Preparation of Diethyl Isopropylideneamino Phosphate (Ib) (a) From 2-Bromo-2-nitropropane and Triethyl Phosphite.—One mole (166 g.) of triethyl phosphite was added dropwise with cooling and stirring to 0.5 mole (84.5 g.) of 2-bromo-2-nitropropane at 55–60°. The mixture was then heated to 75–85° for 30 minutes and the ethyl bromide (94%) removed at reduced pressure. Distillation of the reaction mixture through a 10-inch Vigreux column gave (a) 98 g., b.p. 57–85.5° (0.4 mm.), which is 108% of theory for triethyl phosphate, and (b) 66.5 g. (64%) of Ib, b.p. 101–110° (0.2 mm.). Redistillation gave an analytical sample, b.p. 95–98.5° (0.2 mm.), n^{25}D 1.4359, and d^{25}_4 1.0949.

Anal. Calcd. for $C_7H_{16}NO_4P$: P, 14.8. Found: P, 15.2.

(b) From 2-Chloro-2-nitrosopropane and Triethyl Phosphite.—A solution of 0.5 mole (53.8 g.) of crude 2-chloro-2-nitrosopropane in 200 ml. of carbon tetrachloride was cooled to 0°, and 0.5 mole (83 g.) of triethyl phosphite was added with stirring. When addition of the phosphite was complete, the temperature was raised to 75°, and 21 g. of ethyl chloride containing a small amount of carbon tetrachloride was collected in a cold trap. The remainder of the volatile matter was removed *in vacuo* and the product fractionated to yield 53 g. (51%) of oxime ester, b.p. 88–96° (0.1 mm.), n^{25}D 1.4360.

Anal. Calcd. for $C_7H_{16}NO_4P$: N, 6.7; P, 14.8. Found: N, 6.5; P, 14.9.

The nitroso compound used in this preparation was obtained by adding 1 mole of chlorine to 1 mole each of acetone oxime and sodium hydroxide dissolved in 400 ml. of water. The product was separated from the aqueous solution, dried with calcium sulfate and used without further purification.

(c) From Acetone Oxime and Diethyl Phosphorochloridate.—Two-tenths mole of diethyl phosphorochloridate was added gradually at 15–17° to 0.2 mole of acetone oxime and 0.3 mole of sodium hydroxide dissolved in 100 ml. of water. The mixture was shaken for 30 minutes, the 2 layers separated, and the aqueous layer extracted with ether. After drying the combined organic layers, the ether was evaporated and the product distilled to give 14 g. (33.5%) of oxime ester, b.p. 95–98° (0.2 mm.), n^{25}D 1.4358, and d^{25}_4 1.0940. Infrared spectrograms of this product and the product of method (a) were essentially identical, both absorbing intensely at 6.1 μ.

Anal. Calcd. for $C_7H_{16}NO_4P$: P, 14.8. Found: P, 15.0.

Preparation of Diethyl (1-Chloroethylidene)-amino Phosphate.—With stirring and mild cooling 0.5 mole (83 g.) of triethyl phosphite was added gradually to 0.25 mole (36 g.) of 1,1-dichloro-1-nitroethane at 25–40°. Stirring was continued without cooling, and the temperature rose to 90° where it was held by mild cooling until the reaction began to subside (about 5 minutes). The temperature was then raised to 100° for 15 minutes to complete the reaction. The yield of ethyl chloride was 12 g. (74%). Fractionation of the product gave 42 g. (73%) of oxime ester, b.p. 103° (0.3 mm.), n^{25}D 1.4408, and with intense infrared absorption at 6.1 μ.

Anal. Calcd. for $C_6H_{13}ClNO_4P$: Cl, 15.5; N, 6.1. Found: Cl, 15.2; N, 6.1.

Preparation of Diethyl (Dichloromethylene)-amino Phosphate.—One mole (166 g.) of triethyl phosphite was added gradually at 25° to 0.5 mole (82 g.) of chloropicrin dissolved in 300 ml. of carbon tetrachloride. The reaction was vigorous and appeared to be complete at the end of the mixing period. After removal of ethyl chloride and carbon tetrachloride by distillation, the resulting mixture was separated by fractionation (12 inch column Hastelloy B Heli-Pak) into 4 major fractions: (A) 14.3 g., b.p. 45–50° (0.7–0.3 mm.); (B) 46.4 g., b.p. 45–58° (0.3–0.2 mm.); (C) 26.0 g., b.p. 62.55° (1.4–1 mm.); and (D) 78.5 g. (63%) oxime ester, b.p. 80–85° (0.2 mm.), n^{25}D 1.4518.

Anal. Calcd. for $C_8H_{16}Cl_2NO_4P$: Cl, 28.4; N, 5.6; P, 12.4. Found: Cl, 28.1; N, 5.4; P, 12.4.

Fractions A and B contained 6.6 and 0.54% chlorine, respectively, and if it is assumed that all the chlorine was in the form of diethyl phosphorochloridate, the yield of the latter was 5.8 g. which is equivalent to 3.4% of the phos-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

phite used in the reaction. The chlorine-containing compound was identified as diethyl phosphorochloridate as follows. Thirteen grams of fraction A, containing 0.86 g. of chlorine, was treated with 4.5 g. of aniline (2 moles) and the mixture heated to 80° for 10 minutes. After adding 18 ml. of water, the solution was cooled to 5° and seeded with diethyl N-phenylphosphoroamidate. The resulting solid after recrystallization from ethanol–water had m.p. 95.5–96° which was not depressed by mixing with an authentic sample of diethyl N-phenylphosphoroamidate (lit.[7] m.p. 95–96°).

When this preparation was repeated without solvent at −40°, the reaction was very vigorous and smoke and flame were occasionally observed when a drop of phosphite entered the chloropicrin. The yield of oxime ester was 32% and about 11% of the phosphite was converted to phosphorochloridate.

Preparation of Ethyl Isopropylideneamino Phenylphosphonate.—Sixty-five grams (0.31 mole) of diethyl phenylphosphonite was added dropwise with stirring and cooling at 15–28° to 26 g. (0.155 mole) of 2-bromo-2-nitropropane. When addition was complete, stirring was continued at 30° for 1 hour. Distillation gave 14.5 g. (86%) of ethyl bromide and fractionation of the remainder gave 28.5 g. (82%) of diethyl phenylphosphonate, b.p. 100° (0.5 mm.), and $n^{35}D$ 1.4897 (lit.[8] b.p. 104–105° (0.5 mm.), $n^{25}D$ 1.4935), and 10 g. (27%) of oxime ester, b.p. 140° (0.5 mm.), and $n^{35}D$ 1.5082. There was a large tarry residue.

Anal. Calcd. for $C_{11}H_{16}NO_3P$: N, 5.8; P, 12.8. Found: N, 5.6; P, 12.5.

Preparation of Diethyl Benzylideneamino Phosphate.—To a mixture of 19.6 g. of benzaldehyde oxime (0.16 mole) and 12.6 g. of pyridine (0.16 mole) was gradually added at 0° 27.6 g. of diethyl phosphorochloridate (0.16 mole). The mixture was allowed to warm to room temperature where it was stirred for 1 hr. and then heated at 50–60° for 1 hr. After cooling, ether was added to the mixture and pyridine hydrochloride removed by filtration. Removal of volatile matter by heating *in vacuo* gave 36.5 g. (88%) of crude oxime ester which decomposed when distillation was attempted at 1 mm. pressure.

Anal. Calcd. for $C_{11}H_{16}NO_4P$: P, 12.1. Found: P, 11.9.

Pyrolysis of Diethyl Isopropylideneamino Phosphate.—Twenty grams of oxime ester was placed in a 50-ml. flask equipped with a thermometer dipping into the liquid and a water condenser. When heated to 175°, a vigorous exothermic reaction began which was controlled with difficulty by immersing the flask in a Dry Ice-bath. After the reaction subsided, heating was continued at 180–185° for 2 hr. Distillation at 0.6 mm. gave only 3 g., b.p. 53–55°, $n^{35}D$ 1.4060, the remainder being a viscous tar. Not only is the boiling point of the distillate considerably lower than would be expected for the Beckmann rearrangement product, but the phosphorus and nitrogen contents were low (12.4 and 4.45%, respectively).

Hydrolysis of Diethyl Isopropylideneamino Phosphate.—Ten grams of the oxime ester and 50 ml. of 5% hydrochloric acid were placed in a flask equipped with a distillation condenser. When heated to gentle boiling, a few drops of blue liquid distilled followed by 3.5 ml. of colorless distillate. This was identified as acetone by conversion to the 2,4-dinitrophenylhydrazone, m.p. and mixed m.p. 126° (lit.[9] m.p. 126°).

The Addition of Chloro- and Ethoxysilanes to Vinyl and Allyl Monomers[1,2]

BY LEON GOODMAN, ROBERT M. SILVERSTEIN AND ALLEN BENITEZ

RECEIVED NOVEMBER 6, 1956

The platinum-catalyzed addition of some chloro- and ethoxysilanes to a variety of vinyl and allyl monomers has been accomplished in good yield under mild conditions. Nuclear magnetic resonance spectra make it clear that the addition of methyldichlorosilane to vinyl acetate gives the linear compound $CH_3SiCl_2CH_2CH_2OCOCH_3$ while addition to methyl acrylate gives the branched compound $CH_3SiCl_2CH(CH_3)COOCH_3$. The latter compound represents the first reported example of a reversed addition orientation in additions of the elements of the Si–H bond to carbon–carbon double bonds.

The addition of the elements of the Si–H bond to a carbon–carbon double bond was first reported in 1947[3] and has been the object of much study since that time. Peroxides and ultraviolet light were used as catalysts in the original study,[3] and since that report the reaction has been carried out by employing high temperatures and pressures without catalyst[4] and by using platinum and palladium as catalysts.[5]

We have utilized this platinum-catalyzed reaction for the synthesis of silicon monomers which contain functional groups. The additions of trichlorosilane, methyldichlorosilane and methyldiethoxysilane to a variety of vinyl and allyl monomers were accomplished using mild conditions. These reactions are listed in Table I.

A 5% platinum-on-carbon catalyst was used in all these additions. It was demonstrated to be necessary in the trichlorosilane additions to vinyl acetate and to methyl acrylate, and we presume it to be necessary in all the reactions listed in Table I. The catalyst was used in the amount of about 0.25–0.50% by weight of the silane employed and, in most cases, that same weight of Ionol (2,6-di-*t*-butyl-4-methylphenol) was used as a polymerization inhibitor for the olefin.[6]

Two techniques were used in carrying out these reactions—use of a stainless steel sealed bomb

(5) G. H. Wagner and C. O. Strother (to Union Carbide and Carbon), U. S. 2,632,013 (March 17, 1953).

(6) The effectiveness of polymerization inhibition is shown by an experiment in which methyl acrylate, Ionol and a large excess of trichlorosilane were heated in a steel bomb at 150° for 20 hr. No polymerization of the acrylate was detectable, and there was no evidence of a silane–acrylate addition product.

[a] Trichlorosilane and dimethyl itaconate gave a 40% conversion to 1:1 adduct, b.p. 106–107° (4 mm.), hydrolyzable chlorine, calcd. 36.2, found 35.5. [b] See Experimental. [c] Conversion based on total olefin used, some of which was recovered. Conversions based on wider boiling ranges than in next column. [d] Boiling ranges of analytical samples. [e] Unstable compounds which darkened rapidly and were difficult to handle. [f] Lower boiling materials were present in additions to acrylates. These appear to be isomeric with desired adducts and require further investigation. [g] Chlorine determined by Volhard method after hydrolysis in a water–isopropyl alcohol mixture.

which enabled higher temperatures to be attained, and simple refluxing of the silane while the olefin was slowly added. The sealed bomb technique was necessary in the additions of the low boiling (32°) trichlorosilane to acrylonitrile and to the α,β-unsaturated esters. In these additions a large excess of the silane was necessary in order to obtain good conversions to the 1:1 adduct. The technique of slowly adding the olefin to the refluxing mixture of silane and catalyst allowed good conversion to the 1:1 adduct to be realized when equimolar amounts of the silane and olefin were employed and was used in the additions of methyldichlorosilane[7] (b.p. 42°) and methyldiethoxysilane (b.p. 98°). In the chlorosilane additions to acrylonitrile and the acrylate esters, large residues remained after the distillation of the 1:1 adducts. These contained silicon–chlorine bonds, and it is felt that they are best explained as telomerization products wherein the ratio of olefin to silane is greater than 1. These residues were especially large in the acrylonitrile reactions and were much more prominent in the additions of methyldiethoxysilane than in those of the chlorosilanes.

Methyldiethoxysilane added in excellent yield to the two vinyl ethers, systems where telomerization is not a competing reaction. These olefins gave poor, or no, yields in the reactions with the chlorosilanes where traces of hydrogen chloride, which were present under our conditions, polymerized the ethers. It is interesting to note that Prober has obtained the same products by a base-catalyzed addition of alcohols to vinylmethyldiethoxysilane.[8] Addition of methyldiethoxysilane to acrolein diacetate gave a good conversion to 1:1 adduct. Under the same conditions, the attempted addition of methyldiethoxysilane or methyldichlorosilane to acrolein gave an intractable mixture as did the reaction between methyldichlorosilane and acrolein diacetate.

The additions of the elements of the Si–H bond to olefins, which were catalyzed by peroxides and ultraviolet light, have been regarded as typical free-radical reactions[3] and certainly obey the criteria of such a mechanism. There has been no speculation regarding the mechanism involved in the platinum-catalyzed addition. That addition has been shown to involve the addition of the silicon-containing moiety to the terminal carbon of the vinyl compound in several cases,[9,10] and no example of a reversed addition orientation has been noted. It is clear that the addition of a silane $RSiX_2H$ to an olefin $CH_2 = CHZ$ can lead to two possible products: $RSiX_2CH_2CH_2Z$ (A) or $RSiX_2CH(CH_3)Z$ (B).

Hydrolysis studies of the methyldichlorosilane and methyldiethoxysilane adducts indicated that two classes of compounds had been formed by these reactions. The adducts from vinyl acetate, the vinyl ethers and all of the allyl monomers yielded oils on hydrolysis that did not change after being heated at 200° *in vacuo*. The adducts from acrylonitrile and the acrylate esters gave oils on hydrolysis that became resinous solids after heating *in vacuo* at temperatures up to 200°. Methyl propionate and methoxyethyl propionate were isolated as decomposition products from the hydrolyzate of the methyldichlorosilane adducts with methyl acrylate and methoxyethyl acrylate, respectively. It is known that the ester $(CH_3)_3SiCH_2COOR$ yields CH_3COOR readily on neutral hydrolysis as a result of Si–C bond cleavage[11] while $(CH_3)_3SiCH_2CH_2$-

(7) The addition of methyldichlorosilane to acrylonitrile required the use of the bomb in order to achieve even low conversions to the 1:1 adduct.

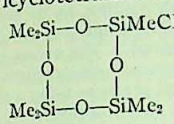
COOR gives $(CH_3)_3SiCH_2CH_2CCOH$ under severe conditions of acidic or basic hydrolysis.[12] The isolation of the above-noted decomposition products was the first hint that some of our adducts had the reversed addition orientation of structure B.

The cohydrolysis of dimethyldichlorosilane and the methyldichlorosilane–vinyl acetate adduct, using a 3:1 mole ratio of the silanes, respectively, gave a reasonable yield (*ca.* 30%) of the functionally substituted cyclic siloxane, β-acetoxyethylheptamethylcyclotetrasiloxane (III).



III

The isolation of III in a reasonable yield shows that this cohydrolysis method offers a convenient route to such unsymmetrical cyclic siloxanes.

Attempts were made to add trimethylsilane to ethyl acrylate using platinum catalysis in an effort to prepare a compound which could be compared with a known compound, $(CH_3)_3SiCH_2CH_2CO-OC_2H_5$, in physical constants and chemical behavior. Such a structure proof is based on the assumption that trimethylsilane and methyldichlorosilane would give the same addition orientation. The only product isolated from the reaction was a low yield of a high-boiling liquid which seems to contain about three acrylate ester units for each trimethylsilane unit. Attempts to add trimethylsilane to vinyl acetate gave no evidence of addition. It should be noted that the platinum-catalyzed addition of methyldichlorosilane to vinyl acetate gives high yields of 1:1 adduct under very mild conditions.

An unequivocal answer to the structure problem was available from a study of the proton nuclear magnetic resonance spectra of the silane adducts. The methyldichlorosilane adducts of vinyl acetate and methyl acrylate (these are isomeric compounds) were chosen as representative examples of compounds which give stable hydrolyzates and unstable hydrolyzates, respectively. Simply on the basis of the proton spin–spin interactions, it is clear that the structures of the two adducts are as shown in Fig. 1. The two triplet peaks (a) and (c) (of equal area) of the vinyl acetate adduct are assignable to the $-CH_2CH_2-$ structure and the doublet, quartet groupings (g) and (f) (with the areas in the ratio 3:1) of the methyl acrylate adduct clearly shows the presence of the $-\overset{CH_3}{\overset{|}{C}}H-$ structure. The fact that (h) lies at a higher field than (a) and that (b) lies at a higher field than (f) conforms to the general pattern of NMR spectra wherein the more highly protonated of two otherwise similar groups shows resonance at a higher field. The NMR spectrum of the methyldichlorosilane–allyl acetate adduct shows that it has the linear structure with three $-CH_2-$ groups. The NMR spectrum of the methyldiethoxysilane-allylidene diacetate adduct shows that it too has the linear structure. This indicates that a route is available to the stable isomers in the additions

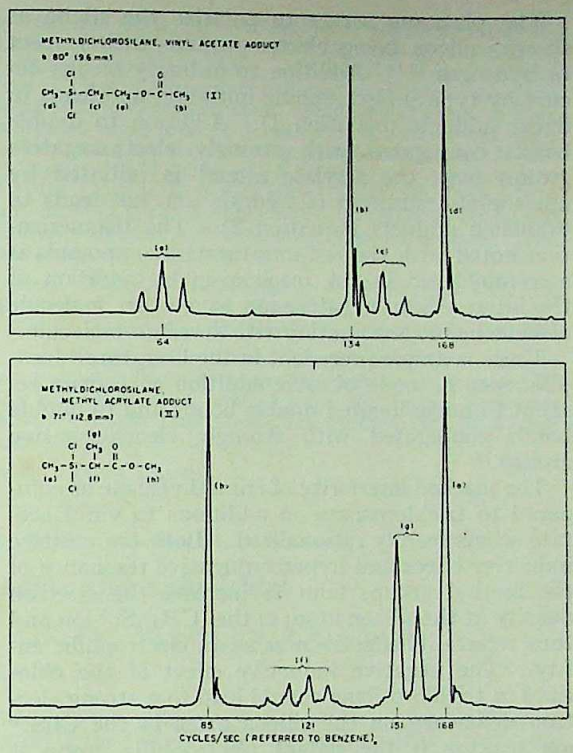


Fig. 1.—Proton nuclear magnetic resonance spectra of methyldichlorosilane adducts. Samples in 5 mm. tubes and Varian Associates High Resolution Spectrometer (V-4300B) at 30 mc. and 7050 gauss.

of Si–H-containing compounds to acrolein *via* acrolein diacetate or acrolein acetals. The methyldichlorosilane–methyl acrylate adduct (and presumably the acrylonitrile adduct and other adducts to α,β-unsaturated carbonyl compounds) then represents the first example of a reversed addition orientation in Si–H additions.

The fact that these platinum-catalyzed silane additions proceed well in the presence of a polymerization inhibitor is an indication, at least, that the reaction is not a typical free-radical reaction. We think that the difference of addition orientation in the two classes of olefins can be accommodated by the ionic mechanism

The platinum serves to polarize the silane as shown, silicon being electro-positive with respect to hydrogen.[13,14] Addition to ordinary olefins occurs by typical electrophilic initiation and leads to linear adducts (equation 1). Addition to double bonds conjugated with strongly electronegative groups (*e.g.*, the acrylate esters) is initiated by nucleophilic addition of hydride ion and leads to branched adducts (equation 2). The telomerization noted with the α,β-unsaturated compounds is accommodated in the mechanism by addition of the intermediate negative ion to another molecule of olefin before terminating with the silane molecule.

There is ample precedent in the literature[15] for a difference in mode of ionic addition of a given reagent to unconjugated double bonds and to double bonds conjugated with strongly electronegative groups.[16]

The marked inferiority of trimethylsilane as compared to trichlorosilane in additions to vinyl acetate seems readily rationalized. Both the positive inductive effect and hyperconjugative resonance of the methyl groups tend to increase the electron density at the silicon atom in the $(CH_3)_3Si^+$ ion and thus reduce its effectiveness as an electrophilic entity. The negative inductive effect of the chlorines in trichlorosilane should lead to a strong electron deficiency on the silicon atom in the Cl_3Si^+ ion making it the potent electrophilic group it seems to be. The NMR measurements show that the silane hydrogen peak in trimethylsilane occurs at 110 ± 5 cycles/sec. higher than in trichlorosilane while the peak in methyldichlorosilane occurs at about 26 cycles/sec. higher than in trichlorosilane. These measurements emphasize the inductive effect of chlorine and indicate that, at least in the ground state, the silane hydrogen in trimethylsilane has a higher electron density than that in trichlorosilane and would be expected to donate a hydride hydrogen better than trichlorosilane. In view of these data it is difficult to understand why trimethylsilane seems to be inferior to trichlorosilane in additions to the acrylate esters. We recognize that our postulated (and admittedly speculative) mechanism may be a gross oversimplification of the picture which neglects the adsorption, desorption interactions of the catalyst and reactants. However we do not expect to do further work on this problem, and we wish to report our work to date.

Acknowledgments.—We gratefully acknowledge the aid of Dr. James N. Shoolery and Mr. Robert C. Jones of Varian Associates in running and interpreting the NMR spectra that are reported. We also express our thanks to Mr. Oliver D. Smith and the members of the analytical staff of the Stanford Research Institute for the analytical data. The Divisional Research Committee of Stanford Research Institute furnished funds to complete certain phases of this work.

(15) L. S. Luskin, G. E. Gantert and W. E. Craig, THIS JOURNAL, **78**, 4965 (1956), have recently pointed out such a difference in the additions of isothiocyanic acid.

(16) A recent report by G. J. M. van der Kerk, J. G. A. Luijten and J. G. Noltes, *Chem. and Ind.*, 352 (1956), is of interest here. These authors added $(C_6H_5)_2SnH$ and $(n\text{-}C_4H_9)_2SnH$ to acrylonitrile and methyl acrylate in an uncatalyzed reaction run at low temperatures (80°). Their adducts had the linear structures $R_3SnCH_2CH_2X$ and the authors were of the opinion that an ionic mechanism was involved. The systems studied seem to be quite analogous to ours, and it would be interesting to observe what effect, if any, platinum catalysis would have on addition orientation in the tin hydride additions.

Experimental[17]

Silane–Olefin Adducts. Method I.—A mixture of the olefin (*ca.* 0.10 mole), the chlorosilane (*ca.* 0.30 mole), Ionol (0.25 g.) and 5% Pt-on-carbon (Baker and Co., Newark, N. J.) (0.25 g.) was sealed in a 100-ml. stainless steel bomb and heated, with rocking, at the proper temperature for the desired time. The bomb was cooled and opened, and the contents were filtered. The excess silane was removed by distillation at atmospheric pressure, and the residue was distilled at reduced pressure using a simple Claisen flask. Analytical samples were obtained by redistillation using a 50 × 1 cm. column packed with glass helices.

When trimethylsilane was used, it was condensed into the bomb using a Dry Ice–acetone bath. Excess trimethylsilane was distilled from the bomb and collected at the end of the reaction. When vinyl acetate was used as the olefin with trimethylsilane, there was no distillation residue after heating at 60° and 35 mm., indicating that no addition had occurred. About 25% of the vinyl acetate was isolated from the distillation trap, and more was present in the trimethylsilane which was distilled from the bomb. When ethyl acrylate was used as the olefin, a brown liquid (4.2 g.) was the residue from 10 g. of ethyl acrylate and 23 g. of trimethylsilane heated at 75° for 30 hr. This residue could not be distilled at 130° and 1 mm.

Anal. Calcd. for $Me_3Si(CH_2CHCOOEt)_3H$: Si, 7.5. Found: Si, 7.1.

About 3.5 g. of ethyl acrylate was recovered from the distillation trap.

Method II.—A mixture of chloro- or ethoxysilane (0.10 mole) and 5% Pt-on-carbon (0.25 g.) was stirred magnetically under reflux, while a solution of Ionol (0.25 g.) in the olefin (0.10 mole) was added dropwise (3–6 hr. was required for the additions). After a further 18 hr. of heating (the temperature gradually rose from the reflux temperature of the silane to that of the adduct), the mixture was filtered, and the filtrate was distilled as in method I.

Hydrolysis Studies.—The adducts from methyldichlorosilane were added slowly to an aqueous solution of sodium sulfate according to the directions of Wright.[18] The siloxanes formed were extracted with ether and, after drying the extract over magnesium sulfate, the ether was evaporated and the residue heated under vacuum to remove volatile materials. The adducts from methyldiethoxysilane were hydrolyzed using 10% hydrochloric acid, and the hydrolyzates were recovered as above with the additional step of a sodium bicarbonate wash of the ether extract to remove acid.

The silane adducts with vinyl acetate, allyl acetate, allyl ethyl ether and the vinyl ethers yielded hydrolyzates that could be heated at 200° and 1 mm. for several hours without change.

The hydrolyzate of the methyldichlorosilane–acrylonitrile adduct was an oil which changed to a resinous solid when it was warmed on the steam-bath. No effort was made to collect volatile decomposition products. The hydrolyzate of the methyldichlorosilane–methyl acrylate adduct was an oil which slowly changed to a resinous solid when it was heated to 200° at 1 mm. The liquid condensed in the trap was redistilled using a Claisen flask and a fraction, presumed to be methyl propionate, b.p. 80–81° (lit.[19] 79.9°), was collected.

Anal. Calcd. for $C_4H_8O_2$: C, 54.46; H, 9.15. Found: C, 54.1; H, 9.01.

The hydrolyzate of the methyldichlorosilane–methoxyethyl acrylate adduct similarly yielded a resinous solid when it was heated *in vacuo* at 200°. The liquid condensed in the trap was redistilled using a 50 × 1 cm. packed column and a fraction, b.p. 92–93° (82.5 mm.), was collected. The in-

frared spectrum of this material showed the strong carbonyl band at 1750 cm.$^{-1}$, weak carboxyl carbonyl at 1725 cm.$^{-1}$, the C-O-C absorptions at 1205, 1136, 1090 and 1045 cm.$^{-1}$ and the absence of typical Si–O–Si bands. It appeared to be an impure sample of methoxyethyl propionate contaminated with propionic acid.

Anal. Calcd. for $C_8H_{12}O_3$: C, 54.5; H, 9.16. Found: C, 51.6; H, 8.75; Si < 0.5.

Cohydrolysis of Dimethyldichlorosilane and the Methyldichlorosilane–Vinyl Acetate Adduct.—A mixture of 53.7 g. of methyldichlorosilane (Dow–Corning, pure grade) and 28 g. of the methyldichlorosilane–vinyl acetate adduct (mole ratio 3:1) was added, over a 5-hr. period, to a well-stirred mixture of 250 ml. of water and 250 ml. of ether, maintained at 0–10°. The ether layer was separated and the aqueous phase was extracted with four 50-ml. portions of ether. The total ether solution was dried over magnesium sulfate and the ether was evaporated to leave a residue (49.5 g.). The residue was first distilled from a Claisen flask to give the following fractions: (1) 6.8 g., b.p. 48–57° (7 mm.), n^{20}D 1.3952–1.3970; (2) 2.1 g., b.p. 56–79° (2.5 mm.), n^{20}D 1.4112; (3) 11.3 g., b.p. 79–86° (2.5 mm.), n^{20}D 1.4137–1.4152; (4) 3.6 g., b.p. 86–91° (2.5 mm.), n^{20}D 1.4155–1.4157; (5) 8.2 g., b.p. 91–132° (2.0 mm.), n^{20}D 1.4198–1.4268. A residue of 14.4 g., n^{20}D 1.4291, remained. Fraction (1) was a mixture of hexamethylcyclotrisiloxane and tetramethylcyclotetrasiloxane. Fractions (3) and (4) were redistilled using a 50 × 1 cm. column packed with glass helices and gave the following fractions: (1) b.p. 75–80° (2 mm.), n^{20}D 1.4122; (2) b.p. 80–81.5° (2 mm.), n^{20}D 1.4141; (3) b.p. 81.5–82°, n^{20}D 1.4150; (4), (5) and (6) b.p. 82.0° (2.0 mm.), n^{20}D 1.4153. Fraction V, considered to be β-acetoxyethylheptamethylcyclotetrasiloxane (III), was analyzed.

Anal. Calcd. for $C_{11}H_{23}O_6Si_4$: C, 35.83; H, 7.65; Si, 30.48; mol. wt., 368.69. Found: C, 35.5, 36.1; H, 7.55, 7.86; Si, 30.85; mol. wt. (cryoscopic in benzene), 361, 353.

Nuclear Magnetic Resonance Spectra.—The samples were sealed in 5 mm. tubes and the spectra were measured by the audio side band method using the Varian Associates Model V-4300B High Resolution Spectrometer at 30 mc. and 7050 gauss.

Hydroxybenzeneboronic Acids and Anhydrides

By Henry Gilman, Ludovico Santucci, D. R. Swayampati and R. O. Ranck

Received January 23, 1957

ortho-, *meta-* and *para*-hydroxybenzeneboronic acids and/or anhydrides were prepared by the reaction of tri-*n*-butyl borate with the corresponding organolithium compounds. The properties of the three "isomers" (boronic acid or anhydride), including anhydride formation ability, were found to vary considerably. The preparation of 2-(*m*-bromophenoxy)-tetrahydropyran and the optimum conditions for the halogen–metal interconversion of *m*-bromophenol also are reported.

In the approach to the synthesis of boron-containing azo dyestuffs,[1,2] which have been found to be of interest in the irradiation therapy of brain tumors,[3] it was thought that compounds such as *o*-hydroxybenzeneboronic acid and *m*-hydroxybenzeneboronic acid or their anhydrides would be active enough to couple with various diazonium salts. This coupling could occur either *ortho* or *para* to the hydroxy group, but primarily *para*. Perhaps the *p*-hydroxybenzeneboronic acid or its anhydride would also couple successfully with various diazonium salts. However, the possibility of losing the boronic acid group exists here more so than in the other two cases unless, of course, the coupling tends to go *ortho* to the hydroxy group. The *para* isomer was thus prepared primarily for comparison with the other members of this series.

In addition to the purposes already discussed, these compounds, as such, should also be of interest for testing in brain tumor therapy, since the work of several[3–12] has shown that any boron compound containing some of the boron isotope 10[13] might be useful in irradiation research of this type. In addition, other pharmacological studies indicate that the hydroxyl group should increase the efficacy of such compounds.

The *m*-hydroxybenzeneboronic acid has been prepared previously[1,14,15] and was used for the preparation of azo boronic acids.[1] In these instances, the compound was prepared from *m*-aminobenzeneboronic acid by diazotization followed by hydrolysis.

The preparation of *p*-hydroxybenzeneboronic acid has been attempted in the past[14] but it never has been isolated.

The *o*-hydroxybenzeneboronic acid anhydride has not been reported as yet.

Only one other arylhydroxyboronic acid is mentioned in the literature. This is 3-hydroxy-4-methylbenzeneboronic acid[14] which was prepared from the 3-nitro-4-methylbenzeneboronic acid using catalytic reduction followed by diazotization and hydrolysis.

In the work reported here, two different approaches were tried for the preparation of each of the three isomers and a third approach was attempted for the *ortho* and *para* isomers.

The best of the three approaches involved the halogen–metal interconversion of a bromophenol isomer with *n*-butyllithium using 2 moles of the lithium reagent to 1 mole of the halogen com-

pound followed by reaction with tri-*n*-butyl borate, usually,[16] and subsequent hydrolysis with dilute acid. Isolation of the *meta* and *para* isomers was somewhat difficult because of their water solubility. Each was isolated successfully from an ether solution by concentration which was preceded by a series of extractions to remove a large portion of the *n*-butyl alcohol and boric acid. The *ortho* isomer could have been isolated by a similar procedure, but this was not necessary due to its limited water solubility. Isolation was effected by acidification of an alkaline extract. The yields of the three compounds prepared by this halogen–metal interconversion procedure differed greatly. The *ortho* isomer was obtained in yields as high as 65%; the *meta* isomer in much lower yields of 32%; and the *para* isomer in intermediate yields of 40%.

Another approach which was used is somewhat the same as that which has just been described except that the hydroxy group of the bromophenol isomers was etherified by the use of dihydropyran.[17,18] Both the 2-(*o*-bromophenoxy)-tetrahydropyran[18] and the 2-(*p*-bromophenoxy)-tetrahydropyran[17] have been reported previously, but the 2-(*m*-bromophenoxy)-tetrahydropyran is new and is reported here. The procedure was the same as in the preparation of the *ortho* and *para* isomers.

In each of these cases, the 2-(bromophenoxy)-tetrahydropyranyl isomer was treated with an equimolar amount of *n*-butyllithium followed by reaction with tri-*n*-butyl borate at a low temperature and subsequent hydrolysis. A 55% yield of the *o*-hydroxybenzeneboronic acid anhydride, which was isolated by acidification of an alkaline extract, was obtained. This is quite comparable to that which was obtained when the unprotected *o*-bromophenol was used as the starting material. The main advantage of using the acetal is the smaller *n*-butyllithium requirement in this case, only half as much being necessary as when *o*-bromophenol is used as the starting material.

The attempt to prepare *m*-hydroxybenzeneboronic acid using 2-(*m*-bromophenoxy)-tetrahydropyran as the starting material was unsuccessful. A solid material which defied purification was isolated but never identified.

When the 2-(*p*-bromophenoxy)-tetrahydropyran was treated with *n*-butyllithium and tri-*n*-butyl borate, followed by acid hydrolysis, 2-hydroxy-5-bromobenzeneboronic acid was isolated instead of *p*-hydroxybenzeneboronic acid.[19]

The third approach to the synthesis of *ortho*- and *para*-hydroxybenzeneboronic acid or anhydride involved the reaction of *o*- and *p*-chloromercuriphenol with boron trichloride in chlorobenzene followed by hydrolysis. This work was unsuccessful. Both benzeneboronic acid[20] and *o*-methoxybenzeneboronic acid[21] have been prepared by similar methods. However, the conversion of *o*-chloromercuriphenol and acetoxymercuribenzene to the corresponding boronic acids with tri-*n*-butyl borate, made by Snyder and Weaver,[1] was not successful.

Purification of the *ortho* and *meta* isomers was best accomplished by recrystallization of the crude material from ethylene chloride.[22] Usually two or three recrystallizations were required to get material of the maximum melting point, both compounds crystallizing as the anhydride. The *para* isomer was purified by recrystallization from acetone containing a small amount of water; recrystallization of this purified acid from ethylene chloride seemed to produce a mixture of anhydride and acid.

In the course of the investigation numerous solvents for the recrystallization of the *ortho* and *meta* isomers were investigated. It was found that the *ortho* isomer could be purified successfully from many solvents including benzene, toluene, water, acetone–water and acetone–benzene. It is interesting to note that regardless of the solvent used, the material always separated as the anhydride. In contrast to this, no solvent other than ethylene chloride seemed to be suitable for recrystallization of the *meta* isomer. No extensive solvent study was made on the *para* isomer.

From these results, it is seen that the ease of anhydride formation of the three isomers varies considerably. The anhydride seems to be the stable form of the *ortho* isomer. Exposure of the *o*-hydroxybenzeneboronic acid anhydride to a moist atmosphere for 6 months failed to convert it to the acid.

Although Bean and Johnson[14] reported a possible acid–anhydride mixture for the *meta* isomer recrystallized from ethylene chloride containing a small amount of acetone (based on the carbon and hydrogen analyses), the material prepared in this current work seems to be definitely the anhydride (based on the neutralization equivalent and boron analysis) which may possibly be the more stable form, although this was not definitely established.

The stable form of the *para* isomer seems to be the acid. This is based on the difficulty of conversion to the anhydride either by heating in the vacuum oven for 70 hr. at 90° or recrystallization from ethylene chloride. In both cases, material having a neutralization equivalent intermediate between the acid and anhydride was obtained.

There was a wide variation in melting point of the *ortho* isomer depending on which solvent was used for recrystallization. For example, material recrystallized from toluene generally melted over the range of 170–175° while material recrystallized from ethylene chloride had a melting point as high as 193–194°, although this was not obtained consistently. What was believed to be an analytically pure sample, obtained by recrystallization from an acetone–water system, melted over the range of 180–183°. Despite these differences in melting points, all of these specimens had the

(16) In some experiments, trimethyl borate was used.

same neutralization equivalent. We believe that the neutralization equivalent is more of a criterion of purity than the melting point. The large differences in melting point as well as the relatively large melting point range possibly can be explained by the ratio of monomer, dimer and perhaps even trimer in the purified material. The fact that these forms may exist is based on a molecular weight determination on material recrystallized from water and having a melting point of 194–195°. This was found to be approximately 200. The molecular weight for the monomer is 120.

Both the melting points and water solubilities of these boronic acids and/or anhydrides follow the general pattern established by their carboxylic acid analogs, although there is a much more pronounced difference between the solubilities of the *o*-hydroxybenzeneboronic acid anhydride and the *meta* and *para* isomers than exists in the carboxylic acid series. There does not seem to be any logical explanation for the good water solubilities of the *meta*-anhydride and the *para*-acid in the boron series. The poor water solubility of the *o*-hydroxybenzeneboronic acid anhydride with respect to the other two isomers might be explained partially by its polymer formation. However, it is not known whether the *meta* and *para* isomers prepared in this work tend to dimerize or not. Table I shows the melting point and solubility correlation of the two series.

TABLE I

CORRELATION OF MELTING POINT AND WATER SOLUBILITIES OF HYDROXYBORONIC ACID ISOMERS WITH THEIR CORRESPONDING CARBOXY ANALOGS

Isomer	Hydroxyboronic acid M.p., °C.	H_2O sol. (qual.)[c]	Hydroxycarboxylic acid M.p., °C.	H_2O sol. (g./100 cc.)
ortho	193–194[a,b]	Poor[c]	159	0.18[20]
meta	225[b]	Very good[c]	201.3	.92[18]
para	238	Very good[c]	213	.79[15]

[a] This is the highest melting point that was obtained for this isomer. Other material of this type with a suitable neutralization equivalent had a melting point range as low as 170–175° depending upon the solvent which was used for recrystallization. [b] The anhydride. [c] Only qualitative solubility information is available.

Since no halogen–metal interconversion study had ever been carried out on the *m*-bromophenol as has been done on the *ortho* and *para* isomers,[23,24] the optimal conditions for this were determined. The amount of halogen–metal interconversion, as determined by carbonation to form the carboxylic acid, increased up through a 4-hour reaction period at 20°. Longer reaction times at this temperature did not show any higher yields. There was some indication that the yield decreased slightly with the longer reaction times (up to 24 hr.), although this was not appreciable. For this reason no reaction temperature higher than 20° was studied. Lower temperatures were not investigated.

A 34% yield of pure *m*-hydroxybenzoic acid was obtained when the halogen–metal interconversion was carried out for 4 hr. at 20° followed by carbonation and hydrolysis. In previous studies,[23,24] a 67% yield of the *ortho* isomer and a 41% yield of the *para* isomer were obtained.

Experimental[25]

o-Hydroxybenzeneboronic Acid Anhydride. (a) From *o*-Bromophenol.—To 91 g. (0.525 mole) of *o*-bromophenol dissolved in 200 ml. of anhydrous ether, cooled in an ice-bath, was added 1.08 moles of *n*-butyllithium[26] in 800 ml. of anhydrous ether. This addition was made over a period of 75 minutes, and agitation was continued for 3 hr. at 20–25° following completion of the addition at which time Color Test II[27] was negative. This halogen–metal interconversion has been reported previously.[23,24] This ether solution of lithium *o*-lithiophenoxide was then added over a period of 1 hr. to a solution composed of 248 g. (1.08 moles) of tri-*n*-butyl borate and 200 ml. of anhydrous ether cooled to −70° by means of a Dry Ice–acetone bath. Color Test I[28] was negative immediately upon completion of the addition. The reaction was permitted to warm to 0° and was hydrolyzed by the addition of 360 ml. (1.045 moles) of 10% hydrochloric acid. The aqueous layer was separated from the ether layer and was washed twice with 200-ml. portions of ether which were combined with the main ether solution. This combined ether solution was then extracted with 800 ml. of 10% sodium hydroxide in three portions. The extract was washed once with 200 ml. of ether. This alkaline solution was heated on the steam plate to expel any residual ether, after which it was acidified by the addition of 10% hydrochloric acid. The solid which precipitated weighed 76 g. after drying and had a melting point range of 130–150°. This crude material was recrystallized twice from toluene to give 35 g. (55.5%) of material melting over the range of 170–175°. This yield includes the additional material obtained by concentration of the recrystallizing liquors.

Other experiments were conducted in which variations were made in the finishing procedure. Using the same procedure as described above for the preparation of the compound, isolation was accomplished after the acid hydrolysis by evaporating the ether layer to dryness. From 98.5 g. (0.57 mole) of *o*-bromophenol, 91 g. of crude product having a melting point range of 130–148° was obtained. This was washed thoroughly with 400 ml. of water leaving 47 g. of insoluble material having a melting point range of 165–170°. This represents a 69% yield of reasonably satisfactory material. Recrystallization of this material from approximately 1 liter of dry ethylene chloride gave 37 g. of material having a melting point range of 175–180°. This represents a 55% yield of nearly pure material.

When using this second finishing procedure, it was thought that trimethyl borate would be more adaptable than tri-*n*-butyl borate since it would then involve the evaporation of methyl alcohol along with the other volatile material instead of *n*-butyl alcohol. An experiment which employed 94 g. (0.545 mole) of *o*-bromophenol with 117 g. (1.12 moles) of trimethyl borate and using the technique just discussed gave 37 g. of washed semi-pure product having a melting point range of 170–175°. This represents a yield of 56.5%. Recrystallization of the product from ethylene chloride gave 30 g. (47%) of material melting over the range of 180–185°.

The analytical sample was recrystallized from an acetone–water system to give material melting over the range of 180–183°. The optimum amounts of material were found to be 5 g. of solute for 300 ml. of water and 60 ml. of acetone.

The infrared spectrum supported the structure.

(24) H. Gilman and C. E. Arntzen, THIS JOURNAL, **69**, 1537 (1947).

(25) All melting points are uncorrected and were measured using a previously unheated oil-bath. The neutralization equivalents were obtained by dissolving 50 to 100 mg. of the compound in 50 ml. of 50% ethanol or in 50 ml. of water if its solubility permitted, adding 20 times the sample weight of D-mannitol and then titrating with standard sodium hydroxide using phenolphthalein as the indicator. In the case of *p*-hydroxybenzeneboronic acid, darkening of the solution during the titration necessitated the use of a Beckman Model G *p*H meter to detect the end-point.

Anal. Calcd. for $C_6H_5BO_2$: C, 60.09; H, 4.20; B, 9.02; neut. equiv., 119.94. Found: C, 60.24, 60.30; H, 4.12, 4.18; B, 9.12, 9.21; neut. equiv., 120.0.

(b) From 2-(*o*-Bromophenoxy)-tetrahydropyran.—To a stirred solution of 25.7 g. (0.1 mole) of 2-(*o*-bromophenoxy)-tetrahydropyran[18] and 100 ml. of anhydrous ether, cooled in an ice-bath, was added 0.1 mole of *n*-butyllithium[26] in 88 ml. of ether over a period of 15 minutes. Agitation was continued for 1 hr. at room temperature following completion of the addition. Color Test II[27] was negative at this time. The reaction mass consisted of a solid suspended in ether.

The 2-(*o*-lithiophenoxy)-tetrahydropyran suspension was then added over a period of 20 minutes to a stirred solution of 34.5 g. (0.15 mole) of tri-*n*-butyl borate in 100 ml. of anhydrous ether previously cooled to −70° by means of a Dry Ice–acetone bath. The temperature was maintained below −65° during the addition and for 2 hr. following completion of the addition at which time Color Test I[28] was negative. After warming to 0°, the reaction mass was hydrolyzed by the addition of 10% hydrochloric acid. The aqueous layer was separated from the ether and washed twice with fresh ether. The combined ether solutions were then extracted with two 50-ml. portions of 10% sodium hydroxide. The alkaline solution was washed with a 100-ml. portion of ether, warmed on the steam-bath to expel any residual ether, treated with Norit-A, filtered, cooled and acidified with 10% hydrochloric acid. The gray product which separated was filtered, washed with water and dried to give 10.0 g. (83%) of crude product melting over the range of 170–175°. Recrystallization of this material from a benzene–acetone system gave 6.6 g. (55%) of product melting at 180–181°. An admixture of this with authentic 2-hydroxybenzeneboronic acid anhydride melted undepressed.

***m*-Hydroxybenzeneboronic Acid Anhydride.**—Thirty-four and six-tenths grams (0.2 mole) of *m*-bromophenol was dissolved in 90 ml. of anhydrous ether in a nitrogen atmosphere. To this stirred solution was added 0.44 mole of *n*-butyllithium[26] in 332 ml. of anhydrous ether over a period of 50 minutes, the temperature being maintained at 20° by means of a water-bath. Agitation was continued for 4 hr. at 20° at which time Color Test II[27] was negative. This ether solution of lithium *m*-lithiophenoxide then was added over a 30-minute period to a stirred solution of 140 g. (0.6 mole) of tri-*n*-butyl borate in 220 ml. of anhydrous ether previously cooled to −70° by means of a Dry Ice–acetone bath. During this time the reaction mixture became extremely viscous. Upon completion of the addition, the mixture was permitted to warm to 0°. Color Test I[28] was negative. The reaction mixture was hydrolyzed with 250 ml. of a saturated ammonium chloride solution followed by 150 ml. of 10% hydrochloric acid to get the *p*H below 7 and 100 ml. of water to dissolve some still remaining solid. The aqueous layer was separated from the ether and was washed twice with 100-ml. portions of ether which were combined with the main portion. The ether solution was extracted ten times with 60-ml. portions of 10% sodium carbonate which were poured into a stirred mixture of 400 ml. of ether and 500 ml. of a saturated ammonium chloride solution. Four hundred milliliters of 10% hydrochloric acid also was added to get the *p*H to 6. The aqueous layer was separated from the ether and was extracted several times with additional ether which was combined with the main portion. Evaporation of the ether layer to dryness left a solid material which upon crystallization from ethylene chloride gave 6 g. (25%) of material having a melting point of 208–212°. The initial ether layer was evaporated to about one-fourth its original volume and the same process was repeated. This gave an additional 1.1 g. (4.5%) of material melting at 208–212°. The two final acid aqueous layers were combined and evaporated to one-fourth volume. This was extracted several times with ether to give 0.9 g. (3.8%) of material melting at 215–230°. All of the crude material was combined and recrystallized from ethylene chloride to give 7.3 g. (30.4%) of material melting at 215–225° dec. The analytical sample was recrystallized an additional time from ethylene chloride.

The infrared spectrum supported the structure.

Anal. Calcd. for $C_6H_5BO_2$: B, 9.02; neut. equiv., 119.94. Found: B, 9.11; neut. equiv., 117, 122.4.

***p*-Hydroxybenzeneboronic Acid.**—The halogen–metal interconversion carried out was essentially that which has been described previously,[23] although a larger excess of *n*-butyllithium was used.

To a stirred solution of 33.7 g. (0.2 mole) of *p*-bromophenol dissolved in 80 ml. of anhydrous ether, 415 ml. of 1.45 *N* *n*-butyllithium (0.6 mole) was added at room temperature over a 45-minute period. Following completion of the addition, the reaction mixture was refluxed for 2 hr. After cooling with an ice-bath, the lithium *p*-lithiophenoxide suspension was added over a period of 50 minutes to a stirred solution of 140 g. (0.6 mole) of tri-*n*-butyl borate in 200 ml. of anhydrous ether previously cooled to −70° by means of a Dry Ice–acetone bath. After agitating for 2 hr. at this temperature following completion of the addition, Color Test I[28] was negative. The mixture was permitted to warm to 0° and was hydrolyzed by the addition of a saturated solution of ammonium chloride. A small amount of 10% hydrochloric acid also was added to lower the *p*H to 6. The two layers which resulted were separated, the aqueous layer being washed with fresh ether which was combined with the main ether portion. This ether extract was concentrated and was shaken with 600 ml. of 10% sodium carbonate in nine portions. Each alkaline extract was poured into a flask containing a stirred excess of saturated ammonium chloride solution and ether. This ether layer was separated from the aqueous layer, the latter being extracted with fresh ether which was combined with this second main ether portion. The ether extract was concentrated under vacuum without applying heat. About 4 g. (14.5%) of product melting at 238° crystallized from the concentrated ether solution. Recrystallization of this material from acetone containing a few drops of water did not alter the melting point.

Evaporation of the ether solution to dryness left a semi-crystalline residue which, after drying on a porous plate, weighed 9.2 g. and melted at 187–191°. Recrystallization of this material from acetone containing a few drops of water and employing a Norit-A treatment gave 4.75 g. (17.4%) of crystals melting at 230.5–231°.

In other experiments, an extraction with 8% sodium bicarbonate preceding the one with sodium carbonate and an extraction with 5% sodium hydroxide following the sodium carbonate extraction, each yielded about 0.4 g. of crude material. A final extraction with 20% sodium hydroxide gave only 0.2 g. more of very impure product.

Other experiments carried out under a variety of conditions were inferior to the procedure described above.

The analytical sample was recrystallized two more times from acetone containing a small amount of water. This material melted at 238° and gave a violet-blue color with ferric chloride. The infrared analysis confirmed the expected structure.

Anal. Calcd. for $C_6H_7BO_3$: B, 7.85; neut. equiv., 137.93. Found: B, 7.82; neut. equiv., 138.4, 136.6, 137.0.

When recrystallizing the material from acetone–water a definite crystal structure first formed, but as the material dried it disintegrated into a powder. It was thought that the anhydride might be forming but the neutralization equivalent does not support this. The powdery product was recrystallized from ethylene chloride to give material having a neutralization equivalent of 130. Heating the acid in a vacuum oven for 70 hr. at 90° gave material having a neutralization equivalent of 125.

2-(*m*-Bromophenoxy)-tetrahydropyran.—To a stirred mixture of 33.6 g. (0.4 mole) of freshly distilled dihydropyran and 4 drops of concentrated hydrochloric acid previously heated to 60° was added 34.6 g. (0.2 mole) of *m*-bromophenol over a period of 30 minutes. The rate was such as to keep the temperature below 70°. Agitation was continued for 2 hr. following completion of the addition, the temperature being permitted to drop to that of the room. Eighty milliliters of ether was added to the reaction mass which was then extracted with three 20-ml. portions of 10% sodium hydroxide. These basic aqueous layers were combined and extracted with three 50-ml. portions of ether. An additional 100 ml. of water was put in to dissolve an orange-colored solid which separated during this operation. The ether extracts were combined and were dried with anhydrous sodium sulfate. The ether and excess dihydropyran were removed by distillation at atmospheric pressure after which the remaining material was subjected to vacuum distillation. The material boiled over the range of 98–105° at 2 mm. This material was distilled a second time, two

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

fractions being collected. The first fraction weighed 5 g. and distilled at 119–120° (1 mm.), while the second fraction distilled at 115° (0.4 mm.), $n^{20}D$ 1.5504, d^{20}_{20} 1.3952, and weighed 38.5 g. This second fraction represents a 75% yield of 2-(*m*-bromophenoxy)-tetrahydropyran. The method used to prepare this compound follows closely that for the *o*-bromo[18] and *p*-bromo[17] isomers.

Anal. Calcd. for $C_{11}H_{13}BrO_2$: Br, 31.08; MR_D, 58.12. Found: Br, 30.60, 30.55; MR_D, 58.75.

***m*-Hydroxybenzoic Acid.**—Eight and sixty-five hundredths gram of *m*-bromophenol was treated with 0.11 mole of *n*-butyllithium for 4 hr. at 20°. The reaction was terminated by pouring it jet-wise into a stirred slurry of Dry Ice and ether. After the mixture had warmed to room temperature, it was hydrolyzed by the addition of 50 ml. of 10% hydrochloric acid. The aqueous layer was separated and was washed twice with 50-ml. portions of ether which were combined with the main portion. The ether solution was extracted with three 25-ml. portions of 10% sodium hydroxide which were combined and acidified with concentrated hydrochloric acid. The solid which precipitated was dried and sublimed under vacuum twice to give 2.3 g. (33.3%) of material melting at 196–198° (lit. value, 201°).

Acknowledgments.—We wish to thank Mr. Robert McCord and Mr. E. Miller Layton, Jr., of the Ames Laboratory of the Atomic Energy Commission for the infrared spectra.

We also wish to acknowledge the financial support of the Division of Biology and Medicine of the United States Atomic Energy Commission which has made this work possible. The results of the biological testing of these compounds will be reported by Dr. Otho D. Easterday of the Brookhaven National Laboratory.

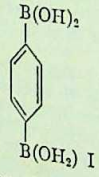
Benzenediboronic Acids

BY DONALD R. NIELSEN AND WILLIAM E. MCEWEN

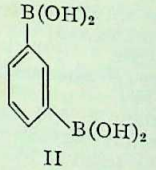
RECEIVED JANUARY 31, 1957

Benzene-1,4-diboronic acid (I) and benzene-1,3-diboronic acid (II) have been synthesized and characterized by conversion to the respective tetra-*n*-butyl esters and bis-(dichloroboryl)-benzenes.

Although more than 70 aliphatic and aromatic monoboronic acids have been described in the literature, there is no report of the synthesis of diboronic acids.[1] As part of a broad investigation of the physical and chemical properties of bifunctional organoboron compounds, syntheses of benzene-1,4-diboronic acid (I) and benzene-1,3-diboronic acid (II) have now been devised.

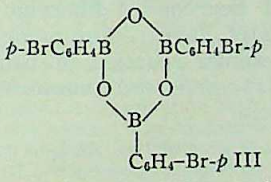


I



II

Benzene-1,4-diboronic acid (I) has been prepared in low yield by four different methods. When a mixture of *p*-bromophenylboronic anhydride (III), dispersed sodium and methyl borate in hexane was heated for two hours, then hydrolyzed, benzene-1,4-diboronic acid (I) was obtained in 4% yield. Reaction of di-*n*-butyl *p*-bromophenylboronate, magnesium and methyl borate in refluxing 1,2-dimethoxyethane for 30 hours gave, after hydrolysis of the reaction mixture, a 10% yield of I. The yield of benzene-1,4-diboronic acid (I) amounted to 26% in a reaction in which methyl borate, which had been frozen and pulverized, was added to a suspension of *p*-dilithiobenzene (IV) in petroleum ether at −30°, followed by hydrolysis of the reaction mixture. The dilithio compound IV was prepared by metal–halogen exchange between *n*-butyllithium and *p*-dibromobenzene according to the procedure of Gilman, Langham and Moore.[2] It is noteworthy that the yield of I is considerably below that of terephthalic acid, which may be obtained in 66–89% yield by an analogous carbonation reaction of the exchange mixture.



III

IV

The best yield of I was obtained by use of the Grignard reaction. A mixture of *p*-dibromobenzene and two equivalents of magnesium in tetrahydrofuran was refluxed for a period of seven hours, then methyl borate was added to the reaction mixture maintained at about −30°. After hydrolysis of the reaction products, the resulting acids were esterified with *n*-butyl alcohol and the esters fractionated. There was obtained tetra-*n*-butyl benzene-1,4-diboronate (V) in 35% yield, together with di-*n*-butyl *p*-bromophenylboronate (5%) and di-*n*-butyl phenylboronate (19%). Hydrolysis of the butyl esters gave quantitative yields of the respective arylboronic acids. The prolonged period of heating is evidently necessary for the formation of the dimagnesium Grignard compound in moderately satisfactory yield, since the yield of benzene-1,4-diboronic acid (I) dropped to 10% when the mixture of *p*-dibromobenzene and magnesium was heated for only 2.5 hours prior to the reaction with methyl borate. Extended refluxing of a solution of *p*-dibromobenzene in ethyl ether

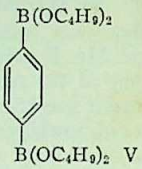
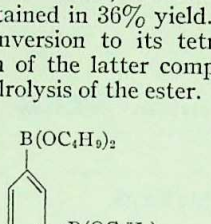
has been reported to give the dimagnesium Grignard reagent in yields of only 4–23%.[3–5]



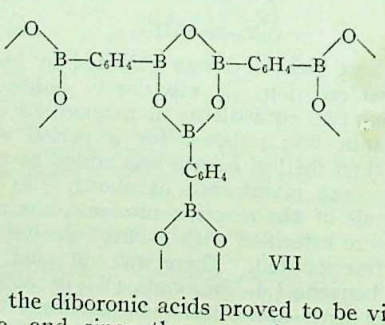
V

Benzene-1,3-diboronic acid (II) was obtained in 10% yield after hydrolysis of the product obtained by addition of methyl borate to the halogen–metal exchange mixture from *m*-dibromobenzene and *n*-butyllithium. By use of the dimagnesium Grignard compound of *m*-dibromobenzene instead of the dilithio derivative, however, the diboronic acid II was obtained in 36% yield. The acid was isolated by conversion to its tetra-*n*-butyl ester VI, purification of the latter compound by distillation, then hydrolysis of the ester.



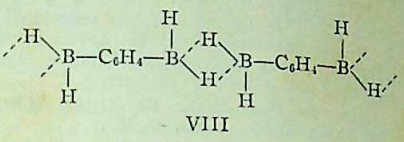
VI

Both of the diboronic acids I and II proved to have exceptionally high melting points. Neither compound melted at temperatures up to 420°. It is thought that the acids gradually lose water upon being heated and form polymers of the type shown in structure VII. The structures of the acids were established by application of Melnikov's procedure.[6] Treatment of benzene-1,4-diboronic acid (I) with bromine water gave *p*-dibromobenzene and boric acid. A similar reaction of benzene-1,3-diboronic acid (II) gave *m*-bromophenylboronic acid plus boric acid.



VII

Since the diboronic acids proved to be virtually infusible, and since the respective tetra-*n*-butyl esters were liquids, an attempt was made to prepare solid derivatives of the acids having convenient melting points. The tetrachlorides were chosen because our future plans include attempts to prepare polymers of the type shown in structure VIII (or polymers which would result upon disproportionation of VIII) by reduction of the tetrachlorides.

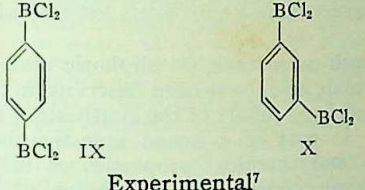


VIII

Inasmuch as the diboronic acids were isolated and purified most conveniently by way of their tetra-*n*-butyl esters, a method for the direct conversion of the esters to the halides was desired. In a model experiment it was found that di-*n*-butyl phenylboronate could be converted to the known phenyldichloroborane by reaction with phosphorus pentachloride. The stoichiometry was established as

$$C_6H_5B(OC_4H_9)_2 + 2PCl_5 \longrightarrow C_6H_5BCl_2 + 2POCl_3 + 2C_4H_9Cl$$

Treatment of tetra-*n*-butyl benzene-1,4-diboronate (V) with four equivalents of phosphorus pentachloride gave 1,4-bis-(dichloroboryl)-benzene (IX), m.p. 93–96°, in 84% yield. An analogous reaction with tetra-*n*-butyl benzene-1,3-diboronate (VI) gave 1,3-bis-(dichloroboryl)-benzene (X), m.p. 54–56°, in 58% yield. Both of the tetrachlorides underwent very rapid hydrolysis upon contact with moist air.



IX X

Experimental[7]

General Experimental Precautions.—All preparations of organoboron compounds were carried out in an atmosphere of dry, oxygen-free nitrogen. All transfer operations involving air-sensitive or moisture-sensitive organoboron compounds were carried out in a dry-box in an atmosphere of pure nitrogen.

Benzene-1,4-diboronic Acid (I). A. Use of 1,4-Dilithiobenzene (IV).—To a solution of 52.0 g. (0.22 mole) of *p*-dibromobenzene in 500 ml. of petroleum ether was added a solution containing 0.50 mole of *n*-butyllithium in petroleum ether. The mixture was heated with stirring for 20 hours. An insoluble solid began to form immediately after the addition of the *n*-butyllithium, and the solid increased in amount as the exchange reaction progressed.

The mixture was placed in an acetone–Dry Ice-bath, and 52 g. (0.50 mole) of methyl borate, which had been frozen and pulverized, was added. The reaction mixture was allowed to warm slowly to room temperature, then hydrolyzed and acidified by the addition of dilute hydrochloric acid. The layers were separated, and the aqueous layer was extracted with ether. The combined ether–petroleum ether solution was concentrated almost to dryness. A solid which had precipitated was collected by filtration, washed with petroleum ether and recrystallized from water. There was obtained 9.45 g. (26%) of benzene-1,4-diboronic acid (I), which did not melt up to a temperature of 420°.

Anal. Calcd. for $C_6H_8B_2O_4$: C, 43.47; H, 4.87; B, 13.06. Found: C, 43.41; H, 4.83; B, 13.28.

Further concentration of the combined ether–petroleum ether filtrate and wash solution left a residue consisting of a colorless solid and a yellow liquid. The solid was collected by filtration and dissolved in ether. Addition of ethanolamine caused a solid product to precipitate. This was recrystallized from benzene, giving a small amount of

aminoethyl di-*p*-bromophenylborinate, m.p. 235.6–237.2°, reported[8] m.p. 236–237°.

Anal. Calcd. for $C_{14}H_{14}BBr_2NO$: C, 43.91; H, 3.69; B, 2.83; Br, 41.74; N, 3.66. Found: C, 44.19; H, 3.50; B, 3.16; Br, 41.75; N, 3.62.

In a second run, liquid methyl borate was used in place of solid methyl borate. Benzene-1,4-diboronic acid was obtained in 23% yield.

When the exchange mixture, prepared as described above, was added to powdered Dry Ice, then acidified with dilute hydrochloric acid, there was obtained terephthalic acid in 66% yield and *p*-bromobenzoic acid in 13% yield. Gilman, Langham and Moore[2] obtained terephthalic acid in 89% yield in a similar experiment.

B. Use of the Dimagnesium Grignard Compound of *p*-Dibromobenzene.—A solution of 36.7 g. (0.155 mole) of *p*-dibromobenzene in 250 g. of anhydrous tetrahydrofuran was added over a period of 35 minutes to 7.45 g. (0.31 g. atom) of magnesium, reaction proceeding vigorously throughout this period. After all of the *p*-dibromobenzene had been added, the mixture was heated to 60–64° for seven hours. During the initial stages of the reaction a colorless solid precipitated, and the amount of this solid increased as the reaction progressed. The mixture was placed in an acetone–Dry Ice-bath, and 27 g. (0.26 mole) of methyl borate was added. The mixture was allowed to warm gradually to room temperature, then hydrolyzed and acidified with dilute hydrochloric acid. After ether extraction of the acid solution and distillation of solvent from the extract, an excess of 1-butanol was added to the residue. The mixture was distilled until the temperature of the distillate, which remained at 90–92° during distillation of the water-butanol azeotrope, rose to 115°. Distillation of the residue at reduced pressure gave 13.9 g. of *n*-butyl borate, b.p. 63–85° (0.1 mm.), and 6.93 g. (19%) of di-*n*-butyl phenylboronate, b.p. 85–90° (0.1 mm.). A dark solid distillation residue became colorless on addition of water. Recrystallization of this solid from water gave 12.31 g. of benzene-1,4-diboronic acid (I) contaminated with some *p*-bromophenylboronic acid. The mixture of acids was esterified with 1-butanol by distillation of the water–butanol azeotrope as described above; then the esters were purified by distillation. There was obtained 2.53 g. (5%) of crude di-*n*-butyl *p*-bromophenylboronate, b.p. 87–130° (0.4 mm.), and 17.9 g. (35%) of tetra-*n*-butyl benzene-1,4-diboronate (V), b.p. 160–176° (0.4 mm.).

Anal. Calcd. for $C_{22}H_{40}B_2O_4$: C, 67.72; H, 10.33; B, 5.55. Found: C, 67.85; H, 10.11; B, 5.83.

Each of the butyl esters cited above underwent rapid hydrolysis on contact with water to give the respective boronic acids and *n*-butyl alcohol in quantitative yield.

C. Use of Grignard Reagent Prepared from Di-*n*-butyl *p*-Bromophenylboronate.—A mixture of 64.0 g. (0.204 mole) of di-*n*-butyl *p*-bromophenylboronate, 21.0 g. (0.20 mole) of methyl borate, 200 ml. of 1,2-dimethoxyethane and 5.0 g. (0.208 g. atom) of magnesium turnings was refluxed for 50 hours. The mixture was hydrolyzed by addition of dilute hydrochloric acid and extracted with ether. The residue obtained upon distillation of the ether was crystallized from water, giving 3.38 g. (10%) of benzene-1,4-diboronic acid (I).

D. Use of *p*-Bromophenylboronic Anhydride (III), Sodium and Methyl Borate.—*p*-Bromophenylboronic anhydride (III) was prepared by dehydration of *p*-bromophenylboronic acid in an evacuated desiccator over concentrated sulfuric acid for one day. A mixture containing 8.0 g. (0.044 mole) of *p*-bromophenylboronic anhydride, 7.8 g. (0.295 g. atom) of dispersed sodium and 400 ml. of hexane was stirred for three hours at room temperature without any apparent reaction taking place. After addition of 15.4 g. (0.148 mole) of methyl borate, the mixture was heated to 75° for two hours. Hydrolysis of the reaction mixture with dilute hydrochloric acid and use of an isolation procedure similar to that described above gave 0.28 g. (4%) of benzene-1,4-diboronic acid (I).

Proof of Structure of Benzene-1,4-diboronic Acid (I).—A solution of 1.00 g. (0.00604 mole) of benzene-1,4-diboronic acid in dilute sodium hydroxide was neutralized to the phenolphthalein end-point with dilute hydrochloric acid. The mixture was cooled, and an excess of bromine in potassium bromide solution was added. The mixture was allowed to stand for several hours, then 1.06 g. (0.0045 mole, 75%) of *p*-dibromobenzene was collected by filtration. After two crystallizations from ethanol its m.p. was 90–92°, and its infrared absorption spectrum in chloroform solution was identical with that of a corresponding solution of authentic *p*-dibromobenzene.

p-Bromophenylboronic Acid.—This acid was prepared by a modification of the procedure of Konig and Scharrnbeck.[9] To *p*-bromophenylmagnesium bromide prepared from 11.3 g. (0.485 g. atom) of magnesium, 114.3 g. (0.485 mole) of *p*-dibromobenzene and 600 ml. of anhydrous ether, cooled in an acetone–Dry Ice-bath, was added 50.5 g. (0.485 mole) of methyl borate. The mixture was allowed to warm to room temperature, refluxed for 30 minutes, then hydrolyzed by addition of dilute hydrochloric acid and extracted with ether. Concentration of the ether solution and crystallization of the residue from water gave 51.9 g. (53%) of *p*-bromophenylboronic acid, m.p. 273–281°; reported[9] m.p. 266° for *p*-bromophenylboronic acid and m.p. 280° for *p*-bromophenylboronic anhydride.

In a second run, the crude acid from the ether extract was added to 110 ml. of *n*-butyl alcohol and distilled. After removal of the water–butanol azeotrope (b.p. 92°) and excess alcohol, the residue was distilled at reduced pressure. There was obtained a 57% yield of di-*n*-butyl *p*-bromophenylboronate, b.p. 122–126° (2 mm.).

1,4-Bis-(dichloroboryl)-benzene (IX).—To 88.9 g. (0.426 mole) of phosphorus pentachloride was added a solution of 41.7 g. (0.107 mole) of tetra-*n*-butyl benzene-1,4-diboronate (V) in 126 g. of carbon tetrachloride, and the mixture was refluxed for seven hours. Distillation of the carbon tetrachloride[10] (together with the by-products, *n*-butyl chloride and phosphorus oxychloride) and sublimation of the residue at 0.5 mm. pressure gave 21.5 g. (0.09 mole, 84%) of 1,4-bis-(dichloroboryl)-benzene (IX). After a second sublimation the material melted at 93–96° in a sealed tube.

Anal. Calcd. for $C_6H_4B_2Cl_4$: C, 30.08; H, 1.68; B, 9.03; Cl, 59.20. Found: C, 30.16; H, 1.86; B, 8.94; Cl, 58.85.

The compound is extremely sensitive to moisture and is hydrolyzed almost instantly on contact with moist air.

Benzene-1,3-diboronic Acid (II). A. Use of the Dimagnesium Grignard Compound of *m*-Dibromobenzene.—A solution of 38.8 g. (0.165 mole) of *m*-dibromobenzene in 410 g. of anhydrous tetrahydrofuran was added over a period of five hours to 8.15 g. (0.34 g. atom) of magnesium. After addition of the *m*-dibromobenzene, the mixture was maintained at a temperature of about 40° and stirred for another five hours. The mixture was then cooled in an acetone–Dry Ice-bath, and 40 g. (0.384 mole) of methyl borate was added. After being allowed to warm gradually to room temperature, the reaction mixture was hydrolyzed by addition of dilute hydrochloric acid and extracted with ether. The residue obtained on distillation of the ether was esterified with *n*-butyl alcohol by the azeotropic method cited for the preparation of tetra-*n*-butyl benzene-1,4-diboronate (V). Distillation at reduced pressure yielded only *n*-butyl borate and a small amount of di-*n*-butyl phenylboronate. The process of esterification of the residue and removal of esters by distillation at reduced pressure was repeated until no more ester distilled. The distillate was collected in four fractions: (1) *n*-butyl borate, b.p. 58–77° (0.1 mm.), 19.61 g.; (2) di-*n*-butyl phenylboronate, b.p. 77–100° (0.1 mm.), 9.97 g. (26%); (3) di-*n*-butyl *m*-bromophenylboronate, b.p. 100–123° (0.1 mm.), 3.56 g. (7%); (4) tetra-*n*-butyl benzene-1,3-diboronate, b.p. 170–181° (0.1 mm.), 22.9 g. (36%). The last fraction was analyzed.

Anal. Calcd. for $C_{22}H_{40}B_2O_4$: C, 67.72; H, 10.33; B, 5.55. Found: C, 67.89; H, 10.26; B, 5.68.

The identity of the major constituent of each of the distillation fractions was established by hydrolysis and isolation of the acid component of the ester. For example, hydrolysis of a portion of fraction 4 was effected by heating the ester in water until it dissolved, then collecting the acid which

(8) R. L. Letsinger and I. H. Skoog, THIS JOURNAL, **77**, 2491 (1955).

(10) Much of the phosphorus pentachloride remained unchanged after the period of refluxing. It was only after the mixture had been concentrated to about 100 ml. that all of the phosphorus pentachloride was consumed.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

crystallized on cooling of the solution. After the product, benzene-1,3-diboronic acid (II), had been recrystallized from water and dried in an evacuated desiccator, it did not melt up to 420°.

Anal. Calcd. for $C_6H_8B_2O_4$: C, 43.47; H, 4.87; B, 13.06. Found: C, 43.71; H, 4.99; B, 12.77.

B. Use of 1,3-Dilithiobenzene.—To a solution of 15.9 g. (0.068 mole) of *m*-dibromobenzene in 300 ml. of petroleum ether was added 100 ml. of a petroleum ether solution containing 0.135 mole of *n*-butyllithium. The mixture was stirred for five hours, the temperature being maintained at about 34°. To the resulting mixture, cooled in an acetone–Dry Ice-bath, was added 14.0 g. (0.135 mole) of methyl borate. The mixture was allowed to warm gradually to room temperature, hydrolyzed with dilute hydrochloric acid and extracted with ether. After distillation of the ether and petroleum ether, the residue was digested with hot water and filtered. From the filtrate there was obtained 1.1 g. (10%) of benzene-1,3-diboronic acid (II).

When the exchange mixture was caused to react with carbon dioxide, rather than with methyl borate, isophthalic acid could be isolated in 30% yield.

Proof of Structure of Benzene-1,3-diboronic Acid (II).—The method used was the same as that described for the proof of structure of benzene-1,4-diboronic acid (I). However, in this experiment *m*-bromophenylboronic acid, m.p. 169–173° (reported[11] m.p. 170°), was isolated instead of *m*-dibromobenzene. The infrared spectrum of a chloroform solution of the product was identical with that of a chloroform solution of authentic *m*-bromophenylboronic acid.

In an independent experiment it was shown that *m*-bromophenylboronic acid is not cleaved by bromine water under the conditions used for the proof of structure of benzene-1,3-diboronic acid (II).

***m*-Dibromobenzene.**—This compound was prepared in 51% yield by a modification of the method of Mathieson and Newberry.[12] A cold solution of *m*-bromobenzenediazonium bisulfate was added to a suspension of cuprous bromide in water, through which a vigorous current of steam was being passed. Mathieson and Newberry[12] obtained *m*-dibromobenzene in 25% yield by adding cuprous bromide to *m*-bromobenzenediazonium bisulfate at 75°.

***m*-Bromophenylboronic Acid.**—The acid, m.p. 161–166°, was obtained in 46% yield from *m*-dibromobenzene, the procedure being the same as that employed for the preparation of *p*-bromophenylboronic acid.

1,3-Bis-(dichloroboryl)-benzene (X).—Tetra-*n*-butyl benzene-1,3-diboronate was caused to react with phosphorus pentachloride in the same manner as described for the preparation of bis-1,4-(dichloroboryl)-benzene (IX). After distillation of the carbon tetrachloride and the by-products *n*-butyl chloride and phosphorus oxychloride at atmospheric pressure, the residue was distilled *in vacuo*. There was obtained a 58% yield of 1,3-bis-(dichloroboryl)-benzene (X), b.p. 82–84° (1.2 mm.). After two sublimations at 50 mm. pressure, the colorless sublimate had a m.p. of 54–56° in a sealed tube.

Anal. Calcd. for $C_6H_4B_2Cl_4$: C, 30.08; H, 1.68; B, 9.03; Cl, 59.20. Found: C, 29.98; H, 1.78; B, 9.23; Cl, 58.95.

Phenyldichloroborane.—Di-*n*-butyl phenylboronate was prepared by the method of Torssell.[13] To a stirred suspension of 57.0 g. (0.274 mole) of phosphorus pentachloride in 130 g. of carbon tetrachloride was added 32.1 g. (0.137 mole) of di-*n*-butyl phenylboronate. A mildly exothermic reaction occurred, but only a small amount of the phosphorus pentachloride was consumed. Distillation of the solvent was commenced and as the distillation proceeded the remainder of the phosphorus pentachloride was consumed. After removal of solvent and the by-products *n*-butyl chloride and phosphorus oxychloride, the residue was distilled *in vacuo*. There was obtained 17.2 g. (79%) of phenyldichloroborane, b.p. 65–67° (14 mm.); reported b.p. 175°[14] and 178°[15] (760 mm.).

Anal. Calcd. for $C_6H_5BCl_2$: C, 45.37; H, 3.17; B, 6.81; Cl, 44.65. Found: C, 45.61; H, 3.44; B, 6.56; Cl, 44.84.

In order to determine the yields of by-products, the reaction was repeated without a solvent. To 130 g. (0.625 mole) of phosphorus pentachloride was added 68.5 g. (0.292 mole) of di-*n*-butyl phenylboronate. Much heat was evolved as the reagents were mixed, but not all of the phosphorus pentachloride was consumed until the mixture had been heated at about 70° for an additional two hours. Fractional distillation of the liquid product gave 53.1 g. (0.574 mole, 98%) of *n*-butyl chloride, b.p. 74–78°; 73.3 g. (0.479 mole, 82%) of phosphorus oxychloride, b.p. 90–105°; and 33.1 g. (0.208 mole, 71%) of phenyldichloroborane, b.p. 63–70° (14 mm.).

The crude *n*-butyl chloride was washed with dilute sodium carbonate solution, dried over anhydrous sodium sulfate, redistilled, converted to the Grignard reagent in ether solution and added to powdered carbon dioxide. *n*-Valeric acid was obtained by acidification of the mixture and extraction with ether. A portion of the acid was converted to the *p*-bromophenacyl ester, m.p. 73.6–75.2°, and another portion to the α-naphthalide, m.p. 112.4–113.8°, by conversion to the acid chloride and reaction of the latter with 1-aminonaphthalene.

The Mechanism of Fluorination. III.[1] Fluorine Atom Reactions. The Olefin Dimerization Reaction[2,3]

BY WILLIAM T. MILLER, JR., AND STANLEY D. KOCH, JR.

RECEIVED AUGUST 10, 1956

A general mechanism is presented for the reactions of elemental fluorine with perhalo-olefins. This mechanism accounts for the formation of dimer addition products by the diffusion-controlled combination of free radicals which are produced in pairs with the intermediate formation of fluorine atoms. This process appears to be unique with fluorine. The important new steps in the mechanism are tested by reactions of fluorine with mixtures of perhalo-olefins of different reactivities and with an olefin and chloroform. The results obtained are shown to support the proposed mechanism and to demonstrate the very great and indiscriminate reactivity of fluorine atoms.

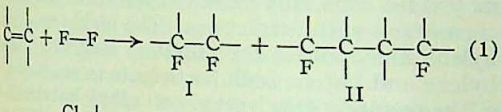
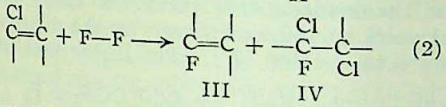
Introduction

A characteristic feature of the reactions of elemental fluorine with organic compounds is the formation of polymeric products.[4] With unsaturated compounds coupling can occur both by dehydrogenation and by reaction with olefinic bonds. As a result complicated mixtures of reaction products usually are formed. In contrast, reactions between fluorine and perhalo-olefins containing only chlorine and/or fluorine can be limited to attack at the double bond and useful yields of pure products obtained. A number of such reactions have been carried out by passing gaseous fluorine into rapidly stirred liquid olefins at 0° or below and described previously as synthetic procedures.[5,6] The principal products are the fluorine addition product I and the dimer addition product II. The yield of dimer addition product varies with olefin structure and parallels the rate of reaction with fluorine. An unreactive olefin yields little dimer while a highly reactive olefin always gives appreciable amounts.[7] Polymeric products higher than dimers are not obtained. With chlorine-containing olefins varying amounts of by-products corresponding to substitution of chlorine by fluorine III[9] and to the addition of chlorine fluoride IV are usually formed.



(1)

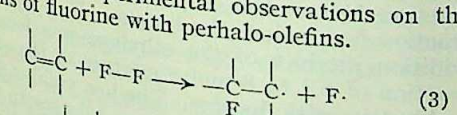


(2)

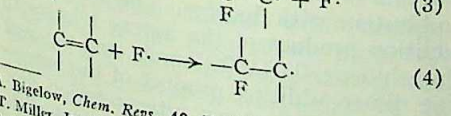
The present paper presents a general free radical mechanism that accounts for the formation of these typical reaction products, and the results of new experiments with mixtures of olefins designed especially to test the proposed mechanism for the formation of fluorine dimer addition products and to furnish information regarding the behavior of fluorine atoms.

Results and Discussion

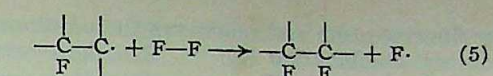
General Reaction Mechanism.—The following series of reactions has been found to be consistent with available experimental observations on the reactions of fluorine with perhalo-olefins.



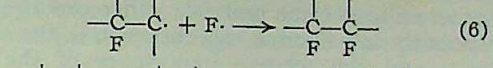
(3)



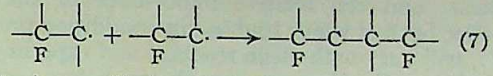
(4)



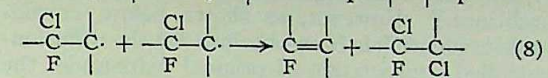
(5)



(6)



(7)



(8)

The key to the over-all mechanism is provided by the discovery that fluorine molecules react rapidly with olefinic bonds at low temperatures to produce a fluorinated free radical and a fluorine atom. This process is formulated as the rate-controlling initiation step 3. The fluorine atom can combine with an adjacent olefin molecule to yield a second free radical (4) or with the first-formed free radical (6). Combination of the radicals produced by reactions 3 and 4 yields fluorine dimer addition product (7).[10,12] Disporportionation and secondary reactions of the resulting olefin account for the principal by-products (8).[14] The occurrence of reactions 3 and 4 was shown by experiments with the addition of oxygen and of chlorine, in which fluorine served as a free-radical initiator. Products corresponding to the initial free radicals were isolated and the formation of the usual fluorination products was inhibited.[1,15] In the presence of an appreciable concentration of fluorine, reactions 5 and 4 similarly lead to the formation of fluorine addition product I. Such conditions are achieved when the rate of mixing of fluorine is fast in terms of reaction 3. However, with most of the olefins which have been investigated reaction 3 appears to occur so rapidly even at −75° (Dry Ice temperature) that it is difficult or impossible to attain an appreciable concentration of fluorine in the liquid phase. Under these conditions it is considered that the pairs of radicals formed in close proximity by reactions 3 and 4 have a relatively high probability of collision and of reaction before diffusing apart or encountering a fluorine molecule. The required very high efficiency of reaction 4 is consistent with the expected great reactivity and small steric requirement for reaction of

(7) The following olefins have yielded fluorine dimer addition products as indicated[5,6]: $CCl_2=CCl_2$, 43% at −15°[8]; CClF=CClF, 44% at −75°; $CF_3CCl=CCl_2$, 15% at 0°; $CF_3CCl=CF_2$, 63% at −75°.

(8) W. T. Miller, Jr., and E. Rutner, unpublished work.

(9) Often separated in the form of secondary reaction products.

(10) Bockemüller early proposed that the formation of fluorine addition and dimer addition products proceeded through an unstable intermediate addition compound formed between fluorine and the olefin.[11] Aside from the nebulous formulation of such a compound for which bonding orbitals are not available, it fails to explain the free radical nature of the fluorination process and the formation of the observed by-products.

(11) W. Bockemüller, *Ann.*, **506**, 20 (1933).

(12) Bigelow has suggested that the formation of fluorine dimer addition product may occur by combination of free radicals but without accounting for how such a process could become a probable one,[4] and, more recently, the possible formation of fluorine dimer addition product by free radical addition to olefin followed by reaction with fluorine.[13] The latter explanation is inconsistent with the failure of most perhalo-olefins to undergo free radical polymerization at low temperatures and with the complete lack of formation of polymers higher than dimers by reaction with fluorine.

(13) L. A. Bigelow, "Fluorine Chemistry," Vol. I, Chap. 11, Academic Press, Inc., New York, N. Y., 1950.

(14) Other by-products that have been isolated in low yields from chlorine-containing olefins[5,6] may be attributed to the presence of oxygen, which by reaction yields chlorine atoms.[15] Chlorine fluoride addition product (IV) may also result from the oxygen reaction.

the fluorine atom and minimizes the occurrence of primary combination (6).[16,19] Reactions between free radicals which diffuse away from their original partners also become probable under conditions of sufficiently low fluorine concentration in the liquid phase, and the relative importance of the two paths, both of which lead to dimer addition product (7), will vary with olefin reactant and experimental conditions.[20] However, as shown below, considerable evidence has been obtained for the diffusion-controlled combination of original pairs under the conditions of the present work.

Low temperatures to −75° have been shown, in general, to favor the formation of fluorine dimer addition product, to reduce the formation of by-products and to a lesser extent to reduce the amount of addition product.[5,6] These observations are consistent with the expected effect of increased viscosity of the reaction medium on the coupling of free radicals produced in pairs and with a lower activation energy for radical coupling (7) as compared with disproportionation (8), which requires transfer of halogen. 2-Chloropentafluoropropene, for which reaction 8 requires shift of fluorine, gave essentially no by-products at −75°.[5,6] On the other hand, it is to be expected that at sufficiently low temperatures the rate of reaction between fluorine and olefin (3) can be reduced to the point where the yield of dimer addition product will be lowered owing to increased concentration of fluorine in the liquid phase. This effect has been observed with hexachloropropene on going from 0 to −75°.[21] The temperature, through its effect on the vapor pressure of the olefin reactant, also controls the proportion of reaction occurring in the vapor phase above the liquid surface. Increased reaction in the vapor phase would be expected to increase the amount of fluorine addition product relative to dimer addition product because of the higher concentration of fluorine present and faster separation of radical pairs.

Fluorine Dimerization of Mixed Olefins.—Experiments designed to test the fluorine–olefin dimerization process outlined above, which requires the formation of pairs of free radicals with a high probability of combination, consisted of a series of reactions between elemental fluorine and mixtures of two olefins of different reactivities. Based on the assumptions that the fluorine atom reacts with all olefinic bonds indiscriminately and that free radical pairs combine with little selectivity, unambiguous predictions could be made regarding expected reaction products. For mixtures of two (or more) olefins participation in the initiation reaction 3 should vary with olefin reactivity and occur predominantly with the more reactive olefin. On the other hand, all olefins present, regardless of their reactivity toward molecular fluorine, should be attacked by fluorine atoms (4) to form free radicals which take part in reaction 7. Consequently, appreciable amounts of mixed-type dimer addition products should be produced as well as the products formed by reaction of each olefin separately with fluorine.[22]

Reactions of fluorine with the individual olefins *sym*-dichlorodifluoroethylene, 1,2-dichlorotetrafluoropropene, hexafluorocyclobutene and 2,3-dichlorohexafluoro-2-butene and with equimolar mixtures of *sym*-dichlorodifluoroethylene and each of the three other olefins were carried out at −75° under standardized reaction conditions. These olefins cover a wide range of reactivity toward fluorine, from fast to slow, and yield dimer addition products in the same order. *sym*-Dichlorodifluoroethylene is highly reactive and readily forms a dimer addition product; 2,3-dichlorohexafluoro-2-butene is unreactive by comparison and could not be shown to yield a dimer-addition product.

The reaction between fluorine and *sym*-dichlorodifluoroethylene and 2,3-dichlorohexafluoro-2-butene yielded especially clean-cut results which were in agreement with predictions. The highly reactive ethylene monopolizes the initiation step (3′); the ethylene and butene both participate in reaction 4′ and the resulting ethyl–ethyl and ethyl–butyl radical pairs combine as shown by the dimer addition products isolated (7′). The higher yield of mixed

$$CClF{=}CClF + F{-}F \longrightarrow CClF_2CClF\cdot + F\cdot \quad (3')$$

$$CClF{=}CClF + F\cdot \longrightarrow CClF_2CClF\cdot \quad (4')$$

$$CF_3CCl{=}CClCF_3 + F\cdot \longrightarrow CF_3CClFCCl(CF_3)\cdot$$

$$CClF_2CClF\cdot + CClF_2CClF\cdot \longrightarrow CClF_2CCClFCClFCClF_2 \quad (7')$$

V

$$CClF_2CClF\cdot + CF_3CClFCCl(CF_3)\cdot \longrightarrow CClF_2CClFCCl(CF_3)CClFCF_3$$

VI

dimer addition product (VI) compared with the dimer addition product of the ethylene (V), 0.13/0.061 mole, can be attributed to a concentration effect on reaction 4 since the ethylene disappears from the reaction faster than the butene. Very little dimer addition product of the ethylene was formed by reaction of a 1 to 8 molar mixture of the ethylene and butene with fluorine. The low yield of fluorine addition product of the butene relative to that of the ethylene, 0.011/0.12 mole, and the lack of fluorine dimer addition product of the butene provide support for the above interpretation and suggest that most of the butyl radicals react with the *corresponding* ethyl radicals of step 3. Other factors such as steric hindrance may conceivably prevent the formation of dimer addition product from the dichloro-2-butene and favor cross combination of the perhalo-radicals. However, no evidence for the importance of such effects has been obtained. Each

(16) Analogous to "primary recombination"[17] of pairs of radicals, produced by a dissociation, within the "cage" in which they are formed. Reaction 7 corresponds to diffusive[18] or "secondary recombination."[17]

(18) J. C. Roy, R. R. Williams, Jr., and W. H. Hamill, *ibid.*, **76**, 3274 (1954).

(19) Experimental evidence for the occurrence of reaction 6 as a primary combination process is provided by the isolation of CCl_2FCCl_2F from the fluorine-sensitized oxidation[15] and chlorination[1] of $CCl_2{=}CCl_2$.

(20) Polymeric products have been obtained in relatively low yields by reaction of perfluoro-olefins with fluorine in the vapor phase due presumably to the production of high radical populations by very rapid reaction of the olefins with fluorine.[5]

(21) W. T. Miller, Jr., and G. Cavalli, unpublished work.

(22) At least one olefin must be sufficiently reactive with fluorine to form a dimer addition product when reacting alone and also to maintain a low concentration of fluorine in the liquid phase of the mixture.

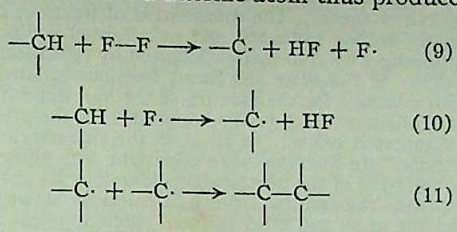
of the three possible dimer addition products was isolated from the reactions described below with hexafluorocyclobutene and 1,2-dichlorotetrafluoropropene. Further, 1,4-dichlorohexafluoro-2-butene, which is more reactive toward fluorine than the 2,3-dichloro isomer and is considered to be subject to a similar steric effect, has been shown to yield dimer addition product at 0°.[6]

Unlike 2,3-dichlorohexafluoro-2-butene, hexafluorocyclobutene and to a greater extent 1,2-dichlorotetrafluoropropene, are sufficiently reactive to take part in the initiation reaction 3 in competition with *sym*-dichlorodifluoroethylene. In all cases each of the three possible dimer addition products was isolated in an amount proportional to the relative reactivity of the olefins involved. These observations support the postulated non-selective combination of free radical pairs. The effect of fluorine concentration was also shown more clearly. Only a trace of fluorine dimer addition product, C_8F_{14}, was formed from hexafluorocyclobutene with incomplete absorption of fluorine under the standard reaction conditions. However, reaction of the butene mixed with *sym*-dichlorodifluoroethylene gave a higher yield of C_8F_{14}, 0.025 mole, with complete absorption of fluorine, as well as the dimer addition and mixed dimer addition products derived from the ethylene. The increased yield of butene dimer addition product is consistent with a reduced fluorine concentration in the liquid phase as a result of more rapid reaction with the ethylene.

Order of Olefin Reactivity with Fluorine.—The order of olefin reactivity toward molecular fluorine as shown both by amount of dimer addition product formed and by conversion under standard conditions is: $CClF{=}CClF > CF_2CF_2CF{=}CF > CF_3CCl{=}CClCF_3 > [(CF_3)_2C{=}C(CF_3)_2]$.[5] This order can be rationalized in terms of electron withdrawal and steric effects. The same reactivity sequence toward chlorine atoms is indicated by qualitative observations on the relative ease of photochemical chlorination.

Application of the Olefin Dimerization Reaction to Synthesis.—The mixed-type fluorine dimer addition products prepared in this work illustrate synthetic procedures of general application to symmetrically substituted perhalo-olefins.[23] Although yields of individual products are usually small, a wide range of compounds may be prepared by a one-step process for which alternative methods are not now available.

Reaction of Fluorine Atoms with Carbon–Hydrogen Bonds.—It has been shown previously that the formation of condensation products from saturated hydrogen-containing compounds by dehydrogenation with fluorine is most satisfactorily explained by combination of free radicals (9, 10, 11).[1] This mechanism, analogous to that for the formation of dimer addition products from olefins, was tested further by treating a mixture of chloroform and *sym*-dichlorodifluoroethylene with fluorine at −75°. At this temperature chloroform is unreactive with fluorine[24] but *sym*-dichlorodifluoroethylene reacts rapidly to produce a free radical and a fluorine atom (3′). It was of interest to determine whether or not a fluorine atom thus produced



would react with high enough efficiency with the carbon–hydrogen bond of chloroform to produce trichloromethyl radicals, in addition to fluoroethyl radicals formed from the olefin, and thus yield the mixed type condensation product $CClF_2CClFCCl_3$.

$$CHCl_3 + F\cdot \longrightarrow CCl_3\cdot + HF \qquad (12)$$

$$CClF_2CClF\cdot + CCl_3\cdot \longrightarrow \underset{\text{VII}}{CClF_2CClFCCl_3} \qquad (13)$$

Utilizing *sym*-dichlorodifluoroethylene and chloroform in the molar ratio of 1 to 2.6 for reaction, it was found possible to isolate the expected mixed condensation product VII, in addition to a larger quantity of the dimer addition product of the olefin.[25] These observations indicate a very low activation energy for reaction 12 and support the free-radical fluorine dehydrogenation mechanism presented previously. Although the fluorine atom reacted preferentially with the olefin, the selectivity is small and furnishes a striking demonstration of the high order of reactivity of the fluorine atom.

Acknowledgment.—The basic mechanism here presented for the reactions of elemental fluorine with perhalo-olefins has been developed gradually in this Laboratory over a period of years. We wish especially to acknowledge significant unpublished work by R. L. Ehrenfeld, H. F. Furber, G. Gavlin, J. M. Phelan, Maurice Prober and S. K. Reed.

Experimental Results

General Method.—Reactions were carried out with Dry Ice cooling under closely comparable conditions in a nickel U-shaped reaction vessel of the type previously described.[5] The reaction vessel was provided with a thermocouple well on the inlet side. For most of the reactions it was charged with either 0.8 mole of olefin and 1.2 moles of trichlorofluoromethane solvent or 0.8 mole of each of two olefins and 0.4 mole of trichlorofluoromethane. A 1.0-to-1.1 fluorine–nitrogen mixture was then passed in during approximately 7 hr. The fluorine–nitrogen mixture was prepared in a small brass storage tank of known volume and metered by pressure measurement.[1] Commercial tank fluorine was utilized as supplied by the Pennsylvania Salt Manufacturing Co. This was found to contain from 1.1 to 2.6% oxygen.[20] Nitrogen was utilized to exclude air during reaction and during separation of products. Reactions occurred smoothly in all cases but with an easily observable heat effect. For Dry Ice-cooled reactions internal temperatures

(23) From a symmetrical olefin and an unsymmetrical olefin two isomeric mixed-type dimer addition products are possible. However, one product may be formed preferentially. For example, $CF_3CCl{=}CF_2 + F_2$ or $F\cdot \rightarrow (CF_3)_2CCl\cdot$ as evidenced by the formation of $CF_3CCl(CF_3)_2$ in high yield.[5,6]

were maintained within the range −77 to −64° and largely below −70° (*ca.* −75°).

The reaction products were colorless and after transfer for distillation corresponded closely in weight to 95% of the combined weight of all reactants. They were separated by repeated distillations using glass and nickel wire helix packed columns. The composition of fractions containing closely boiling saturated and unsaturated compounds was determined by chlorination followed by redistillation. The weights of the more significant fractions isolated together with evidence for the identity of the new dimer-type products which are of primary importance to the present work are reported below. In all cases the characteristics of the intermediate fractions were consistent with those expected on the basis of the new products identified for the first time and with the results of previous reactions between fluorine and the same and other olefins. Boiling points are uncorrected but were determined within the range of 722 to 744 mm. pressure, unless otherwise noted. Molecular weights were determined cryoscopically in benzene. Chlorine was determined gravimetrically after sample decomposition in Parr bombs.

sym-Dichlorodifluoroethylene.—Reactants: 107 g. CClF=CClF, b.p. 20.8–21.1°, prepared from CCl_3CCl_3,[28] dissolved in 165 g. of CCl_3F, b.p. 23.6–24.6°, Freon 11, Kinetic Chemicals, Inc., and 18.6 g. of fluorine. The fluorine was added with nitrogen as described above and was completely absorbed. The following fractions were separated from the 277.4 g. of colorless liquid product.

$CClF_2CClF_2$: A saturated fraction, 14.2 g., 0.083 mole, b.p. 2.0–10.3°, was indicated as largely $CClF_2CClF_2$; previously reported[28] b.p. 3.8°.

CClF=CClF: Recovered as the dichloride, CCl_2FCCl_2F, 10.3 g., b.p. 90.7–91.2°, corresponding to 6.7 g., 0.051 mole, CClF=CClF; previously reported[28] for CCl_2FCCl_2F, b.p. 92.8°.

CCl_2FCClF_2: 5.3 g., 0.027 mole, b.p. 46–47°; previously reported[29] b.p. 46.5°.

$CClF_2CClFCClFCClF_2$: 22.4 g., b.p. 70.8–71.5° (100 mm.); 21.6 g., b.p. 71.0–71.6° (100 mm.), $n^{20}D$ 1.3849; total 44 g., 0.145 mole; previously reported[6] b.p. 134.1° $n^{20}D$ 1.3853.

2,3-Dichlorohexafluoro-2-butene (I).—Reactants: 188 g. of $CF_3CCl{=}CClCF_3$, b.p. 66.8–67.0°, Hooker Electrochemical Co., dissolved in 165 g. of CCl_3F and 19.4 g. of fluorine. Unreacted fluorine was present in the exit gases throughout the reaction. The following fractions were separated from 353.8 g. of colorless reaction product.

$CF_3CClFCClFCF_3$: 4.7 g., b.p. 50–57°; 22.6 g., b.p. 56.8–57.0°; 24.8 g., b.p. 57.5–60.5°; total 52.1 g., 0.19 mole; previously reported[30] b.p. 62.9°.

$CF_3CCl{=}CClCF_3$: Recovered as the dichloride CF_3CCl_2-CCl_2CF_3, 106.0 g., b.p. 130.5–132.5°, corresponding to 81.2 g., 0.35 mole, $CF_3CCl{=}CClCF_3$; previously reported[31] for $CF_3CCl_2CCl_2CF_3$, b.p. 131°.

$CF_3CCl_2CClFCF_3$: 1.2 g., b.p. 102–106° (micro-distillation), $n^{20}D$ 1.3529; previously reported[30] b.p. 97.5°, $n^{20}D$ 1.3530. Approximately 1 g. of higher boiling material was found.

2,3-Dichlorohexafluoro-2-butene (II).—A duplicate reaction was carried out with ice-bath cooling, internal temperature 0 to 2.3°. The fluorine was incompletely absorbed throughout.

$CF_3CClFCClFCF_3$: 62.5 g., 0.23 mole, b.p. 62.6–62.8°.

$CF_3CCl{=}CClCF_3$: Recovered as $CF_2CCl_2CCl_2CF_3$: 7.8 g., b.p. 128.0–131.1°; 78.6 g., b.p. 131.5–131.9°; corresponding to 66.2 g., 0.28 mole of $CF_3CCl{=}CClCF_3$.

$CF_3CCl_2CClFCF_3$: 10.2 g., 0.036 mole, b.p. 95.0–97.0°. Approximately 1 g. of higher boiling material was found.

sym-Dichlorodifluoroethylene and 2,3-Dichlorohexafluoro-2-butene (I).—Reactants: 107 g. of CClF=CClF and 187 g. of $CF_3CCl{=}CClCF_3$ dissolved in 107 g. of CCl_3F and 19 g. of fluorine. A trace of unabsorbed fluorine was detected in the exit gases.

$CClF_2CClF_2$: 20.7 g., 0.12 mole, b.p. 3–11°.

CClF=CClF: Recovered as the dichloride CCl_2FCCl_2F: 12.8 g., b.p. 85.0–89.5°; 23.6 g., b.p. 85.9–90.0°; corresponding to 25.4 g., 0.19 mole, CClF=CClF.

CCl_2FCClF_2: 5.0 g., 0.027 mole, b.p. 49–51°.

$CF_3CClFCClFCF_3$: 3.0 g., 0.011 mole, b.p. 56.0–56.5°.

$CF_3CCl{=}CClCF_3$: Recovered as $CF_3CCl_2CCl_2CF_3$, 154.9 g., b.p. 128.5–131.5°, corresponding to 119 g., 0.51 mole, $CF_3CCl{=}CClCF_3$.

$CF_3CCl_2CClFCF_3$: 1.6 g., 0.0056 mole, b.p. 96–100°.

$CClF_2CClFCClFCClF_2$: 18.4 g., 0.061 mole, b.p. 132–136°.

$CF_3CClFCCl(CF_3)CClFCClF_2$: 27.5 g., b.p. 171.2–*176.6*–176.8°; 19.8 g., b.p. 176.8–177.0°; 3.8 g., b.p. 175.0–175.5°; total 51.1 g., 0.13 mole. Redistillation yielded a center cut of 30.5 g., b.p. 107.7–*108.0–108.2*°–108.4° (100 mm.), formed glass between −75° and −100°, $n^{20}D$ 1.3861, d^{20}_4 1.9016. Calcd. for $C_6Cl_4F_{10}$: $MR^{20}D$, 50.1[32]; mol. wt., 404; Cl, 35.1. Found: $MR^{20}D$, 49.9; mol. wt., 415, 427, 421; Cl, 35.2, 35.2.

sym-Dichlorodifluoroethylene and 2,3-Dichlorohexafluoro-2-butene (II).—Reactants: 13.3 g., 0.10 mole, of CClF=CClF, and 186 g. of $CF_3CCl{=}CClCF_3$ dissolved in 151 g. of CCl_3F and 19.0 g. of fluorine. Small amounts of unabsorbed fluorine were detected throughout the reaction.

$CClF_2CClF_2$: 4.1 g., 0.024 mole, b.p. 5.0–6.5°.

$CF_3CClFCClFCF_3$: 44.7 g., 0.16 mole, b.p. 59.0–63.0°.

$CF_3CCl{=}CClCF_3$: Recovered as the dichloride CF_3CCl_2-CCl_2CF_3: 4.0 g., b.p. 125–132.0°; 127.1 g., b.p. 130.0–132.2°; corresponding to 100.2 g., 0.43 mole, of $CF_3CCl{=}CClCF_3$.

$CF_3CCl_2CClFCF_3$: 2.7 g., 0.0094 mole, b.p. 94.0–107.0°.

$CF_3CClFCCl(CF_3)CClFCClF_2$: 4.7 g., b.p. 102.0–107.8° (100 mm.); 4.3 g., b.p. 107.8–109° (100 mm.); 8.2 g., b.p. 108.8–110.0° (100 mm.), $n^{20}D$ 1.3861, mol. wt. 402, 408; 1.6 g., b.p. 110.0–110.5°; total 18.8 g., 0.047 mole.

Hexafluorocyclobutene.—Reactants: 125 g. of $\overline{CF_2CF_2}$-$\overline{CF{=}CF}$, b.p. 0.0–0.2°, prepared by dechlorinating $\overline{CF_2CF_2CClFCClF}$,[34] dissolved in 165 g. of CCl_3F and 18.6 g. of fluorine. About 10% of the fluorine was unabsorbed as determined iodometrically. A 61.3-g. loss was incurred in working up the fraction b.p. 2–19° obtained by initial distillation.

$\overline{CF_2CF_2CF_2CF_2}$: 26.6 g., 0.13 mole, b.p. −1.0 to 0.0°; previously reported[6] b.p. −4.0°.

$\overline{CF_2CF_2CF{=}CF_2}$: Recovered as the dichloride $\overline{CF_2CF_2}$-$\overline{CClFCClF}$, 54.0 g., b.p. 57.2–57.7°, corresponding to 37.5 g., 0.23 mole, $\overline{CF_2CF_2CF{=}CF}$; previously reported[35] for $\overline{CF_2CF_2CClFCClF}$, b.p. 59.87°.

$[\overline{CF_2CF_2CF_2CF}-]_2$: The presence of this compound was indicated by the isolation of 0.8 g., micro b.p. 85–93°, f.p. near 0° (see below for properties). Evidence for the formation of C_8F_{14}, b.p. within the range 85–102°, by reaction of fluorine with $\overline{CF_2CF_2CF{=}CF}$ had been obtained previously.[8]

sym-Dichlorodifluoroethylene and Hexafluorocyclobutene.—Reactants: 107 g. of CClF=CClF and 130 g. of $\overline{CF_2CF}$-$\overline{CF{=}CF}$ in 55 g. of CCl_3F, and 19.4 g. of fluorine. Complete absorption of fluorine was observed. An 81-g. loss was incurred from the initial fraction, b.p. 2.5–24.0°.

$\overline{CF_2CF_2CF_2CF_2}$ and $ClCF_2CClF_2$: 2.5 g., b.p. −6.9 to −5.9°; 3.6 g., b.p. −5.9° to −1.0°; 7.2 g., b.p. −1.0 to 5.3°, largely b.p. 1.3–3.2°.

$\overline{CF_2CF_2CF{=}CF}$: Recovered as dichloride $\overline{CF_2CF_2CClFC}$-

ClF, 77.2 g., b.p. 51.7–75.0°, largely b.p. 58.0°; corresponding to 53.5 g., 0.33 mole, $CF_2CF_2CF{=}CF$.

ClF=ClF: Recovered as the dichloride, CCl_2FCCl_2F, 17.3 g., b.p. 89.5–90.0°; corresponding to 11.3 g., 0.085 mole, ClF=ClF.

$CClF_2CClFCClFCClF_2$: 21.2 g., 0.070 mole, b.p. 67.0–68.3° (100 mm.).

$[CF_2CF_2CF_2CF{-}]_2$: 6.1 g., b.p. 83.4–86.8°; 2.8 g., b.p. 87.4–92.7°, total 8.9 g., 0.025 mole. Redistillation yielded a center cut of 3.8 g., b.p. 85.2–86.3° (737 mm.), f.p. −6.8°, $n^{20}D$ 1.295[37]; d^{20}_4 1.7511. Calcd. for C_8F_{14}: $MR^{20}D$ 37.2; mol. wt., 362; Cl, 0.00. Found: $MR^{20}D$ 38.0; mol. wt., 368, 364; Cl, 0.7, 0.5.

$CF_2CF_2CF_2CFCClFCClF_2$: 6.9 g., b.p. 100.0–103.9°; 18.1 g., b.p. 103.7–104.1° (738 mm.), formed glass between −84 and −100°, $n^{20}D$ 1.3294, d^{20}_4 1.7410; total 25.0 g., 0.075 mole. Calcd. for $C_6Cl_2F_{10}$: $MR^{20}D$ 38.8; mol. wt., 333; Cl, 21.3. Found: $MR^{20}D$ 38.9; mol. wt. 343, Cl, 21.4, 21.0.

1,2-Dichlorotetrafluoropropene.—Reactants: 146.4 g. of $CF_3CCl{=}ClF$, b.p. 46.5° (742 mm.), dissolved in 164 g. of CCl_3F and 19.0 g. of fluorine. The $CF_3CCl{=}ClF$ was prepared by the following reaction sequence: $CF_3CCl{=}CCl_2 \rightarrow CF_3CCl_2CCl_3$[38] $\rightarrow CF_3CCl_2CCl_2F$[39] $\rightarrow CF_3CCl{=}ClF$.[40] Approximately 3% of the fluorine was not absorbed.

$CF_3ClFCClF_2$: 23.0 g., 0.10 mole, b.p. 32.7–35.2°; previously reported b.p. 34.7°.

$CF_3CCl{=}ClF$: 32.8 g., b.p. 43.4–46.5°; 4.9 g., b.p. 47–53°; total wt. 37.7 g., 0.21 mole.

$C_6Cl_4F_{10}$: 34.5 g., 0.09 mole, b.p. 107.5–110.0°, largely b.p. 108.0–109.1° (100 mm.), $n^{20}D$ 1.3883; previously found[41] b.p. 170.5–176.7° (732 mm.).

The fluorine dimer addition product $C_6Cl_4F_{10}$ may be composed of a mixture of three possible isomers. However, the symmetrical structure $ClF_2CCl(CF_3)CCl(CF_3)ClF_2$ is favored by analogy with the structure of the corresponding product obtained from $CF_3CCl{=}CF_2$.[23]

sym-Dichlorodifluoroethylene and 1,2-Dichlorotetrafluoropropene.—Reactants: 106.3 g. of ClF=ClF and 146 g. of $CF_3CCl{=}ClF$ dissolved in 54.9 g. of CCl_3F and 19.2 g. of fluorine. The fluorine was absorbed completely.

ClF_2CClF_2: 19.8 g., 0.12 mole, b.p. 1.5–3.7°.

ClF=ClF: Recovered as CCl_2FCCl_2F, 32.7 g., b.p. 90.0–92.0°, corresponding to 21.3 g., 0.16 mole, of ClF=ClF.

$CF_3CCl{=}ClF$: Recovered as $CF_3CCl_2CCl_2F$, 105.4 g., b.p. 110.2–111.2°, corresponding to 77.0 g., 0.42 mole, of $CF_3CCl{=}ClF$.

ClF_2CCl_2F: 2.5 g., 0.013 mole, b.p. 47.2–48.5°.

$ClF_2CClFCClFCClF_2$: 8.3 g., b.p. 130.1–135.9°; 6.1 g., b.p. 134.0–135.9°; 4.4 g., b.p. 135.9–146.1°; total 18.8 g., 0.062 mole.

$C_5Cl_4F_8$: 9.7 g., b.p. 146.1–153.0°; 5.5 g., b.p. 152.4–153.0° (738 mm.), forms glass between −111 and −126°, $n^{20}D$ 1.3885, d^{20}_4 1.8335; 10.1 g., b.p. 153.1–154.7°; total 25.3 g., 0.072 mole. Calcd. for $C_5Cl_4F_8$: $MR^{20}D$ 45.3; mol. wt., 354; Cl, 40.1. Found for fraction b.p. 152.4–153.0°: $MR^{20}D$ 45.5; mol. wt., 342, 353; Cl, 38.6, 39.4.

Two structures are possible for $C_5Cl_4F_8$ without rearrangement of groups initially present. Of these $ClF_2CCl(CF_3)$-$CClFClF_2$ is preferred by analogy with the reaction of CF_3-$CCl{=}CF_2$ with fluorine.[23]

$C_6Cl_4F_{10}$: 6.1 g., b.p. 96.0–102.5° (100 mm.); 1.2 g., b.p. 103.0° (100 mm.), $n^{20}D$ 1.3859; total wt. 7.3 g., 0.018 mole.

sym-Dichlorodifluoroethylene and Chloroform.—Reactants: 83 g., 0.62 mole, of ClF=ClF; 195 g., 1.63 moles, of chloroform; and 19.0 g. of fluorine. The fluorine was almost completely absorbed. Two duplicate reactions were carried out and the products combined for separation.

CF_3ClF_2: 3.2 g., 0.021 mole, b.p. −40.2 to −38.8°; previously reported[28] b.p. −38°.

ClF_2CClF_2: 5.6 g., b.p. −1.1 to 1.3°; 33.8 g., b.p. 1.3–2.7°; 7.7 g., b.p. 2.7–3.7°; total 47.1 g., 0.28 mole.

ClF=ClF: 20.7 g., 0.16 mole, b.p. 19.2–23.7°.

ClF_2CCl_2F: 19.6 g. of material, b.p. 37.9–50.1°, was collected.

$ClF_2CClFCClFCClF_2$: 7.5 g., b.p. 69.5–72.2° (100 mm.); 45.2 g., b.p. 72.0–72.2° (100 mm.); total 52.7 g., 0.17 mole.

$CCl_3CClFCClF_2$: 4.7 g., b.p. 87.2–87.3° (100 mm.); 3.7 g., b.p. 87.5–88.0° (100 mm.), estimated b.p. 153° (760 mm.), formed glass between −109° and −117°, $n^{20}D$ 1.4384, d^{20}_4 1.7603; 2.2 g., b.p. 88.3–88.8° (100 mm.); 5.1 g., b.p. 89.0–94.0° (100 mm.); total 15.7 g., 0.058 mole. Calcd. for $C_3Cl_3F_3$: $MR^{20}D$ 40.3; mol. wt., 270; Cl, 65.6. Found for fraction b.p. 87.5–88.0° (100 mm.): $MR^{20}D$ 40.3; mol. wt., 261, 261; Cl, 66.0, 66.1.

The following properties have been reported for CCl_3-$CClFCClF_2$: b.p. 153.3°, f.p. −14.8°, $n^{20}D$ 1.43919, d^{20}_4 1.7702, $MR^{20}D$ 40.18.[43] However, the evidence for the assigned structure is not entirely conclusive[44] and would now appear to require re-examination.

The residue from the above separation contained 1.2 g. of sublimable white solid which appeared to be hexachloroethane.

Polyalkylene Disulfides

BY C. S. MARVEL AND L. ELMER OLSON[1]

RECEIVED FEBRUARY 20, 1957

The oxidation of alkylene dimercaptans by air in soap emulsion has been found to be a useful method of producing polyalkylene disulfides.

The oxidation of a dimercaptan by air to a polydisulfide has been patented as a polymer-forming reaction by Patrick,[2] but it has never been very widely used in scientific work.

In the distillation of some dimercaptans which were being purified for other uses, it was noted that a polymeric material built up in the flask apparently

(1) Some of the preliminary experiments which led to the work discussed in this manuscript were performed as a part of the research project sponsored by the Reconstruction Finance Corporation, Office of Synthetic Rubber, in connection with the government synthetic rubber program.

[a] Polymer $[\alpha]^{25}D$ +19.5°, *c* 2 in chloroform. [b] Calculated after one reprecipitation from chloroform by methanol. [c] Measured in chloroform after one reprecipitation. [d] This polymer was prepared by Eugene D. Vessel. [e] Fractionation of the polymers by repeated reprecipitation from chloroform and methanol gave a rubber-like material with an inherent viscosity of 0.95.

due to oxidation. Some of these polymeric residues had inherent viscosities of 0.08. This observation suggested that the air oxidation of dimercaptans might be a useful polymer-forming reaction.

When a dimercaptan was dispersed in an aqueous soap solution and air was passed through the mixture, oxidation to a polydisulfide readily occurred and a stable polymer latex was produced. Foaming was troublesome but the addition of a little silicone antifoam agent[3] controlled it. It was also necessary to add water to the reaction mixture from time to time to maintain the volume. The reaction at room temperature was slow and required 4 to 10 days to yield a polymer with an inherent viscosity of 0.2 to 0.3. The addition of a little selenious acid[4] to the reaction mixture speeded up the oxidation so that high molecular weight polymers could be prepared in a shorter time. The limiting factors on the molecular size seem to be the purity of the dimercaptan and the time of oxidation. Tough, plastic, odorless polydisulfides with inherent viscosities as high as 1 have been obtained.

The polydisulfide derived from the dimercaptan prepared by adding two moles of thiolacetic acid to 4-vinyl-1-cyclohexene and hydrolyzing was heated with sulfur at 150° for three hours. This reaction yielded a more rubber-like polymer which was far less soluble in organic solvents than the untreated polymer. Analysis of the new polymer showed that approximately 0.7 atom of sulfur had been added for each disulfide link[5] in the original material.

Some experiments were conducted to determine whether such oxidizing agents as halogen, nitric acid or ferric chloride could be used in place of air, but none of these worked as satisfactorily as air in our emulsion systems. One experiment on the oxidation of hexamethylene dimercaptan with bromine is described in the Experimental part.

Experimental

Polymerizations.—A typical oxidation polymerization was carried out as follows. In a 4-ounce wide-mouth bottle were placed 50 ml. of distilled water, 1.5 g. of lauric acid, 4 g. of potassium hydroxide and 5 ml. of dimercaptan. When these ingredients were dissolved, 1 drop of Antifoam A was added. Filtered compressed air was bubbled through the mixture from a piece of 6 mm. glass tubing at a rate of about two bubbles a second for four to ten days. More Antifoam A was added as needed to control foaming and the volume of the mixture was maintained by adding distilled water as needed. At the end of the oxidation period the Antifoam A was removed by skimming it off the surface and the polymer latices were coagulated. Polymers coagulated with 20 ml. of alum coagulant, prepared by dissolving 100 g. of aluminum potassium sulfate in a mixture of 100 ml. of concentrated hydrochloric acid and one liter of distilled water, had up to 20% ash as residue after combustion. The ash could be diminished but not eliminated by repeated reprecipitations of the polymer from benzene or chloroform into methanol. Polymers coagulated by pouring the emulsion into methanol containing some hydrochloric acid and then reprecipitated gave satisfactory analyses. The polymers were dried in a vacuum desiccator, then dissolved in 50 ml. of chloroform and reprecipitated by pouring these solutions into 400 ml. of methanol.

In later runs approximately 5–20 mg. of selenious acid was introduced in the emulsion as a catalyst. When 20 mg. of this catalyst was used, the polymer obtained by breaking the emulsions varied in color from pink to red. This color could be removed by adding a small amount of sodium hydroxide (about 1 g. per 400 ml.) to the methanol used in the reprecipitation of the polymer from chloroform solution.

Some of the oxidation polymerization experiments are recorded in Tables I and II.

Addition of Sulfur to Polydisulfide from 1-β-Mercaptoethyl-3(or 4)-mercaptocyclohexane.—In a 125-ml. erlenmeyer flask containing 50 ml. of carbon disulfide were dissolved 0.60 g. of sulfur and 1.22 g. of disulfide polymer from β-mercaptoethyl-3(or 4)-mercaptocyclohexane, inherent viscosity 0.27. The carbon disulfide was allowed to evaporate in the hood and the flask and contents were heated in an oil-

(3) Dow Corning Antifoam A was used.

bath at 150° for three hours. When the flask was removed from the bath for inspection, the molten contents solidified and would not remelt when heated to 165°. The polymer was suspended in 100 ml. of chloroform and slowly poured into 400 ml. of rapidly stirred methanol. The polymer was washed with methanol and dried for analysis; yield 1.35 g. The original polymer was tough and plastic while the final polymer was rubbery. The new polymer became tacky when heated to 245° and became molten at 320°. The new polymer was 34% soluble in chloroform and the soluble portion had an inherent viscosity of 0.39.

Anal. Calcd. for $C_8H_{14}S_2$: C, 55.12; H, 8.10; S, 36.79. Calcd. for $C_8H_{14}S_4$: C, 40.29; H, 5.92; S, 53.79. Found: C, 49.07; H, 7.29; S, 43.83. Calcd. for $C_8H_{14}S_{2.7}$: C, 48.84; H, 7.17; S, 44.00.

Oxidation of Hexamethylenedithiol with Bromine.—Five ml. of hexamethylenedithiol was added to 50 ml. of 2% MP-635-S[7] solution in a four-ounce polymerization bottle. Three grams of sodium hydroxide was added and the mixture shaken until solution was complete. Then 6 g. of bromine was added and the bottle was capped and shaken on a mechanical shaker for 3 hours. Some polymer formed almost immediately and separated as precoagulant. At the end of the shaking period alum coagulant[7] was added to break the emulsion and the polymer was collected on a filter. The precipitate contained a great deal of inorganic material. By extracting with chloroform and evaporating this solution, about 60% of the theoretical yield of polymer was obtained as a white powder with an inherent viscosity of 0.21.

Anal. Calcd. for $C_6H_{12}S_2$: C, 62.00; H, 10.41; S, 27.59. Found: C, 61.62; H, 9.98; S, 28.11.

Allylic Chlorides. XXIV. 1,1,3-Trichloro-1-propene, 1,1-Dibromo-3-chloro-1-propene and Related Compounds[1,2]

BY LEWIS F. HATCH AND STANLEY D. ZIMMERMAN

RECEIVED DECEMBER 26, 1956

1,1,3-Trichloro-1-propene and 1,1-dibromo-3-chloro-1-propene have been prepared by conversion of the dihalopropenes to the corresponding allylic bromides using N-bromosuccinimide, basic hydrolysis of the bromides to the allylic alcohols and treatment of the alcohols with phosphorus trichloride. Relative reactivities of the allylic chlorides with sodium ethoxide in ethanol were determined. The reaction with potassium iodide in acetone gave kinetically anomalous data. The products from this reaction were 1,1-dihalo-3-iodo-1-propenes.

A number of closely related allylic chlorides have been prepared and their relative reactivities toward sodium ethoxide in ethanol and potassium iodide in acetone determined. The ones of interest in the present work are $CY_2{=}C(H){-}CH_2Cl$ (Y = H, CH_3) and $CCl_2{=}C(Y){-}CH_2Cl$ (Y = F, Cl, CH_3). The introduction of two methyl groups on the *gamma* carbon atom increases the reactivities of the allylic chlorine atom in both reactions. Since the methyl group is electron releasing, it was desirable to determine the effect of electron attracting groups in this position. For this purpose 1,1,3-trichloro-1-propene and 1,1-dibromo-3-chloro-1-propene have been prepared and studied.

Both of these allylic chlorides were prepared by the series of reactions shown in Fig. 1 for 1,1,3-trichloro-1-propene. The allylic chlorides and all of the intermediate compounds are lachrymators and vesicants. The preparation of 1,1,3-trichloro-1-propene by other methods has been reported.[3]

Attempts to prepare both 1,1,3-trichloro-1-propene and 1,1-dibromo-3-chloro-1-propene directly by the reaction between N-chlorosuccinimide and the corresponding dihalopropene ($CX_2{=}CHCH_3$) were unsuccessful. No definite product could be separated from either reaction. The oxidation of 1,1-dichloro-1-propene to 3,3-dichloro-2-propen-1-ol using selenium dioxide was attempted under various conditions of temperature and solvent. Apparently no oxidation took place.

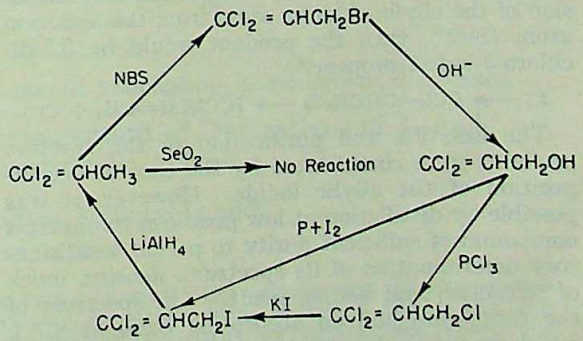

Fig. 1.—1,1-Dichloro-3-halo-1-propenes.

The relative reactivities of the two allylic chlorides with sodium ethoxide in ethanol are given in Table I. The greater reactivity of the dibromo compound is consistent with previous work with the 1,3-dichloropropenes[4] and the 1-bromo-3-chloro-1-propenes.[5] A comparison between the effect of halogen atoms and methyl groups in this position is complicated by the possibility of hydro-

[a] Allyl chloride as 1.00 with k = 1.18.

The kinetic data for the reaction of 1,1,3-trichloro-1-propene and 1,1-dibromo-3-chloro-1-propene with potassium iodide in acetone were of such a nature that constant values of second-order rate constants were not obtained. This behavior of polyhalo allylic chlorides has been observed previously.[7] Since these kinetic studies with potassium iodide gave anomalous results, the products from each of the dihalo allylic chlorides were isolated and characterized.

If the reaction of 1,1,3-trichloro-1-propene with iodide ion is an SN2 reaction, there should be a simple exchange of the allylic chlorine atom by an iodine atom.

$$CCl_2{=}CHCH_2Cl + KI \longrightarrow CCl_2{=}CHCH_2I + KCl$$

If the reaction were to proceed by a nucleophilic attack on the γ-carbon atom followed by, or simultaneous with, an allylic rearrangement and expulsion of the allylic chlorine atom from the α-carbon atom (SN2′), then the product would be 3,3-dichloro-3-iodo-1-propene.[8,9]

$$I^- \longrightarrow CCl_2{=}CHCH_2Cl \longrightarrow ICCl_2CH{=}CH_2 + Cl^-$$

The isolation and purification of the reaction products were complicated by the ease of decomposition of the allylic iodide. However, it was possible by distillation at low pressures to obtain a compound of sufficient purity to permit a satisfactory determination of its spectrum, density, index of refraction and boiling point. The spectrum of the compound had an absorption band at 8.7 μ which was indicative of the allylic iodide structure ($CCl_2{=}CHCH_2I$).[10] It did not have an absorption band at 10.1 μ which is characteristic of a monosubstituted ethylene.

This compound also was treated with lithium aluminum hydride, and 1,1-dichloro-1-propene was obtained as the only product.[11] The structure was further established by comparison of the compound with an authentic sample prepared by the treatment of 3,3-dichloro-2-propen-1-ol with red phosphorus and iodine (Fig. 1). The spectrum of the allylic iodide was essentially identical with that obtained for the compound isolated from the reaction with potassium iodide. The physical properties of the two compounds were as close as expected for compounds as unstable as these.

As a further check on the identity of the unknown product from the potassium iodide reaction, its 3,5-dinitrobenzoate was prepared by the use of silver 3,5-dinitrobenzoate and compared with that obtained from an authentic sample of 1,1-dichloro-3-iodo-1-propene as well as with the 3,5-dinitrobenzoates of the corresponding chloride, bromide and alcohol. Mixtures of all possible pairs of these 3,5-dinitrobenzoates in no instance gave a lowering of the melting point.

The compound isolated from the reaction of 1,1-dibromo-3-chloro-1-propene and potassium iodide was shown to be 1,1-dibromo-3-iodo-1-propene in the same manner as that used for the identity of the product from 1,1,3-trichloro-1-propene.

Infrared spectra obtained for the various compounds prepared during this investigation were the same as would have been predicted for the particular compound. It is of especial significance that with the allylic chlorides there was always an absorption at 8.01 μ; with the allylic bromides the absorption was at 8.30 μ and with the iodides at 8.7 μ.[10]

Experimental

3-Bromo-1,1-dichloro-1-propene.—3-Bromo-1,1-dichloro-1-propene was prepared in a 75% yield by the bromination of 2.00 moles of 1,1-dichloro-1-propene (b.p. 76.5–77.0°; n^{25}D 1.4418; d^{25}_4 1.1675) using N-bromosuccinimide (1.00 mole) and conventional procedures. The 3-bromo-1,1-dichloro-1-propene had the following physical properties: b.p. 45.1° (10 mm.); n^{20}D 1.5363, n^{25}D 1.5337, n^{30}D 1.5310; d^{20}_4 1.7593, d^{25}_4 1.7506, d^{30}_4 1.7421. *Anal.* Calcd. for $C_3H_3BrCl_2$: total halogen, 79.4; Br, 42.1. Found: total halogen, 79.7, 79.5; Br, 41.8, 42.0.

3,3-Dichloro-2-propen-1-ol.—3-Bromo-1,1-dichloro-1-propene (1.00 mole) was hydrolyzed by use of a 7.5% sodium carbonate solution at 65 to 70° for 8 hr. An 85% yield of 3,3-dichloro-2-propen-1-ol was obtained. The dichloro-alcohol had the following physical properties: b.p. 75–77° (20 mm.); n^{20}D 1.4918, n^{25}D 1.4898, n^{30}D 1.4879; d^{20}_4 1.3830, d^{25}_4 1.3770, d^{30}_4 1.3718 (lit.[12] b.p. 72° (18 mm.); n^{16}D 1.4883; d^{16} 1.3617). *Anal.* Calcd. for $C_3H_4Cl_2O$: Cl, 55.9. Found: Cl, 56.1, 56.0.

1,1,3-Trichloro-1-propene.—1,1,3-Trichloro-1-propene was prepared by treating 3,3-dichloro-2-propen-1-ol (0.50 mole) with phosphorus trichloride (0.20 mole) in dry pyridine (0.11 mole) at 65° for 2 hr. A 90% yield was obtained. Physical properties of the 1,1,3-trichloro-1-propene were: b.p. 59.5° (50 mm.); n^{20}D 1.4958, n^{25}D 1.4930, n^{30}D 1.4904; d^{20}_4 1.4030, d^{25}_4 1.3953, d^{30}_4 1.3876 (lit.[3b] b.p. 132–133°; n^{20}D 1.4962; d^{20}_4 1.3983). *Anal.* Calcd. for $C_3H_3Cl_3$: Cl, 73.2. Found: Cl, 73.4, 73.6.

1,1-Dichloro-3-iodo-1-propene from the Alcohol, Red P and I_2.—A mixture of 3,3-dichloro-2-propen-1-ol (0.50 mole) and red phosphorus (0.10 mole) was stirred vigorously, and cooled while iodine (0.10 mole) was added portionwise and cautiously to the flask. After all of the iodine was added, the mixture was warmed to 70–80° until the iodine coloration of the condensate on the flask walls had disappeared. Then 0.05 mole of iodine was added and heating continued

until once again the iodine coloration was gone. The mixture was cooled and filtered and the filtrate distilled. The 1,1-dichloro-3-iodo-1-propene had the following physical properties: b.p. 34° (1 mm.); $n^{20}D$ 1.6030, $n^{25}D$ 1.5998, $n^{25}D$ 1.5968; d^{20}_4 2.0480, d^{25}_4 2.0401, d^{30}_4 2.0300. *Anal.* Calcd. for $C_3H_3Cl_2I$: total halogen, 83.5; I, 53.6. Found: total halogen, 83.7, 83.7; I, 54.1, 54.0.

Lithium Aluminum Hydride Reduction of 1,1-Dichloro-3-iodo-1-propene from 3,3-Dichloro-2-propen-1-ol, Red P and I_2.—A mixture of 1,1-dichloro-3-iodo-1-propene (0.27 mole) and 10 ml. of ether was stirred rapidly while a suspension of lithium aluminum hydride (0.075 mole) in 20 ml. of ether was added at a rate to produce gentle refluxing. The excess lithium aluminum hydride was destroyed by 2% sulfuric acid and the organic layer was worked up in the usual manner. 1,1-Dichloro-1-propene (b.p. 75–76° (750 mm.); $n^{25}D$ 1.4441) was obtained as the only product.

1,1-Dichloro-3-iodo-1-propene from 1,1,3-Trichloro-1-propene and KI.—1,1,3-Trichloro-1-propene (0.25 mole) was added slowly to 0.25 mole of potassium iodide in 600 ml. of acetone at 10°. The reaction product was worked up in the usual manner and gave 1,1-dichloro-3-iodo-1-propene as the only product. Its physical properties were: b.p. 34.5–35° (1 mm.); $n^{20}D$ 1.6017, $n^{25}D$ 1.5990, $n^{30}D$ 1.5959; d^{20}_4 2.0529, d^{25}_4 2.0440, d^{30}_4 2.0346. *Anal.* Calcd. for $C_3H_3Cl_2I$: total halogen, 83.5; I, 53.6. Found: total halogen, 83.8, 83.9; I, 54.0, 53.7.

Lithium Aluminum Hydride Reduction of 1,1-Dichloro-3-iodo-1-propene from 1,1,3-Trichloro-1-propene and KI.—The same procedure was used as in the reduction of the product obtained from the reaction of 3,3-dichloro-2-propen-1-ol, red phosphorus and iodine. The physical properties of the 1,1-dichloro-1-propene were: b.p. 75–76° (750 mm.); $n^{25}D$ 1.4439.

1,1-Dibromo-3-chloro-1-propene.—A similar series of reactions were carried out for the preparation of 1,1-dibromo-3-chloro-1-propene from 1,1-dibromo-1-propene as used in the preparation of 1,1,3-trichloro-1-propene from 1,1-dichloro-1-propene. The yields and physical properties of the various compounds follow.

1,1-Dibromo-1-propene: b.p. 41.5° (30 mm.); $n^{25}D$ 1.5245.

1,1,3-Tribromo-1-propene: yield 73%; b.p. 62–64° (0.5 mm.); $n^{20}D$ 1.6030, $n^{25}D$ 1.6006, $n^{30}D$ 1.5980; d^{20}_4 2.4408, d^{25}_4 2.4304, d^{30}_4 2.4207. *Anal.* Calcd. for $C_3H_3Br_3$: Br, 86.0. Found: Br, 85.7, 85.7.

3,3-Dibromo-2-propen-1-ol: yield 80%; b.p. 62–64° (0.5 mm.); $n^{20}D$ 1.5652, $n^{25}D$ 1.5633, $n^{30}D$ 1.5611; d^{20}_4 2.1788, d^{25}_4 2.1707, d^{30}_4 2.1632. *Anal.* Calcd. for $C_3H_4Br_2O$: Br, 74.0. Found: Br, 73.5, 73.6.

1,1-Dibromo-3-chloro-1-propene: yield 81%; b.p. 35.5–36.0° (0.6 mm.); $n^{20}D$ 1.5663, $n^{25}D$ 1.5634, $n^{30}D$ 1.5610; d^{20}_4 2.1365, d^{25}_4 2.1260, d^{30}_4 2.1162. *Anal.* Calcd. for $C_3H_3Br_2Cl$: total halogen, 83.3; Cl, 15.1. Found: total halogen, 83.4, 83.6; Cl, 14.7, 14.8.

1,1-Dibromo-3-iodo-1-propene from 3,3-Dibromo-2-propen-1-ol, Red P and I_2: b.p. 50° (0.1 mm.); $n^{20}D$ 1.6737, $n^{25}D$ 1.6708, $n^{30}D$ 1.6681; d^{20}_4 2.7283, d^{25}_4 2.7171, d^{30}_4 2.7060. *Anal.* Calcd. for $C_3H_3Br_2I$: total halogen, 88.0; I, 39.0. Found: total halogen, 88.3, 88.3; I, 39.1, 39.2.

Lithium Aluminum Hydride Reduction of 1,1-Dibromo-3-iodo-1-propene from 3,3-Dibromo-2-propen-1-ol, Red P, and I_2.—1,1-Dibromo-1-propene was the only product; b.p. 40° (29 mm.); $n^{25}D$ 1.5245.

1,1-Dibromo-3-iodo-1-propene from 1,1-Dibromo-3-chloro-1-propene and KI: b.p. 51° (0.2 mm.); $n^{20}D$ 1.6731, $n^{25}D$ 1.6703, $n^{30}D$ 1.6675; d^{20}_4 2.7196, d^{25}_4 2.7082, d^{30}_4 2.6975. *Anal.* Calcd. for $C_3H_3Br_2I$: total halogen, 88.0; I, 39.0. Found: total halogen, 88.1, 88.2; I, 39.1, 39.3.

Lithium Aluminum Hydride Reduction of 1,1-Dibromo-3-iodo-1-propene from 1,1-Dibromo-3-chloro-1-propene and KI.—1,1-Dibromo-1-propene was the only product; b.p. 41° (30 mm.); $n^{25}D$ 1.5247.

3,5-Dinitrobenzoates.—3,5-Dinitrobenzoates of the alcohols and all of the allylic halides were prepared using 3,5-dinitrobenzoyl chloride for the alcohols and the silver salt of 3,5-dinitrobenzoic acid for the halides. All of the alcohol derivatives with each of the corresponding allylic halide derivative showed no melting point depression. The melting point range for the dichloro derivatives was 69.5–70.8° and 90.2–91.2° for the dibromo derivatives. *Anal.* Calcd. for $C_{10}H_6Cl_2N_2O_6$ (from the alcohol): Cl, 22.1; N, 8.73. Found: Cl, 21.8, 22.0; N, 8.94. Calcd. for $C_{10}H_6Br_2N_2O_6$ (from the alcohol): Br, 39.0; N, 6.83. Found: Br, 38.6, 38.8; N, 7.05.

Reaction with Potassium Iodide in Acetone at 20°.—No consistent rate data could be obtained with either 1,1,3-trichloro-1-propene or 1,1-dibromo-3-chloro-1-propene. The weight of potassium chloride formed during the reaction indicated a 66% reaction in 15 minutes and an 88% reaction in 30 minutes.

Reaction of Sodium Ethoxide in Ethanol at 50°.—The procedure was the same as that previously described[4] and the data were calculated using the rate expression for a second-order reaction. The sodium ethoxide solution was 0.09931 molar for the reaction with 1,1,3-trichloro-1-propene (0.1025 molar) and 0.09182 molar for 1,1-dibromo-3-chloro-1-propene (0.1025 molar). A plot of $\log b(a-x)/a(b-x)$ *vs.* time gave a straight line for 1,1,3-trichloro-1-propene between 26 and 81% reacted and for 1,1-dibromo-3-chloro-1-propene between 18 and 72% reaction. Selected data are given in Table I. Reaction of the vinyl halogens under these conditions was less than 1%.

Studies of Configuration. III. The Rearrangement of Derivatives of 3- and 4-Methoxycyclohexanecarboxylic Acids[1]

BY DONALD S. NOYCE AND HAROLD I. WEINGARTEN[2]

RECEIVED NOVEMBER 10, 1956

The mechanism of the ether–acid halide rearrangement has been further clarified. The rearrangement of *cis*-3-methoxycyclohexanecarboxylic acid to methyl *trans*-3-chlorocyclohexanecarboxylate by the action of thionyl chloride has been studied. The *trans* isomer does not undergo rearrangement. These facts not only clarify the rearrangement process, but serve as independent evidence for the configuration of the isomers of 3-methoxycyclohexanecarboxylic acid. Similar results are obtained with 4-methoxycyclohexanecarboxylic acid. The cyclic oxonium ion intermediate opens by a process largely S_N2 in character, with an additional factor of accelerated reaction in the case of ring-breaking displacement on a five-membered ring. Olefin formation accompanies the rearrangement. The olefin formed, methyl 3-cyclohexene-1-carboxylate is free of isomers, and this suggests that the elimination process is a synchronous reaction not proceeding from the simple carbonium ion.

The cleavage of ethers by acid halides has been investigated sporadically for many years. Benzoyl iodide was shown to cleave ether by Kishner.[3] Acid halides and acid anhydrides cleave ethers in the presence of Lewis acids.[4] These reactions un-

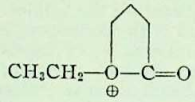
doubtedly involve the preliminary formation of an oxonium salt by reaction of the ether with the acid derivative, with concomitant weakening of the two carbon–oxygen ether bonds. The weakened carbon–oxygen bonds may then be subsequently cleaved bimolecularly or unimolecularly depending upon the structure of the molecule and the medium.

The intramolecular counterpart of these reactions also has received some attention. Blicke, Wright and Zienty[5] studied the rearrangement of γ-alkoxybutyryl chloride, but reached no conclusions concerning the mechanism. Prelog and Heinbach-Juhasz[6] investigated the kinetics of the rearrangement of ω-ethoxybutyryl chloride and ω-ethoxyvaleryl chloride to the ethyl ω-chloro esters, and found them to be first order in the acid chloride. The reaction was pictured as proceeding through the cyclic oxonium ion I which could react with chloride ion to form the ester. Wiberg[7] showed



I

that with an optically active homolog, the second step in this sequence was stereospecific with inversion.

In the present study, we have shown that the further consequence of this mechanism, namely, that a suitably chosen pair of *cis* and *trans* isomers should show distinctive differences in behavior, is correct.

Pure *cis*-3-methoxycyclohexanecarboxylic acid (*cis*-II) was obtained by fractional crystallization from pentane of the mixed *cis*- and *trans*-II obtained by reduction of *m*-methoxybenzoic acid. When *cis*-II was heated with phosphorus tribromide at 100° for two hours, there resulted 80% of methyl *trans*-3-bromocyclohexanecarboxylate (III) and a small quantity of an unsaturated ester. The structure of III was established by unambiguous synthesis. The lactone of *cis*-3-hydroxycyclohexanecarboxylic acid was converted to *trans*-3-bromocyclohexanecarboxylic acid of melting point 65°[8] with hydrogen bromide and esterified with diazomethane to give III. Though Perkin and Tattersall[9] originally assigned the *cis* configuration to the 65° isomer, Siegel and Morse have pointed out that it is undoubtedly *trans*. III could not be hydrolyzed successfully to the known acid of m.p. 65° due to its instability in hydroxylic solvents. This instability also has been observed by Siegel and Morse, and constitutes additional evidence for the *trans* configuration of the 65° isomer. Comparison of the infrared spectra of the synthetically prepared III and III resulting from the rearrangement revealed no differences.

When *cis*-II was heated in thionyl chloride for two hours, two products subsequently were isolated, the expected methyl *trans*-3-chlorocyclohexanecarboxylate (IV) and methyl 3-cyclohexene-1-carboxylate (V). IV and V, formed in the ratio of 3:5, were isolated in a combined yield approaching 90%. Acidic hydrolysis of IV gave *trans*-3-chlorocyclohexanecarboxylic acid, m.p. 52°. The structure was assigned on the basis of the analogous bromine compounds.

The olefinic ester V from the rearrangement, isolated in minor quantities in the treatment of *cis*-II with phosphorus tribromide, and in major quantities on treatment of *cis*-II with thionyl chloride, was shown to be methyl 3-cyclohexene-1-carboxylate by comparison of the infrared spectrum with that of an authentic sample prepared from methyl acrylate and butadiene. The infrared spectra of the two alternate isomers showed distinctive differences. There was no evidence for the presence of any of the isomers within the limits of accuracy of the analysis.

To determine the generality of the ether acid halide rearrangement in the cyclohexanecarboxylic acid derivatives, pure *cis*-4-methoxycyclohexanecarboxylic acid (*cis*-VI) was prepared and treated with both thionyl chloride and phosphorus tribromide. *cis*-VI was prepared by high pressure hydrogenation of methyl anisate, the derived methyl 4-methoxycyclohexanecarboxylate being then hydrolyzed and the 4-methoxycyclohexanecarboxylic acid separated into its component isomers by fractional crystallization.

On heating in thionyl chloride *cis*-VI gave rise to methyl *trans*-4-chlorocyclohexanecarboxylate (VII) and V in a ratio of 3:4 and in an over-all yield of 80%. Rearrangement of *cis*-VI in phosphorus tribromide led to the formation of 58% of methyl *trans*-4-bromocyclohexanecarboxylate (VIII) and 16% of *trans*-4-bromocyclohexanecarboxylic acid, which could have arisen either by cleavage of VIII or *cis*-VI.

VIII was hydrolyzed in low yield to the *trans*-4-bromocyclohexanecarboxylic acid, m.p. 170.8–171.4°, which compares favorably with the value, 167°, recorded by Perkin.[10] *trans*-4-Chlorocyclohexanecarboxylic acid, m.p. 159.0–159.8°, obtained by hydrolysis of VII in 88% yield, has to our knowledge not been reported previously in the literature. The structure is assigned by analogy with the acid obtained from VIII.

When the *trans*-3-methoxycyclohexanecarboxylic acid (*trans*-II) was subjected to treatment with thionyl chloride, the acid chloride was obtained. In fact, treatment of the mixed isomers of II obtained directly from the hydrogenation with thionyl chloride followed by treatment with water, led directly to the isolation of *trans*-II, with *cis*-II being converted to IV and V. In like fashion, *trans*-4-methoxycyclohexanecarboxylic acid (*trans*-VI) with thionyl chloride was converted to the acid chloride and did not undergo rearrangement. The treatment of *trans*-II and *trans*-VI led to reaction different from that observed with the *cis* isomers.

Discussion

The following sequence is in accord with the facts presented here and the discussion which fol-

lows. The first step is the formation of the acid halide (IX), which in the diaxial conformation IXa may undergo intramolecular displacement of the halide ion to give the bicyclic oxonium salt X. There are several pathways of reaction open to X, and each presents points of interest. X may undergo (a) elimination of a proton to give the unsaturated ester which has been shown to be V; (b) reaction with halide ion at carbon-3 to give III or IV; (c) reaction with halide ion at the methyl carbon to give the lactone or products resulting therefrom.

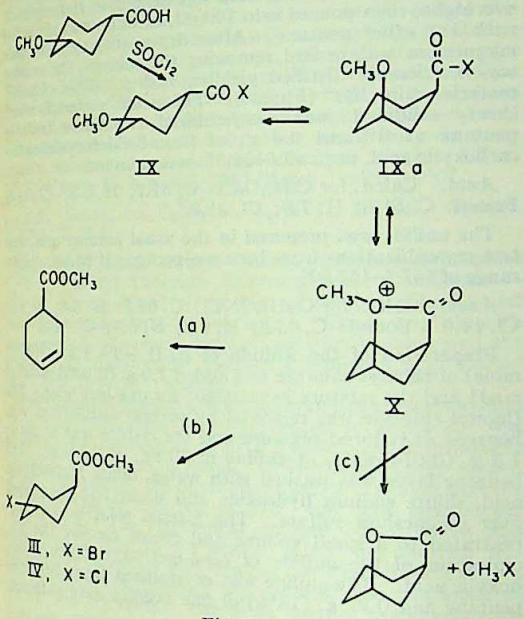

Fig. 1.

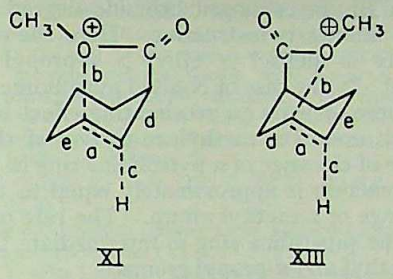
It is first instructive to consider the competitive formation of the unsaturated ester. In the present cases, there is a greater proportion of unsaturated ester formed than was reported by Winberg or Prelog. This is undoubtedly due to the fact that in the intermediate X, the planar four-center arrangement favorable to elimination is appropriately locked in place. This makes it possible for elimination to compete favorably on an energetic basis with further substitution.

The preference for elimination of the 4-hydrogen over the 2-hydrogen warrants further comment. Examination of the postulated transition state XI leading to methyl 2-cyclohexene-1-carboxylate (XII) reveals that as the double bond (a) is forming and bonds (b) and (c) are breaking, bonds (a), (d) and (e) must be rotated into coplanarity. These three events may be difficult to coördinate since (d) and (e) cannot be rotated a great deal until (b) is broken—*i.e.*, in order to rotate (d) into the (a)(e) plane the carbomethoxy group must be moved rather far from carbon-3.

In the postulated transition state (XIII) leading to methyl 3-cyclohexene-1-carboxylate (V), as the double bond (a) is forming and bonds (b) and (c) are breaking bonds (a), (d) and (e) must be rotated into coplanarity. The three events occurring in this transition state can be more easily coördinated since the carbomethoxy group formed is one carbon farther removed from the developing double bond. Furthermore, an investigation of a Fisher–Hirshfelder–Taylor model of V shows that the centers of the methoxyl oxygen and the center of the carbon-3, when in the conformation permitting their closest approach, are about 3.5 Å. apart. The corresponding distance in XII is about



4.0 Å. Therefore, at the instant bond (b) is broken, the conformation of the distorted XII will be at a higher energy than the distorted V by an amount related to the 0.5 Å. difference between the methoxyl oxygen and carbon-3 in the conformations pictured above. This energy difference will be reflected in their transition states.

It is further to be noted that the ionization of X to the ring carbonium ion is not consistent with the facts since it has been shown[11] that methyl *cis*-3-tosyloxycyclohexanecarboxylate (XV) undergoes normal solvolysis and elimination. The products of elimination resulting from XV are V and XII, with V predominating.

It is thus clear that the elimination process is synchronous, and that the geometry of the transition state exerts a profound control upon the product formed.

Turning now to the question of the two substitution processes available to the oxonium ion X, it is noteworthy that ring substitution occurs, with no evidence for substitution at the methyl carbon (pathway c above). The preference for reaction at a secondary carbon is not simply explicable upon the basis of SN1 behavior for the following reasons. The examples studied by Prelog and by Heinbach-Juhasz[6] would have been expected on this basis to give a mixture of products. This was not observed. The cleavage of methyl *sec*-butyl ether by acetyl iodide[12] affords 52% methyl iodide and 28% *sec*-butyl iodide. Were the cleavage SN1 in character, the secondary iodide should be the major product. Were the mechanism a normal SN2 displacement the methyl iodide should be more highly favored. It is suggestive at this point to conclude that the mechanism is of the displacement type, but with the effect of the positively charged leaving group being that differences in rate of reactions at primary, secondary and tertiary carbons are minimized or leveled.

Further comparison may be drawn with the displacement reaction accompanying the decomposition of sulfonium salts.[13] Methylethyl-*n*-propylsulfonium hydroxide affords both methanol and

ethanol,[14,15] while dimethyl-2-phenylethylsulfonium iodide in sodium ethoxide affords more ethyl 2-phenylethyl ether than methyl ethyl ether. These results are consistent with the hypothesis that displacement of oxonium, sulfonium or ammonium groups shows less selectivity than simple SN2 displacement reactions.

In accord with this hypothesis, comparison with the von Braun cyanogen bromide degradation of tertiary amines is instructive. Here the order of reactivity is methyl > ethyl > *n*-propyl > isopropyl.[16] In the case of N-alkyl pyrrolidine derivatives, there appears an accelerating effect involved in attack upon the methylene carbon of the ring. The rate of cleavage of a pyrrolidine ring in the von Braun reaction is approximately equal to the rate of cleavage of a methyl group. The rate of cleavage of the piperidine ring is intermediate between that of ethyl and *n*-propyl groups.

It would thus appear that in reactions involving ring-breaking displacement,[17] increased rates of reaction are observed. This hypothesis then serves to correlate the reactions reported here with the previously observed examples.

Experimental[18]

Preparation of 3-Methoxycyclohexanecarboxylic Acid (II).—*m*-Methoxybenzoic acid, 65 g. (0.43 mole), dissolved in 300 ml. of 95% ethanol, to which 4 g. of platinum oxide was added, was reduced with hydrogen in 30 hours on a Parr low pressure hydrogenator at room temperature.

The catalyst was removed by filtration and most of the ethanol was removed under reduced pressure. The residue was poured into 500 ml. of water, extracted four times with 1:1 ether–pentane and the combined extracts dried over magnesium sulfate. After removal of the solvent the residue was fractionally distilled yielding 24.7 g. (43%) of cyclohexanecarboxylic acid, b.p. 103–104° (5 mm.), and 28.3 g. (40%) of 3-methoxycyclohexanecarboxylic acid, b.p. 140–142° (5 mm.).

Isolation of *cis*-3-Methoxycyclohexanecarboxylic Acid (*cis*-II).—The mixed acids, II, 28.3 g. (0.18 mole), obtained from the reduction of *m*-methoxybenzoic acid were dissolved in a minimum of refluxing *n*-pentane and seeded with *cis*-II. The precipitate obtained was recrystallized three times from *n*-pentane yielding 8.0 g. of *cis*-II, m.p. 51–52°. An additional 8.3 g. of *cis*-II, m.p. 51–52°, was obtained by continued fractional crystallization of the combined filtrates, a recovery of 60% from the mixed isomers.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.7; H, 8.9. Found: C, 60.6; H, 8.9.

Rearrangement of *cis*-3-Methoxycyclohexanecarboxylic Acid (*cis*-II) in Thionyl Chloride.—To 10 g. (0.063 mole) of *cis*-II was added 15 g. (0.13 mole) of thionyl chloride. After the initial reaction subsided the resulting solution was heated under reflux on a steam-bath for two hours. The excess thionyl chloride was then removed by several distillations with benzene at reduced pressure. The residue was taken up in additional benzene and washed with sodium carbonate solution and then with water. After drying the benzene solution over magnesium sulfate and evaporating, the residue was fractionally distilled to give two main fractions. Fraction A afforded 2.4 g. (28%) of methyl 3-cyclohexene-1-carboxylate (V), b.p. 82–83° (26 mm.), $n^{25}D$ 1.4584. V was refractionated for analysis.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.5; H, 8.6. Found: C, 68.1; H, 8.8.

Fraction B, 5.7 g. (51%), b.p. 117° (22 mm.), $n^{25}D$ 1.4689, was methyl *trans*-3-chlorocyclohexanecarboxylate (IV). IV was refractionated for analysis.

Anal. Calcd. for $C_8H_{13}O_2Cl$: C, 54.4; H, 7.4; Cl, 20.0. Found: C, 54.4; H, 7.5; Cl, 19.9.

Hydrolysis of (IV).—A solution of 25 ml. of water and 20 ml. of dioxane containing 3.5 g. (0.02 mole) of IV and 2.5 ml. of concd. sulfuric acid was heated on a steam-bath overnight, then poured into 100 ml. of water and extracted with 1:1 ether–pentane. After drying the extracts over magnesium sulfate and removing the solvent, the residue was fractionally distilled yielding 1.35 g. (40%) of acidic material, b.p. 133° (5 mm.). This acidic material, which slowly solidified, was recrystallized two times from *n*-pentane at 0° and 0.4 g. of *trans*-3-chlorocyclohexanecarboxylic acid, m.p. 49.5–51.5°, was obtained.

Anal. Calcd. for $C_7H_{11}O_2Cl$: C, 51.7; H, 6.8; Cl, 21.8. Found: C, 51.8; H, 7.0; Cl, 21.6.

The anilide was prepared in the usual manner and after two crystallizations from benzene–pentane it had a melting range of 157.5–157.9°.

Anal. Calcd. for $C_{13}H_{16}ONCl$: C, 65.7; H, 6.8; N, 5.9; Cl, 14.9. Found: C, 65.8; H, 6.6; N, 6.1; Cl, 14.8.

Preparation of the Anilide of *cis*-II.—To 1.3 g. (0.012 mole) of thionyl chloride was added 1.0 g. (0.0063 mole) of *cis*-II and the mixture kept at 40° for one half hour. The thionyl chloride was removed by several distillations with benzene at reduced pressure and the residue was added to 1.3 g. (0.014 mole) of aniline in 20 ml. of benzene. The benzene layer was washed with water, dilute hydrochloric acid, dilute sodium hydroxide and water and then dried over magnesium sulfate. The filtered solution was concentrated to a small volume and cooled causing the precipitation of the anilide of *cis*-3-methoxycyclohexanecarboxylic acid. The anilide was crystallized from benzene–pentane and 0.27 g. (18%) of fine needles were obtained, m.p. 130.5–131.5°.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.2; H, 8.1; N, 5.9.

Preparation of the Anilide of *trans*-II.—A sample of 4 g. (0.025 mole) of the mixed *cis*-II and *trans*-II acids obtained by concentrating the combined filtrates from which *cis*-II had been removed was added to 6 g. (0.05 mole) of thionyl chloride. This solution was heated on a steam-bath for two hours and then treated as in the above experiment to afford 1.4 g. of the anilide of *trans*-II, m.p. 137.6–138.6°. A mixed melting point with the anilide of *cis*-II depressed to 109–115°.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.1; H, 8.3; N, 5.8.

Rearrangement of *cis*-3-Methoxycyclohexanecarboxylic Acid (*cis*-II) in Phosphorus Tribromide.—Ten grams (0.063 mole) of *cis*-I was added to 15 g. (0.055) mole of phosphorus tribromide and the mixture was heated on a steam-bath for two hours. At the end of this time the reaction mixture was poured into ice, neutralized with solid sodium carbonate and extracted three times with benzene. The benzene solution was dried and evaporated and methyl *trans*-3-bromocyclohexanecarboxylate (III), 9.75 g. (70%) was obtained upon fractional distillation of the residue, b.p. 129–131° (24 mm.).

A small forerun, 0.5 g., boiling at a temperature corresponding to V was also isolated but was not further characterized.

Preparation of III from the Lactone of *cis*-3-Hydroxycyclohexanecarboxylic Acid.—Gaseous hydrogen bromide was passed into a mixture of 6 g. (0.047 mole) of the lactone of *cis*-3-hydroxycyclohexanecarboxylic acid in 15 ml. of 40% hydrobromic acid until saturated at 0°, then permitted to stand overnight. The resulting solution was poured into water, extracted with 1:2 ether–pentane, dried, evaporated and the product fractionally distilled. The obtained *cis*-3-bromocyclohexanecarboxylic acid, 5.2 g. (35%),

b.p. 141–142° (5 mm.), was crystallized once from *n*-pentane, m.p. 64–65° (lit. m.p. 62–63°,[9] m.p. 67–68°[8]).

The bromo acid was dissolved in dry ether and an excess of diazomethane in ether was added. The ether was removed after drying and the residue fractionally distilled yielding 3.5 g. of authentic III, b.p. 120–121° (15 mm.), $n^{25}D$ 1.4923. Authentic III was characterized by infrared analysis.

Anal. Calcd. for $C_8H_{13}O_3Br$: C, 43.5; H, 5.9; Br, 36.2. Found: C, 43.1; H, 5.9; Br, 36.1.

Isolation of *trans*-3-Methoxycyclohexanecarboxylic Acid (*trans*-II).—Thirteen grams of the mixed acids (*cis*-II and *trans*-II), obtained from the combined filtrates which yielded *cis*-II, was dissolved in 20 g. of thionyl chloride and heated on a steam-bath for two hours. At the end of this time the excess thionyl chloride was removed by distillation with several portions of benzene. The reaction mixture was then poured into water, neutralized with solid sodium carbonate and extracted twice with pentane. The aqueous phase was acidified with hydrochloric acid to a *p*H of 2 and extracted with ether. This solution was dried over magnesium sulfate, evaporated and distilled to give 4.3 g. (33%) of *trans*-II, b.p. 123–125° (2 mm.), $n^{25}D$ 1.4661.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.7; H, 8.9. Found: C, 60.8; H, 8.9.

Behavior of Methyl *trans*-3-Chlorocyclohexanecarboxylate (IV) in Thionyl Chloride Rearrangement Conditions.—IV, 4.3 g., was dissolved in 4 g. of thionyl chloride and placed on a steam-bath for two hours. The thionyl chloride was removed by several distillations with benzene and the residue was fractionally distilled yielding 3.8 g. (89%) of IV, b.p. 119–120° (25 mm.).

Preparation of Methyl 4-Methoxycyclohexanecarboxylate.—To a hydrogenation bomb preheated to about 30° was added a warm solution of 50 g. (0.3 mole) of methyl anisate in 50 ml. of absolute ethanol. Commercial Raney nickel, 3-6 g., was added, the bomb mounted on a shaker and the hydrogenation carried out at 170° and 3600 pounds per square inch. The theoretical amount of hydrogen was taken up in four to six hours. After the catalyst was removed by filtration and most of the ethanol removed by low pressure distillation, the residue was fractionated giving two fractions. The first, methyl cyclohexanecarboxylate, weighed 11.2 g. (26%) and had a boiling range of 85–110° (30 mm.). The second, methyl 4-methoxycyclohexanecarboxylate, weighed 29.0 g. (56%) and had a b.p. of 122–124° (30 mm.).

Hydrolysis of Methyl 4-Methoxycyclohexanecarboxylate.—Methyl 4-methoxycyclohexanecarboxylate, 29 g. (0.17 mole), was combined with a solution of 80 ml. of water, 30 ml. of methanol and 23 g. (0.41 mole) of potassium hydroxide. This mixture was heated on a steam-bath for 90 minutes then poured into 200 ml. of water. The aqueous solution was extracted once with *n*-pentane to remove any neutral material then acidified to a *p*H of 2 and extracted three times with 1:1 ether–pentane. The extracts were dried over magnesium sulfate and following the removal of the solvent the residue was fractionally distilled to yield 23.4 g. (90%) 4-methoxycyclohexanecarboxylic acid (VI), b.p. 142° (6 mm.).

Isolation of *cis*-4-Methoxycyclohexanecarboxylic Acid (*cis*-VI).—VI, 23.4 g., was dissolved in ether and then cooled in a Dry Ice-bath. The ether was decanted after precipitation without collecting the precipitate. This process was repeated and following the second crystallization the solid was collected, dried and recrystallized twice from *n*-pentane at room temperature. A sample of *cis*-VI, 7.2 g. (31%), m.p. 54.6–55.6°, was obtained.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.7; H, 8.9. Found: C, 60.7; H, 8.8.

The anilide of *cis*-VI was prepared in the same way that the anilide of *cis*-II was prepared, m.p. 123.3–124.3°.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2. Found: C, 71.9; H, 7.9.

Isolation of *trans*-4-Methoxycyclohexanecarboxylic Acid (*trans*-VI).—An 8.6-g. sample of V was treated with thionyl chloride in the same process used to isolate *trans*-II. *trans*-VI, 1.65 g. (19%), was obtained and on several crystallizations from *n*-pentane gave a m.p. 0.5–60°.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.7; H, 8.9. Found: C, 60.9; H, 8.8.

The anilide of *trans*-VI was prepared in the usual way and on recrystallization from benzene–pentane had a m.p. of 186.0–186.4°.

Anal. Calcd. for $C_{14}H_{19}O_2N$: C, 72.1; H, 8.2; N, 6.0. Found: C, 72.2; H, 8.1; N, 6.1.

Rearrangement of *cis*-4-Methoxycyclohexanecarboxylic Acid (*cis*-VI) in Thionyl Chloride.—Seven grams (0.044 mole) of *cis*-VI was added to 14 g. (0.12 mole) of thionyl chloride and the solution heated on a steam-bath for 2.5 hours. At the end of this period the thionyl chloride was removed by repeated distillation with benzene and the product was then fractionally distilled. The first fraction proved to be 2.7 g. (44%) of V, b.p. 91° (39 mm.). V was refractionated and an infrared spectrum obtained, which was identical to that of authentic V.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.5; H, 8.6. Found: C, 68.4; H, 9.1.

The second fraction proved to be methyl *trans*-4-chlorocyclohexanecarboxylate (VII), 2.3 g. (30%), b.p. 119° (20 mm.), $n^{25}D$ 1.4670. This compound was also characterized by an infrared spectrum.

Anal. Calcd. for $C_8H_{13}O_2Cl$: C, 54.4; H, 7.4; Cl, 20.1. Found: C, 54.2; H, 7.3; Cl, 19.9.

Hydrolysis of VII.—To 40 ml. of 1:1 solution of water–dioxane was added 1.0 g. of VI and 2 ml. of concentrated sulfuric acid. This two-phase mixture was heated on a steam-bath for six hours. The resulting solution was then poured into 70 ml. of water and placed in a refrigerator overnight. The precipitate of *trans*-4-chlorocyclohexanecarboxylic acid was collected and on drying weighed 0.55 g. (61%), m.p. 157–159°. A second crop yielded 0.25 g. (27%). The first crop was crystallized from benzene–pentane giving 0.3 g. of acid having a m.p. of 159.0–159.8°.

Anal. Calcd. for $C_7H_{11}O_2Cl$: C, 51.7; H, 6.8. Found: C, 51.5; H, 6.7.

The anilide was prepared in the usual way, and recrystallized from benzene–pentane, m.p. 196.5–196.8°.

Anal. Calcd. for $C_{13}H_{16}ONCl$: C, 65.7; H, 6.8; N, 5.9; Cl, 14.9. Found: C, 65.4; H, 6.7; N, 6.1; Cl, 14.9.

Rearrangement of *cis*-4-Methoxycyclohexanecarboxylic Acid (*cis*-VI) with Phosphorus Tribromide.—*cis*-VI, 7 g. (0.044 mole), was added to 12 g. (0.044 mole) of phosphorus tribromide and the reaction mixture was heated on a steam-bath for 2.5 hours. The resulting mixture was then poured into water made basic with solid sodium carbonate and extracted with pentane. After drying the pentane extracts over magnesium sulfate and removing the solvent the product was fractionally distilled affording 5.7 g. (59%) of methyl *trans*-4-bromocyclohexanecarboxylate (VIII) b.p. 128–130° (18 mm.), $n^{25}D$ 1.4916. VII was characterized by an infrared spectrum.

Anal. Calcd. for $C_8H_{13}O_2Br$: C, 43.5; H, 5.9; Br, 36.1. Found: C, 43.8; H, 5.7; Br, 35.5.

The basic aqueous layer was acidified and yielded a precipitate of *trans*-4-bromocyclohexanecarboxylic acid, 1.5 g. (17%) with a melting point range of 160–170°. One crystallization from benzene–pentane raised the melting point to 169–171° (lit.[19] m.p. 167°).

No methyl cyclohexenecarboxylate was detected among the products.

Hydrolysis of VIII.—Four grams of VII was heated under reflux with a 1:1 solution of water–dioxane, 125 ml., containing 8 ml. of concentrated sulfuric acid for four hours. The resulting solution was poured into 150 ml. of water and placed in a refrigerator overnight. The precipitate of *trans*-4-bromocyclohexanecarboxylic acid weighed 0.8 g. (22%) and melted over a wide range to 170°. Three recrystallizations from benzene–pentane gave 0.5 g., m.p. 170.8–171.4° (lit.[19] m.p. 167°).

Anal. Calcd. for $C_7H_{11}O_2Br$: C, 40.6; H, 5.3; Br, 38.6. Found: C, 40.6; H, 5.2; Br, 38.6.

The anilide was prepared in the usual way and was crystallized from benzene–pentane, m.p. 191.0–191.7°.

Anal. Calcd. for $C_{13}H_{16}O_2NBr$: C, 55.3; H, 5.7; N, 5.0; Br, 28.4. Found: C, 55.6; H, 5.7; N, 5.3; Br, 28.4.

Methyl 3-Cyclohexene-1-carboxylate (V).—Methylacrylate and butadiene were heated at 140° in a steel bomb for five hours, and the mixture distilled to afford 85% of methyl 3-cyclohexene-1-carboxylate (V).[20]

Methyl 1-Cyclohexene-1-carboxylate and Methyl 2-Cyclohexene-2-carboxylate.—The mixture of cyclohexenecarboxylic acids obtained from cyclohexanone cyanohydrin through cyclohexenecarbonitrile was fractionally crystallized from pentane to afford 1-cyclohexene-1-carboxylic acid which was esterified with diazomethane to afford methyl 1-cyclohexene-1-carboxylate, b.p. 105° (40 mm.), n^{25}D 1.4808. The mother liquors from the fractional crystallization were fractionated, collecting the lower boiling fractions (enriched in 2-cyclohexene-1-carboxylic acid). Esterification with diazomethane was followed by fractionation to give the ester, methyl 2-cyclohexene-1-carboxylate, b.p. 94–95° (40 mm.), n^{25}D 1.4605.

Studies of Configuration. IV. The Rearrangement of Methoxycyclohexanecarboxylic Acids with Acetic Anhydride[1]

BY DONALD S. NOYCE AND HAROLD I. WEINGARTEN[2]

RECEIVED NOVEMBER 10, 1956

Treatment of *cis*-3-methoxycyclohexanecarboxylic acid with acetic anhydride and catalytic amounts of sulfuric acid leads to a mixture of three products, methyl cyclohex-3-ene-carboxylate, methyl *trans*-3-acetoxycyclohexanecarboxylate and methyl *trans*-4-acetoxycyclohexanecarboxylate. Under the same conditions *cis*-4-methoxycyclohexanecarboxylic acid leads to a mixture of the same products in different proportions. The mechanism of the rearrangement between the 3- and 4-positions is discussed. It is suggested that the rearrangement proceeds through a transition state which is doubly bridged.

In the previous paper of this series, it was shown[3] that the intramolecular rearrangement of γ- and δ-alkoxy carboxylic acid chlorides to the corresponding chloro esters could be extended to suitable derivatives of cyclohexanecarboxylic acid. Ethers may also be cleaved by acetic anhydride and acidic catalysts. Acetic anhydride has been reported to cleave ethers in the presence of catalytic amounts of Lewis acids such as boron trifluoride, zinc chloride, ferric chloride and aluminum chloride.[4] Nudenberg and Butz[5] reported the cleavage of 1,4-epoxycyclohexane with acetic anhydride and zinc chloride to *trans*-1,4-diacetoxycyclohexane. The cleavage of tetrahydrofurans has been investigated by Wilson[6] and Paul.[7]

In view of the apparent generality of the cleavage of ethers with acetic anhydride, it appeared feasible to demonstrate the intramolecular counterpart of this reaction. Such is the purpose of the present report.

The reaction between *cis*-3-methoxycyclohexanecarboxylic acid (*cis*-I), acetic anhydride and a small amount of sulfuric acid was investigated. Under these conditions, it would be expected that appreciable quantities of the mixed anhydride (II) of *cis*-I and acetic acid would be formed in equilibrium with acetic anhydride. The mixed anhydride (II) may then be expected to undergo intramolecular reaction to give methyl *trans*-3-acetoxycyclohexanecarboxylate (*trans*-III). The products were separated by fractional distillation. The lower boiling fraction was identified as methyl 3-cyclohexene-1-carboxylate (IV) as previously described,[3] and the higher boiling fraction (B) has the elemental composition and saponification equivalent appropriate for (*trans*-III).

It is to be noted that the isolation of esters III and IV clearly establishes the success of the *intramolecular* rearrangement. Were the methoxyl fragment ever to be released into solution, exclusive reaction with the solvent acetic anhydride would occur.

Further experiments designed to establish the structure of III showed that fraction B is in fact a mixture of isomers. Hydrolysis of fraction B afforded crystalline *trans*-4-hydroxycyclohexanecarboxylic acid (*trans*-V), identified by melting point and mixed melting point, and an oil. Crystallization of fraction B from pentane afforded the crystalline methyl *trans*-4-acetoxycyclohexanecarboxylate (*trans*-VI), identified by comparison with an authentic sample. Since it was apparent that fraction B was a mixture, several attempts were made to separate by crystallization some of the second component. These attempts failed. The composition of the mixture was determined by infrared analysis, by comparing the spectrum of fraction B with the infrared spectra of methyl *cis*-3-acetoxycyclohexanecarboxylate (*cis*-III), *trans*-III, methyl *cis*-4-acetoxycyclohexanecarboxylate (*cis*-VI) and *trans*-VI and with appropriate mixtures. The comparison of the infrared spectra indicated that only *trans*-III and *trans*-VI were present in the rearrangement product. Absorption bands at 12.22 and 10.15 μ characteristic of *trans*-III and at 7.60 μ, characteristic of *trans*-VI were observed. From the spectra of fraction B and of synthetic mixtures, it was determined that fraction B consisted of 57 ± 3% of *trans*-VI, and 43 ± 3% of *trans*-III.

cis-4-Methoxycyclohexanecarboxylic acid (*cis*-VII) was subjected to similar treatment with acetic anhydride and on fractional distillation two fractions were again obtained. The lower boiling fraction was IV, and the higher boiling fraction was

a mixture of ester acetates. The acetate fraction appeared at first to contain only *trans*-VI, but its infrared spectrum showed small inconsistencies in the regions where *trans*-III was known to absorb strongly. Therefore, the acetate fraction was crystallized from *n*-pentane yielding solid *trans*-VI and a filtrate. This filtrate was distilled and an infrared spectrum taken of the distillate. The analysis of this spectrum, made in the same way as before, revealed that the original acetate fraction contained approximately 5% of *trans*-III.

To show that the *cis* and *trans* isomers of the 3- and 4-methoxycyclohexanecarboxylic acids would behave differently, *trans*-I was subjected to the reaction conditions. Under these conditions *trans*-I yielded two products believed to be 3-cyclohexene-1-carboxylic acid and the anhydride of 3-cyclohexene-1-carboxylic acid.

Discussion

The first step in the intramolecular ether–acid anhydride rearrangement is clearly similar to that of the ether–acid chloride rearrangement,[2] the conversion of II (in the diaxial conformation) to the cyclic oxonium ion VIII. VIII may then proceed by any of three paths to products (Fig. 1). The first two, (a) elimination of a proton to yield methyl 3-cyclohexene-1-carboxylate (IV) and (b) solvolytic displacement by acetic acid to give methyl *trans*-3-acetoxycyclohexanecarboxylate (*trans*-III), completely parallel the analogous processes described previously.[3]

The third pathway (c), which produces methyl *trans*-4-acetoxycyclohexanecarboxylate (*trans*-VI) requires additional comment. The possibility that *trans*-VI arises by the addition of acetic acid to IV is ruled out by the fact that IV can be recovered in 80% yield from a reaction mixture of acetic anhydride, acetic acid and sulfuric acid after treatment under the conditions of the rearrangement. Further, the *cis*-3-methoxycyclohexanecarboxylic acid-*d* (prepared by equilibrating *cis*-I dissolved in toluene with D_2O) was treated with acetic anhydride with deuteriosulfuric acid as the catalyst. No deuterium could be detected in any of the products.

It is thus clear that an intramolecular hydrogen shift is responsible for the formation of *trans*-VI.

Intramolecular hydrogen shifts frequently have been suggested to proceed through a bridged cation transition state or intermediate.[8] Cram[9] has postulated ion-pair a as a possible intermediate in the rearrangement of 3-phenyl-2-butyl tosylates. Barnes[10] in proposing a mechanism for the formation of phenanthrene derivatives from β-arylethylcyclohexanols postulates ion b as an intermediate. To explain the formation of isobutyraldehyde in the solvolysis of 2-methoxy-2-methyl-1-propyl-*p*-bromobenzenesulfonate, Winstein, Lindegren and Ingraham[11] postulated ion c as a likely intermediate. Winstein and Holness[8a] also have postulated the bridged ions d and e to explain various products arising from the solvolysis of *cis*-4-*t*-butylcyclohexyl tosylate.

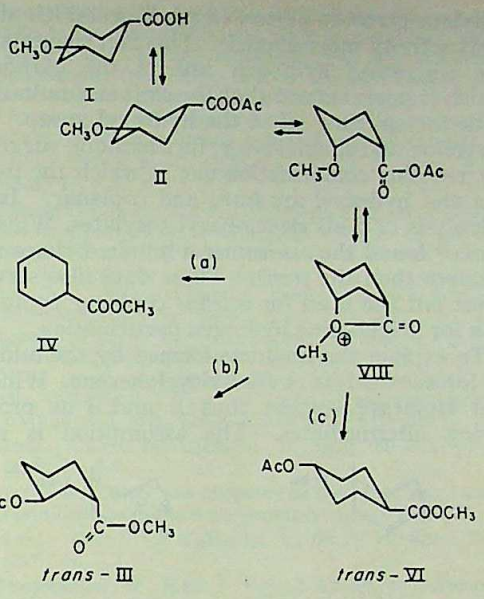

Fig. 1.

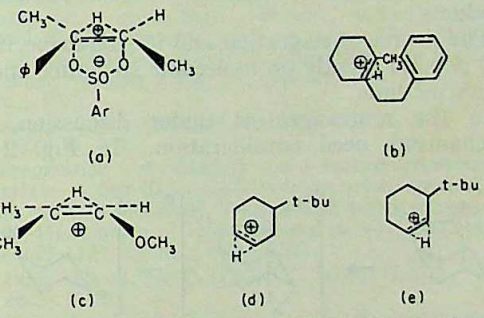
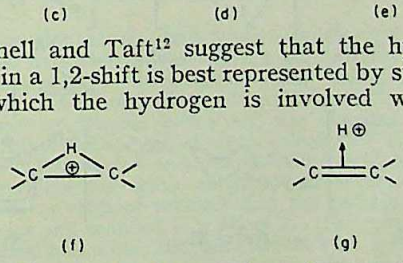


Cannell and Taft[12] suggest that the hydrogen bridge in a 1,2-shift is best represented by structure f in which the hydrogen is involved with the



sp^3-hybrid orbitals of the carbon atoms rather than the π-complex (g) suggested by Dewar.[8b] This conclusion was reached after a study of migrations occurring upon the diazotization of isobutylamine in a deuterated solvent. Since exchange with the deuterated solvent was observed, Taft eliminates the π-complex (g) from consideration, which would rapidly exchange with the solvent,[13] and demonstrates the intramolecular nature of the reaction.

Mislow and Siegel[14] observed that in the rearrangement of optically active α-phenyl β-(*o*-tolyl)-

ethylene glycol to phenyl-(*o*-tolyl)-acetaldehyde optical activity was retained. This fact suggests that the migrating hydrogen inverts the carbon to which it migrates and that the shift is simultaneous with the splitting off of the hydroxyl group. The inversion and simultaneity, furthermore, suggest as the reacting conformation one in which the hydrogen and hydroxyl are *trans* and coplanar. In the solvolysis of 2-alkylcyclohexyl tosylates, Winstein, *et al.*,[15] found the *cis* isomer a hundred times more reactive than the *trans*. These data also serve to point out the need for a *trans* coplanar conformation for neighboring hydrogen participation.

To explain the products formed by the addition of formic acid to 4-*t*-butylcyclohexene, Winstein and Holness[8a] suggest ions h and i as product giving intermediates. The assumption is made

(h) (i)

that the hydrogen-bridged ions tend to open stereospecifically to give axial products, by analogy with the direction of opening of steroidal epoxides[16] and with the addition of halogens to steroids.[17] The ion h yields *trans*-3 products while ion i yields *cis*-4 products.

The degree of migration and its stereospecificity will depend greatly on molecular structure and reaction medium.

In the rearrangement under discussion, two mechanisms need consideration. In Fig. 2 the

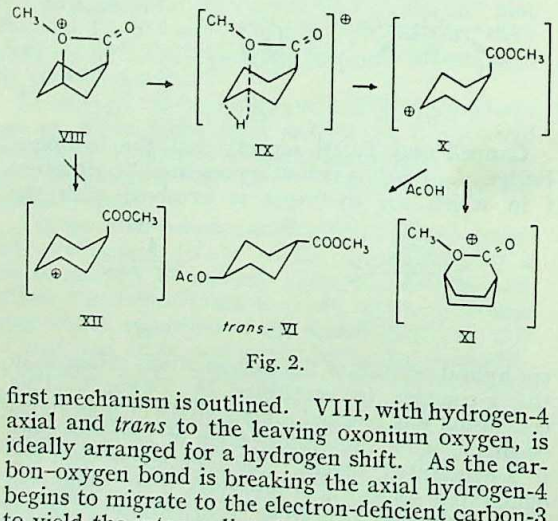

Fig. 2.

first mechanism is outlined. VIII, with hydrogen-4 axial and *trans* to the leaving oxonium oxygen, is ideally arranged for a hydrogen shift. As the carbon–oxygen bond is breaking the axial hydrogen-4 begins to migrate to the electron-deficient carbon-3 to yield the intermediate hydrogen bridged species IX. IX may open to give ion X which can react with acetic acid to form *trans*-VI, or it may internally coördinate to give oxonium ion XI, which can also react to give *trans*-VI. The possibility of ion VIII opening to the externally solvated ion XII prior to the migration of a hydrogen has been excluded for the following reason. If XII were formed, it would be expected to give largely *cis*-III; however, no *cis* products were ever observed. Likewise, *cis*-VI is the product expected to arise from the hydrogen bridged species, IX. Since no *cis* products are observed, the existence of IX is somewhat doubtful and it is preferable to exclude it as an intermediate. Further, were IX to open to the solvated "classical" carbonium ion X, the exclusive formation of *trans*-4 products would require internal participation by the ester grouping to give XI. The solvolytic studies of the 3-carbomethoxycyclohexyl tosylates reported[18] indicate that there is no transannular participation by the ester group. Such results make the transformation X → XI unlikely.

The mechanism for the rearrangement which is in accord with all the facts is presented in Fig. 3.

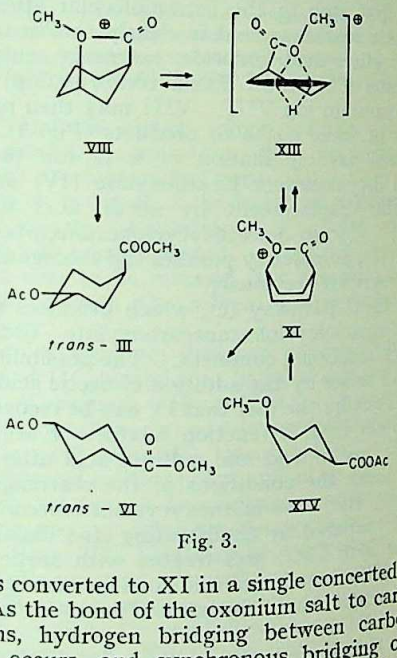

Fig. 3.

VIII is converted to XI in a single concerted process. As the bond of the oxonium salt to carbon-3 weakens, hydrogen bridging between carbons 3 and 4 occurs, and synchronous bridging of the oxygen to carbon-4 occurs. The doubly bridged ion XIII thus represents the transition state for that path leading to *trans*-VI from II. In like manner the small amount of *trans*-III resulting from the treatment of *cis*-VII with acetic anhydride and sulfuric acid may be considered to arise by the path VII → XIV, through XIII to VIII, to *trans*-III (Fig. 3). This pathway is then consistent with the formation of some *trans*-III to the exclusion of *cis*-III. Were the solvated carbonium ion XII formed by rearrangement from XI, the expected product would be largely *cis*-III.

An examination of the model of XIII reveals no unusual or prohibitive amounts of strain. An analogous doubly bridged species is suggested by Denney[19] as a transition state or short-lived intermediate for the rearrangement of the benzoate of

9-decalyl hydroperoxide to 1-benzoyloxy-1,6-epoxycyclodecane.

There are several other reactions in which facile rearrangements in cyclohexane systems are observed. Examples are the Friedel–Crafts reactions of cyclohexene with *t*-butyl chloride,[20,21] with acetyl chloride and benzene,[22] of 1,2-dibromocyclohexane with benzene,[23] the conversion of 3-methylcyclohexanol to 1-chloro-4-methylcyclohexane (as a minor product) with hydrochloric acid,[24] and the conversion of 4-chlorocyclohexanol to a mixture of 1,3- and 1,4-dichlorocyclohexanes.[25]

It is attractive to suggest that many of these transformations also proceed through hydrogen bridged species, rather than by addition–elimination as has been suggested.[21]

Experimental[26]

Rearrangement of *cis*-3-Methoxycyclohexanecarboxylic Acid (*cis*-I) in Acetic Anhydride.—To a solution of 10 g. (0.063 mole) of *cis*-I in 50 ml. of acetic anhydride was added 0.2 g. of concentrated sulfuric acid. The solution was heated on a steam-bath for six hours, diluted with water and the aqueous mixture was extracted three times with *n*-pentane. The pentane extracts were combined and washed with sodium carbonate solution and water. After drying the extract over magnesium sulfate, evaporating and fractionally distilling the residue, two fractions were obtained. The first fraction, methyl cyclohex-3-enecarboxylate (IV), b.p. 94° (40 mm.), n^{25}D 1.4570, weighed 3.25 g. (37%). The second fraction (fraction B) was a mixture of methyl *trans*-3-acetoxycyclohexanecarboxylate (*trans*-III) and methyl *trans*-4-acetoxycyclohexanecarboxylate (*trans*-VI). The mixture was obtained to the extent of 38% (4.8 g.), b.p. 116–119° (7 mm.), and was characterized by infrared spectrum.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 60.1; H, 7.8.

Hydrolysis of Fraction B.—Two grams (0.01 mole) of fraction B was added to a solution of 3 g. (0.053 mole) of potassium hydroxide in 6 ml. of water and 3 ml. of methanol and the mixture placed on a steam-bath for one hour. At the end of this time the solution was poured into 100 ml. of water, washed once with pentane and acidified to a *p*H of 3. The oily material obtained after 12 hours of continuous extraction with ether was recrystallized three times from acetonitrile at 0° yielding 0.2 g. of *trans*-4-hydroxycyclohexanecarboxylic acid, m.p. 147.4–148.0° (lit.[29] m.p. 148°). A mixed melting point with authentic *trans*-4-hydroxycyclohexanecarboxylic acid showed no depression (m.m.p. 147–148°). The filtrates from the above recrystallizations yielded an uncrystallizable oil believed to be a mixture of *trans*-4-hydroxycyclohexanecarboxylic acid and *trans*-3-hydroxycyclohexanecarboxylic acid.

Isolation of Methyl *trans*-4-Acetoxycyclohexanecarboxylate (*trans*-VI).—Fraction B, 2.8 g., was crystallized from *n*-pentane in a Dry Ice-bath and was crystallized three times by decantation. The third precipitate was collected and recrystallized from *n*-pentane at 0° giving 0.7 g. (25%) of *trans*-VI, m.p. 48.0–48.5°. A mixed melting point with authentic *trans*-VI showed no depression.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 59.8; H, 8.1.

Separation of *cis*- and *trans*-3-Hydroxycyclohexanecarboxylic Acids.—Crystallization of the mixed acids (obtained by reduction of methyl *m*-hydroxybenzoate, followed by saponification) from ethyl acetate afforded *cis*-3-hydroxycyclohexanecarboxylic acid, m.p. 131.6–132° (lit.[27] 131.5°).

The phenacyl ester was prepared in the usual way[28] and was crystallized from benzene–pentane, m.p. 89.6–90.3°.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.7; H, 6.9. Found: C, 68.8; H, 6.3.

The combined ethyl acetate filtrates from the above separation were evaporated and the residue heated on an oil-bath between 170 and 190° until the water which was formed no longer distilled over. The products were then separated by distillation. The first fraction, the lactone of *cis*-3-hydroxycyclohexanecarboxylic acid, b.p. 130–140° (20 mm.), weighed 7.0 g. (23%). The second fraction, 4.2 g. (12%) of *trans*-3-hydroxycyclohexanecarboxylic acid, b.p. 140–160° (5 mm.), was recrystallized four times from acetonitrile, affording 2.0 g. of *trans*-3-hydroxycyclohexanecarboxylic acid, m.p. 118.8–119.6° (lit.[27] 119–120°).

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.3; H, 8.4. Found: C, 58.8; H, 8.8.

A phenacyl ester was prepared in the usual way, and was recrystallized from benzene–pentane, m.p. 97.7–98.5°.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.7; H, 6.9. Found: C, 68.6; H, 7.1.

Preparation of Methyl *trans*-3-Acetoxycyclohexanecarboxylate (*trans*-III).—*trans*-3-Hydroxycyclohexanecarboxylic acid, m.p. 118.8–119.6°, 1.5 g. (0.01 mole), was dissolved in ether and an excess of diazomethane in ether was added. After drying and removal of the ether the methyl *trans*-3-hydroxycyclohexanecarboxylate was fractionally distilled, b.p. 115–115.5° (5 mm.), to give 1.4 g. of the ester.

The methyl ester was then dissolved in 10 ml. of pyridine and 3 ml. of acetic anhydride. The resulting solution was heated on a steam-bath overnight, poured into water, acidified and extracted with pentane. The extract was dried over magnesium sulfate, evaporated and fractionally distilled, yielding 1.6 g. of *trans*-III, b.p. 122° (9 mm.), n^{25}D 1.4510.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 60.0; H, 8.0.

Preparation of Methyl *cis*-3-Acetoxycyclohexanecarboxylate (*cis*-III).—*cis*-3-Hydroxycyclohexanecarboxylic acid, m.p. 131.6–132.0°, 2.4 g. (0.015 mole), was converted to *cis*-III as above. Three grams of *cis*-VIII was obtained, b.p. 112–113° (5 mm.), n^{25}D 1.4512.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 60.2; H, 8.3.

Separation of *cis*- and *trans*-4-Hydroxycyclohexanecarboxylic Acid Derivatives.—The crude mixture of *cis*- and *trans*-4-hydroxycyclohexanecarboxylic acid obtained by Raney nickel reduction of ethyl *m*-hydroxybenzoate, followed by alkaline hydrolysis, was dissolved in 100 ml. of pyridine and 100 ml. of acetic anhydride. The resulting solution was heated on a steam-bath overnight. Most of the pyridine and acetic anhydride were removed by distillation at reduced pressure and the residue was poured on to ice and acidified to a *p*H of 2. The resulting oil was extracted into ether, and the extracts were dried over magnesium sulfate, evaporated and the remaining oil distilled to yield two fractions. The first fraction, the lactone of *cis*-4-hydroxycyclohexanecarboxylic acid, 5.7 g. (21%), b.p. 120–140° (15 mm.), was recrystallized from benzene–pentane and 3.0 g. of lactone, m.p. 126–128° (lit.[29] m.p. 128°), was obtained. The second fraction, a mixture of *cis*- and *trans*-4-acetoxycyclohexanecarboxylic acids, b.p. 140–150° (3 mm.), weighed 18 g. (46%). Three recrystallizations from chloroform–pentane gave 6.2 g. of *trans*-4-acetoxycyclohexanecarboxylic acid, m.p. 137–139° (lit.[29] m.p. 139°). *cis*-4-Acetoxycyclohexanecarboxylic acid, 2.1 g., m.p. 81–83° (lit.[29] m.p. 80°), was obtained by repeated concentration and crystallization of the combined filtrates from which the *trans* isomer was largely removed.

Preparation of Methyl *cis*-4-Acetoxycyclohexanecarboxylate (*cis*-VI).—Three grams (0.024 mole) of the lactone of *cis*-4-hydroxycyclohexanecarboxylic acid was heated with 10% potassium hydroxide for three hours. Following this period the solution was acidified to a *p*H of 2 and continuously extracted with ether. After drying the ether solution over magnesium sulfate, and evaporating to dryness, 2.4 g. (70%) of *cis*-4-hydroxycyclohexanecarboxylic acid was obtained. Crystallization from acetonitrile gave 2.0 g. of acid, m.p. 149.4–150.2° (lit.[29] m.p. 152°).

A phenacyl derivative was prepared in the usual way[28] and after one crystallization from benzene–pentane had m.p. 107.0–107.4°.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.7; H, 6.9. Found: C, 68.6; H, 6.7.

The acid was dissolved in ether and an excess of diazomethane in ether was added. The solution was dried over magnesium sulfate, evaporated and the esterified product dissolved in 15 ml. of pyridine to which was added 7 ml. of acetic anhydride. The reaction mixture was heated on a steam-bath for six hours, poured into water, neutralized with dilute sulfuric acid and extracted twice with pentane. The pentane extracts were washed once with sodium carbonate solution, dried over magnesium sulfate, evaporated and the residual oil fractionally distilled. *cis*-VI, 2.3 g., b.p. 110° (5 mm.), $n^{25}D$ 1.4521, was obtained.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 60.2; H, 8.3.

Preparation of Methyl *trans*-4-Acetoxycyclohexanecarboxylate (*trans*-VI).—Two grams of 4-acetoxycyclohexanecarboxylic acid, m.p. 137–139°, was dissolved in ether and an excess of diazomethane in ether was added. The solution was dried over magnesium sulfate, the ether removed by distillation, and the residue was crystallized from *n*-pentane at −70°, yielding 1.4 g. of *trans*-VI. Two more crystallizations from *n*-pentane at 0° gave a product melting at 48.0–48.4°. The infrared spectrum was identical with that of the sample obtained from fraction B.

Behavior of Methyl 3-Cyclohexene-1-carboxylate (IV) under the Acetic Anhydride Rearrangement Conditions.—To 8.8 g. (0.063 mole) of IV was added 5.7 g. (0.095 mole) of acetic acid, 50 ml. of acetic anhydride and 0.2 g. of concentrated sulfuric acid. This solution was heated on a steam-bath for six hours and then poured into water and extracted into pentane. The pentane extracts were washed with water and sodium carbonate solution, dried, evaporated and the residue fractionally distilled. The recovered IV, 7.35 g. (83.5%), b.p. 94° (40 mm.), was the only product isolated.

Behavior of Methyl *trans*-3-Acetoxycyclohexanecarboxylate (*trans*-III) in the Acetic Anhydride Rearrangement Conditions.—To 4.25 g. (0.021 mole) of *trans*-III was added 30 ml. of acetic anhydride, 0.2 g. of concentrated sulfuric acid and 0.4 g. (0.022 mole) of water. This solution was treated in a manner identical with the foregoing experiment, and on fractional distillation of the crude product, 3.3 g. (77%) of *trans*-III was recovered. The infrared spectrum of the recovered ester was superimposable on that of authentic *trans*-III.

Behavior of *trans*-3-Methoxycyclohexanecarboxylic Acid (*trans*-I) in the Acetic Anhydride Rearrangement Conditions.—To 10 g. (0.063 mole) of *trans*-I was added 50 ml. of acetic anhydride and 0.2 g. of concentrated sulfuric acid and this solution was heated on a steam-bath for six hours. At the end of this time the solution was poured into water and extracted with pentane. The extracts were dried over magnesium sulfate, evaporated and the remaining oil fractionally distilled. The first fraction was 3-cyclohexene-1-carboxylic acid, b.p. 113–116° (5 mm.), m.p. 17–18.8° (lit.[30] m.p. 17°). The second fraction, believed to be the anhydride of the first, boiled at 128–132° (3 mm.) and had a saponification equivalent of 115 (calcd. 117).

Rearrangement of *cis*-4-Methoxycyclohexanecarboxylic Acid (*cis*-VII) in Acetic Anhydride.—*cis*-VII, 10 g. (0.063 mole), was treated in the same manner as *cis*-I and also yielded two fractions. The first, IV, weighed 3.2 g. (37%), b.p. 93° (40 mm.). The second was a mixture of *trans*-VI and *trans*-III, 4.7 g. (37%), b.p. 115° (5 mm.). This mixture was refractionated and an infrared spectrum obtained.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 60.3; H, 8.1.

Hydrolysis of the Mixed *trans*-VI and *trans*-III from the Rearrangement of *cis*-V.—Two grams (0.01 mole) of mixed *trans*-VI and *trans*-III was hydrolyzed under conditions identical to those employed for fraction B. Two crystallizations of the oily material obtained from the continuous extractions yielded 0.6 g. of *trans*-4-hydroxycyclohexanecarboxylic acid, m.p. 146.5–147.5° (lit.[29] m.p. 148°). A mixed melting point with authentic *trans*-4-hydroxycyclohexanecarboxylic acid showed no depression.

Isolation of Mixture of *trans*-III and *trans*-VI Enriched in *trans*-III from the Acetic Anhydride Rearrangement of *cis*-VII.—A sample of the mixed *trans*-III and *trans*-VI, 4.0 g., from the rearrangement of *cis*-VII, was recrystallized once from *n*-pentane at −70°. The supernatant solution was decanted and fractionally distilled to give a sample of the mixture enriched in *trans*-III, 0.8 g.

Anal. Calcd. for $C_{10}H_{16}O_4$: C, 60.0; H, 8.1. Found: C, 59.9; H, 8.1.

Preparation of Sulfuric Acid-d_2.—From fuming sulfuric acid containing 30% sulfur trioxide was distilled 9.084 g. (0.1135 mole) of sulfur trioxide. This sulfur trioxide was then distilled into 2.26 g. (0.113 mole) of deuterium oxide through a simple distilling tube containing joints only for distilling flask, receiving flask and a vent leading to a calcium chloride drying tube. The distilling flask was heated in a water-bath while the very vigorous reaction of sulfur trioxide with heavy water was kept under control by keeping the receiving flask in cold water. A yield of 10.56 g. (93%) of product was obtained and shown by titration to be 97% deuteriosulfuric acid.

Preparation of *cis*-3-Methoxycyclohexanecarboxylic Acid-*d*.—To 20 g. (0.126 mole) of powdered *cis*-I in a dry separatory funnel was added 10.65 g. (0.53 mole) of deuterium oxide and the mixture was occasionally shaken over a 0.5-hour period. Dry toluene, 50 ml., was then added and the mixture shaken over another half-hour period. Then the two layers were separated and the toluene solution was placed in a distilling flask. The toluene and residual heavy water were distilled off at atmospheric pressure and the deuterated *cis*-I was distilled at 135–140° (3 mm.) yielding 18.9 g. (94%), m.p. 50.6–51.4°. Infrared analysis of deuterio *cis*-I showed the changes expected by deuteration.

Rearrangement of Deutero *cis*-I in Acetic Anhydride.—A solution of 9 g. (0.056 mole) of deuterio *cis*-I in 50 ml. of acetic anhydride, free of acetic acid, was prepared and 0.2 g. of 97% sulfuric acid-d_2 was added. The solution was kept on a steam-bath for 5.5 hours, then poured into 350 ml. of water and extracted with pentane. The extracts were washed with sodium carbonate solution, dried over magnesium sulfate, evaporated and the products fractionally distilled to give 3.2 g. (40%) of methyl 3-cyclohexene-1-carboxylate (IV), b.p. 92–93° (40 mm.). The infrared spectrum of IV was compared to the spectrum of an authentic sample and was shown to contain no deuterium. Also obtained was a mixture of *trans*-III and *trans*-VI, 4.5 g. (40%), b.p. 113–114° (5 mm.), from which pure *trans*-VI was isolated by crystallization from *n*-pentane, m.p. 48.0–48.5°. The infrared spectra of this *trans*-VI were compared with spectra of authentic samples at various concentrations and showed no deuterium content.

The Solvolysis of the Methyl 3-Tosyloxycyclohexanecarboxylates

BY DONALD S. NOYCE AND H. I. WEINGARTEN[1]

RECEIVED NOVEMBER 10, 1956

The acetolysis and formolysis of methyl *cis*-3-tosyloxycyclohexanecarboxylate (I) and methyl *trans*-3-tosyloxycyclohexanecarboxylate (II) have been shown to be normal. No rate acceleration is observed. The product formed is a mixture of olefins and the inverted acetate in each case.

Results

In connection with other studies concerning the rearrangement of disubstituted cyclohexane derivatives,[2,3] it became of importance to examine the solvolysis of the isomeric pair, methyl *cis*-3-tosyloxy cyclohexanecarboxylate (I) and methyl *trans*-3-tosyloxycyclohexanecarboxylate (II). Of importance was the question: would transannular participation manifest itself during these solvolyses, either structurally or kinetically? It is the purpose of the present report to answer this question.

The well known *cis*-3-hydroxycyclohexanecarboxylic acid was converted to its methyl ester and treated with *p*-toluenesulfonyl chloride to give I; and the *trans*-hydroxy acid similarly was converted to II. It also was found possible to separate by fractional crystallization the mixed isomers derived from methyl 3-hydroxycyclohexanecarboxylate.

The rate constants obtained for the solvolysis of I and II in acetic acid and formic acid are summarized in Table I, together with pertinent data for comparison from the work of Winstein and coworkers.[4,5]

TABLE I

RATES OF SOLVOLYSIS OF SUBSTITUTED CYCLOHEXYL TOSYLATES

Tosylate	$k_1 \times 10^5$ sec.$^{-1}$ Acetic acid, 75°	Formic acid, 40°	Rel. rate in acetic acid
Cyclohexyl	4.27[5]	28[a]	1.00
trans-4-*t*-Butylcyclohexyl (VII)	3.75[4]	23[a]	0.88
cis-4-*t*-Butylcyclohexyl (VIII)	10.2[4]	87[a]	2.39
cis-3-Carbomethoxycyclohexyl (I)	0.331 ± 0.008	0.62 ± 0.06	0.078
trans-3-Carbomethoxycyclohexyl(II)	1.59 ± 0.04	2.6 ± 0.2	0.37

[a] Interpolated from data at other temperatures, ref. 4.

Under the conditions of the solvolyses both elimination and substitution take place. From I there was isolated methyl *trans*-3-acetoxycyclohexanecarboxylate (III), 25%, and a mixture of methyl 3-cyclohexene-1-carboxylate (IV) and methyl 2-cyclohexene-1-carboxylate (V). III is the expected, normal, product of solvolytic substitution. The mixture of unsaturated esters, identified by infrared analysis, consisted largely of methyl 3-cyclohexene-1-carboxylate but contained 5–10% methyl 2-cyclohexene-1-carboxylate.

The products resulting from the acetolysis of II are similar. There was obtained methyl *trans*-3-acetoxycyclohexanecarboxylate (VI) in 20% yield and a mixture of IV and V, in similar ratio to that obtained above.

Discussion

The clean inversion accompanying the solvolysis of both I and II shows that the reactions are normal, and establishes the lack of transannular participation. Were such participation to occur, both I and II would be expected to give III.

The relative rate of solvolysis is also normal for each isomer in acetic acid. From the σ^*-value of Taft[6] for the carbomethoxyl group and from the recent correlation of Streitwieser[7] one may calculate the relative rate for I. In I both groups are equatorial, and hence the rate should be that of *trans*-4-*t*-butylcyclohexyl tosylate (VII), modified by the appropriate contribution for the polar influence of the carbomethoxy group. The calculated rate ratio of VII:I is 11:1. The observed ratio is 11:1. For II, the predominant conformation is probably that with the tosylate group in the axial position. This conclusion is reached by the following reasoning. The *A* value for the tosylate group is given by Winstein as 1.7.[4] The *A* value for the ester grouping may be estimated as being between that of ethyl and isopropyl, since there is branching adjacent to the ring. Using a value of 2.5, one concludes that the rate of reaction for II should show the same acceleration relative to I, that VIII shows relative to VII. The observed ratio, 4.5:1, is somewhat higher. However, there is an additional factor which requires consideration. The developing dipole associated with the solvolytic transition state is developing in a plane perpendicular to the dipole associated with the carbomethoxy group in II. In I, however, the developing charge separation will be developed largely in one plane at an angle of about 120°. This will make the polar retardation somewhat more effective for I than for II. Hence the rate ratio would be expected to be slightly larger for II to I, than the ratio of VIII to VII. The polar opposition to "ionization" is very similar to the polar assistance to ionization of *cis*- and *trans*-3-bromocyclohexanecarboxylic acids.[8] The acid dissociation constants of the acids show differences also due

to the direction of the bond dipole associated with the carbon–bromine bond.

The polar effect of the carbomethoxy group is more effective in retarding the rate. The rate ratio VII:I in formic acid is 40:1. This effect would be anticipated on the basis of the greater ionizing power of formic acid as solvent. The rate ratio in formic acid, 4.3, is likewise similar. The evidence clearly establishes that the solvolysis of I and II is normal.

The olefins fraction formed during the solvolysis also gives no evidence of transannular interaction. Exclusive formation of methyl 3-cyclohexene-1-carboxylate was observed in the elimination reaction accompanying the rearrangement of 3-methoxycyclohexanecarboxylic acid chloride. Were transannular interaction important, similar results would be expected. The difference in the relative rates of formation of the two olefins IV and V reflects the inductive influence of the ester grouping in stabilizing the hydrogen in the two position.

Experimental[9]

Methyl *cis*-3-Tosyloxycyclohexanecarboxylate (I).—An authentic 1-g. sample of *cis*-3-hydroxycyclohexanecarboxylic acid,[2,3] m.p. 131.6–132.0°, was converted to its methyl ester with diazomethane in ether. The ether solution was dried over magnesium sulfate, evaporated, and 1.3 g. of *p*-toluenesulfonyl chloride and 10 ml. of pyridine were added. The mixture was allowed to stand overnight. It was then poured into water, acidified and extracted with ether; the ether extract was washed with dilute sulfuric acid, sodium carbonate solution and dried. Crystallization from pentane of the residue obtained on evaporating the ether afforded 1.0 g. of methyl *cis*-3-tosyloxycyclohexanecarboxylate (I), m.p. 86.2–86.5°.

Anal. Calcd. for $C_{15}H_{20}O_5S$: C, 57.7; H, 6.5; S, 10.3. Found: C, 57.8; H, 6.7; S, 10.1.

Methyl *trans*-3-Tosyloxycyclohexanecarboxylate (II).—*trans*-3-Hydroxycyclohexanecarboxylic acid,[2,3] m.p. 118.8–119.6°, 0.1 g., was converted to authentic II as in the above experiment. The m.p. of the II thus obtained is 90.0–90.5°.

Anal. Calcd. for $C_{15}H_{20}O_5S$: C, 57.7; H, 6.5; S, 10.3. Found: C, 57.7; H, 6.5; S, 10.0.

Preparation and Isolation of the Methyl *cis*- and *trans*-3-Tosyloxycyclohexanecarboxylates (I and II).—A 34-g. (0.22 mole) sample of methyl 3-hydroxycyclohexanecarboxylate (mixed isomers) was dissolved in 100 ml. of pyridine and 45 g. (0.24 mole) of *p*-toluenesulfonyl chloride was added and allowed to stand overnight. The solution was then poured into water and extracted with 3:1 ether–pentane. The extracts were washed with water, dilute sulfuric acid and sodium carbonate solution, then dried over magnesium sulfate. The dry extracts, about 400 ml., were concentrated to three-fourths their volume and 700 ml. of *n*-pentane was added, making the ether–pentane ratio approximately 1:4. By a process of fractional crystallization and mechanical separation of the differently appearing crystals, 12 g. (18%) of I (polyhedral prisms), m.p. 85.5–86.3°, and 31 g. (47%) of crude I, m.p. 85–86°, were obtained. A dimorph of I was isolated first (m.p. 63°, long needles from *n*-pentane) but no longer appeared after the isolation of the higher melting form.

Also obtained was 13 g. (19%) of II (soft light plates), m.p. 89–90.5°.

Kinetic Procedure.—Acetic anhydride, 0.1%, was added to purified acetic acid, which analyzed for water content 0.01% by Karl Fischer titration. It was used in this form as solvent.

Formic acid was treated with boric anhydride and fractionated. It titrated 99.95% formic acid.

The volumetric equipment was calibrated, and the progress of the reactions was followed by potentiometric titration, with sodium acetate in acetic acid using a procedure similar to that of Winstein and Marshall.[10] For the acetolyses of I and II, the course of the reaction was followed to 80% completion.

The formolysis experiments were carried out on a much more limited basis and the rate constants are likely to be precise to only 10%.

Product Analysis of I Acetolysis.—I, 10 g. (0.032 mole), was dissolved in 100 ml. of acetic acid and 3.2 g. (0.032 mole) of potassium acetate was added. The flask, equipped with a spiral condenser capped by a calcium chloride tube, was placed on a steam-bath for 48 hours (about three half-lives). The solution was then poured into water, neutralized with solid sodium carbonate and extracted two times with pentane. The extracts were dried, evaporated and the products separated by fractional distillation. Fraction 1, weighing 1.9 g. (40%), proved on infrared analysis to be a mixture of methyl 2-cyclohexene-1-carboxylate and methyl 3-cyclohexene-1-carboxylate, b.p. 92–93° (40 mm.), $n^{25}D$ 1.4598. Fraction 2, 1.6 g. (25%), proved on infrared analysis to be methyl *trans*-3-acetoxycyclohexanecarboxylate, b.p. 110–112° (5 mm.), $n^{25}D$ 1.4521.

Product Analysis of II Acetolysis.—II, 10 g. (0.032 mole), was solvolyzed as in the above experiment for 12 hours on a steam-bath (about three half-lives) and also yielded two fractions on fractional distillation. Fraction one, b.p. 93–94° (40 mm.), weighed 1.3 g. (29%) and on infrared analysis proved to be a mixture of methyl 2-cyclohexene-1-carboxylate and methyl 3-cyclohexene-1-carboxylate, $n^{25}D$ 1.4589. Fraction two, weighing 1.3 g. (20%), was shown to be methyl *cis*-3-acetoxycyclohexanecarboxylate, b.p. 115–117° (5 mm.), by infrared spectrum.

Fraction two was hydrolyzed in the usual way and yielded 0.3 g. of *cis*-3-hydroxycyclohexanecarboxylic acid, m.p. 131–131.9° (no depression on admixture with an authentic sample).

Neighboring Carbon and Hydrogen. XXVII. Ar_1-5 Aryl Participation and Tetralin Formation in Solvolysis[1,2]

By Richard Heck and S. Winstein

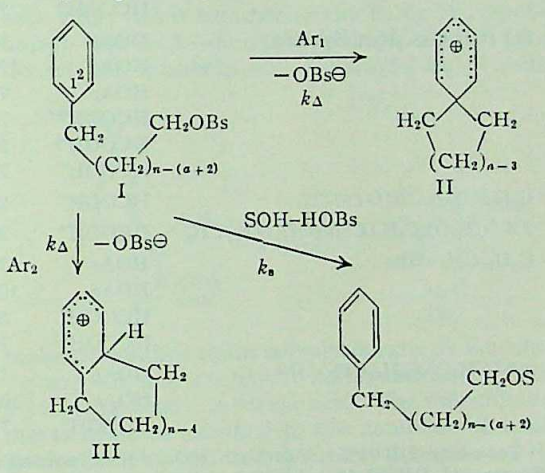
Received November 10, 1956

It is possible, by suitable choice of structure and solvent, to arrange for participation of δ-aryl groups in solvolysis of 4-aryl-1-butyl *p*-bromobenzenesulfonates. When the aryl group is activated by one *p*- or two *o,p*-methoxyl groups, the participation is Ar_1-5 in type; a spiro-carbonium ion is produced by anchimerically assisted ionization of the 4-aryl-1-butyl bromobenzenesulfonate. Rearrangement of the spiro-carbonium ion intermediate and proton loss give rise to a tetralin product. On the assumption that k_s, the rate constant of anchimerically unassisted solvolysis, is associated with formation of ester, and that k_Δ, the rate constant of anchimerically assisted ionization, is associated with formation of tetralin, it is possible to dissect the acetolysis and formolysis rate constants for 4-phenyl-1-butyl bromobenzenesulfonate into the appropriate k_s and k_Δ values. Assuming k_s is insensitive to methoxyl substitution, one can assign k_s and k_Δ values in solvolysis of the substituted 4-aryl-1-butyl bromobenzenesulfonates. These values of k_s and k_Δ predict product compositions within experimental error, assuming k_s and k_Δ are associated with formation of ester and tetralin, respectively. As regards variation of k_Δ in Ar_1-*n* participation with the size of the ring being formed in the intermediate spiro-carbonium ion, the observed rate sequence is $3 \gg 4 \ll 5 \gg 6$. Both the 3:5 and 5:6 ratios are of the order of 10^2. Of the *n* values, 4, 5 and 6, only in the case of 5 were substantial values of k_Δ and k_Δ/k_s observed.

Many cases of ionization of a β-arylethyl *p*-bromobenzenesulfonate, with the degree of methyl or phenyl substitution sufficiently large[3] on C_β and not too large[3] on C_α, are anchimerically[4] assisted,[3,5] leading to a bridged intermediate[6,7] or a rearranged carbonium ion. It is convenient to employ the symbol k_Δ for the rate constant of such anchimerically assisted ionization. Still other cases of ionization, rate constant k_s, are anchimerically unassisted. Such ionization may lead to an unrearranged carbonium ion intermediate which may rearrange subsequently. With a properly substituted structure, which is not too favorable[8] for one of the classical open forms of the carbonium ion, the bridged form of the carbonium ion is preferred.

It is convenient to adopt a notation[2] in which participation of a β-phenyl group is symbolized Ar_1-3. The general notation is Ar_a-*n*, where Ar denotes aryl and the subscript *a* refers to the position in the participating aryl group involved in the creation of the ring in the transition state for anchimerically assisted ionization. The size of the ring being made is indicated by the number *n*.

As has already been reported in preliminary communications,[2] it is possible, by suitable choice of structure and solvent, to arrange for participation of aryl groups more distant than β in solvolysis of arylalkyl benzenesulfonates I. Examples of such participation are Ar_1-5 and Ar_2-6, illustrated schematically by the conversion of I to II ($n = 5$) or III ($n = 6$), respectively.



In seeking information on Ar-4, 5 and 6 participation, a large number of arylsulfonates has been studied. Some of the results bearing principally on the Ar_1-variety are reported in the present paper, while Ar_2 is treated in the following one.

In searching for anchimeric effects of aryl groups, the procedure employed was first to explore the rates of solvolysis of various phenylalkyl bromobenzenesulfonates and the corresponding methoxyphenylalkyl esters. We expected[9] anchimerically unassisted solvolysis, with rate constant k_s, to be quite insensitive to methoxyl substitution, but anchimerically assisted solvolysis, with rate constant k_Δ, quite sensitive to suitably oriented methoxyl groups. On this basis, an anchimerically assisted process was not contributing seriously to the solvolysis of a methoxyphenylalkyl bromobenzenesulfonate unless the introduction of the methoxyl group was accompanied by an increase in solvolysis rate. Using kinetics as a guide, cases were selected for examination of the products of solvolysis for further elucidation of the nature of the solvolysis in question.

Arylalkyl Systems.—The various arylsulfonates employed in this work appear in Table I, which

summarizes also the kinetic data obtained with them.

Of the required primary alcohols, 3-phenyl-1-propanol was available commercially. 3-*p*-Anisyl-1-propanol and 3-(2,4-dimethoxyphenyl)-1-propanol were prepared from the corresponding cinnamic acids by reduction with lithium aluminum hydride, the cinnamic acids being obtained from anisaldehyde[10] and 2,4-dimethoxybenzaldehyde[10] by the Knoevenagel reaction. The several butyl alcohols, 4-phenyl-, 4-*p*-anisyl-, and 4-(2,4-dimethoxyphenyl)-1-butanols were all prepared by Friedel–Crafts succinoylation of the proper benzene derivatives, followed by Clemmensen and lithium aluminum hydride reduction.

Of the two primary pentanols which were studied, the 5-phenyl-1-pentanol was prepared from γ-phenylpropylmagnesium chloride and ethylene oxide, while the 5-(2,4-dimethoxyphenyl)-1-pentanol was prepared from the corresponding acid by reduction with lithium aluminum hydride. The 5-(2,4-dimethoxyphenyl)-pentanoic acid was prepared by Clemmensen reduction of γ-(2,4-dimethoxybenzoyl)-butyric acid, prepared by a Friedel–Crafts reaction between *m*-dimethoxybenzene and glutaric anhydride.

One of the two secondary alcohols which were studied, 1-phenyl-4-pentanol, was prepared from γ-phenylpropylmagnesium chloride and acetaldehyde.[11] The 1-(2,4-dimethoxyphenyl)-4-pentanol was prepared from the corresponding ketone by reduction with lithium aluminum hydride. This ketone was obtained from the reaction of 4-(2,4-dimethoxyphenyl)-butyric acid with methyllithium.

Kinetic Search for Ar_1.—As summarized in Table I, all the arylsulfonates displayed good first-order kinetics of acetolysis and formolysis, except 3-(2,4-dimethoxyphenyl)-1-propyl *p*-bromobenzenesulfonate. This substance displayed a downward drifting first-order rate constant in acetolysis, an extrapolated initial value being given in Table I.

In the kinetic search for neighboring aryl participation, the ω-phenylalkyl arylsulfonates are reference compounds, and the relative rates of acetolysis and formolysis of these reference compounds are summarized in Table II. For this comparison, rate

ment is to be ascribed to participation of the *ortho* methoxyl group with formation of the intermediate IV. Such participation is common with ω-*o*-anisylalkyl arylsulfonates,[12,13] and the 3-*o*-anisyl-1-propyl *p*-bromobenzenesulfonate displays even a slightly higher rate constant[12] than the one observed with the 3-(2,4-dimethoxyphenyl)-1-propyl ester. Thus, the comparison in Table III shows that no appreciable incursion of Ar_1-4 (or Ar_2-5) aryl participation is indicated for the methoxyphenylpropyl esters examined.

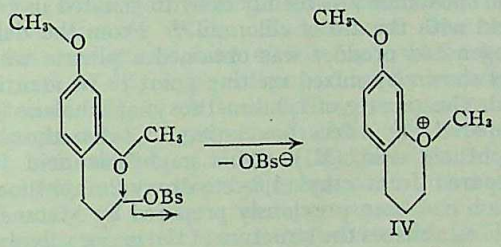
[a] k_Δ is below 8×10^{-8} sec.$^{-1}$. [b] From data reported in the following article.

constants for 3-phenyl-1-propyl *p*-bromobenzenesulfonate are taken as unity. Using the entropy of activation as a guide to mechanism,[9] the indications are that substantially the whole of the solvolysis is anchimerically unassisted in acetolysis of the 3-, 4- and 5-phenyl-1-alkyl esters. In formic acid, the ω-phenyl-1-alkyl esters except 2-phenylethyl again have the low $\Delta S^{\ddagger}$ characteristic of anchimerically unassisted solvolysis. The relatively high $\Delta S^{\ddagger}$ for the phenylethyl ester was ascribed previously[9] to the importance of anchimerically assisted ionization in formic acid.

The relative rates themselves support the conclusions derived on the basis of the $\Delta S^{\ddagger}$ values in Table II. The relatively smooth small increase in acetolysis rate, by less than a factor of two, in the series from phenylethyl to phenylpentyl is in line with the decreasing rate-retarding polar (and steric) effect of the phenyl group. The rate constants for the 4-phenyl-1-butyl and 5-phenyl-1-pentyl esters are essentially equal to the value for the *n*-butyl ester, giving no indication of substantial contribution from anchimerically assisted solvolysis. The situation is similar in formic acid, except that the rate-retarding effect of the phenyl group in phenylethyl *p*-bromobenzenesulfonate is more than compensated by the incursion of anchimerically assisted ionization.[4,9]

Methoxy substitution in the phenyl group of the ω-phenylalkyl esters will, of course, tend to favor aryl participation in solvolysis. In scrutinizing the effect of such substitution on solvolysis rate, it is convenient to consider first the series of 3-phenyl-1-propyl derivatives. In Table III are summarized the relative solvolysis rates of 3-phenyl-1-propyl *p*-bromobenzenesulfonate, together with those of the 4- and 2,4-methoxy derivatives, substituted so as to favor Ar_1-4 aryl participation. Included also in the comparison are the 3- and 3,5-methoxy derivatives, reported in detail in the next article. Examination of Table III reveals that all the 3-aryl-1-propyl *p*-bromobenzenesulfonates display nearly identical solvolysis rates, except the 2,4-dimethoxy derivative which displays a higher initial acetolysis rate constant than the others. However, there is no reason to ascribe the observed rate enhancement to Ar_1-4 participation. Instead, this

fonates, substantial rate enhancements are observed when methoxyl groups are substituted in the benzene ring. As is summarized in Table IV, the 4-*p*-anisyl- and 4-(2,4-dimethoxyphenyl)-1-butyl esters exceed the unsubstituted 4-phenyl-1-butyl *p*-bro-



IV

mobenzenesulfonate in solvolysis rate by factors of 1.3 and 4.3, respectively, in acetic acid and 1.77 and 9.91, respectively, in formic acid. The rate enhancements must be ascribed to the incursion of anchimerically assisted solvolysis in the case of the methoxyl-substituted 4-phenyl-1-butyl esters. Otherwise, methoxyl substitution would be expected to be without appreciable effect on solvolysis rate, just as in the case of the 3-phenyl-1-propyl esters.

Additional support for the idea that Ar_1-5 participation grows more important with methoxyl substitution in 4-phenyl-1-butyl bromobenzenesulfonate is provided by the $\Delta S^{\ddagger}$ values recorded in Table I. These change from the level of *ca.* −17 e.u. associated with anchimerically unassisted solvolysis (rate constant k_s) to a level of *ca.* −10 e.u. for 4-(2,4-dimethoxyphenyl)-1-butyl bromobenzenesulfonate. The latter substance, with the most enhanced formolysis rate, must undergo very largely anchimerically assisted solvolysis, so $\Delta S^{\ddagger}$ for Ar_1-5-assisted ionization in formic acid must be close to −10 e.u.

Products.—Further insight into the nature of the solvolytic reactions of the 4-aryl-1-butyl bromobenzenesulfonates is provided by the results of an examination of the derived products. In this examination, the crude product from formolysis or acetolysis was reduced with lithium aluminum hydride to reduce ester to alcohol. Then hydro-

[a] Data of R. Glick. [b] Assuming products are the same at 75° as at 100°. At 100°, k_s is 1.53×10^{-5} and k_Δ is 9×10^{-7} sec.$^{-1}$.

carbon and alcoholic products were separated by chromatography.

From formolysis of 4-(2,4-dimethoxyphenyl)-1-butyl bromobenzenesulfonate (V) was obtained an 8% yield of an alcohol which was converted into *p*-nitrobenzoate in *ca.* 70% yield. This was shown by mixed melting point to be the *p*-nitrobenzoate of 4-(2,4-dimethoxyphenyl)-1-butanol (VI). A second product, obtained in 76% yield, was a colorless liquid which later crystallized. It was inert to potassium permanganate in acetone, and it analyzed correctly for a tetralin. It yielded a monobromide on treatment with bromine in carbon tetrachloride. The substance was readily dehydrogenated in good yield with the aid of chloranil.[14] From the dehydrogenated product was obtained a picrate which was shown by mixed melting point to be identical with the picrate of 1,3-dimethoxynaphthalene (X) prepared by decarboxylating 1,3-dimethoxy-2-naphthoic acid (XI). This naphthoic acid was prepared from ethyl 1,3-dihydroxy-2-naphthoate, which had been previously prepared by Metzner.[15] This establishes the structure of the major solvolysis product as 5,7-dimethoxytetralin (IX).

Except for the proportions of tetralin and alcohol products, 4-*p*-anisyl-1-butyl bromobenzenesulfonate behaved analogously to the 4-(2,4-dimethoxyphenyl)-1-butyl derivative in formolysis. From the 4-*p*-anisyl-1-butyl ester was obtained a 43% yield of alcohol and a 51% yield of a material, inert to potassium permanganate in acetone, with physical properties in agreement with those reported for 7-methoxytetralin.[16,17]

The solvolysis of 4-phenyl-1-butyl *p*-bromobenzenesulfonate was also examined in both formic and acetic acids. In the former solvent, 4-phenyl-1-butyl bromobenzenesulfonate gave rise to a 16.7% yield of tetralin, identified by boiling point, refractive index, infrared spectrum and by its conversion in high yield to naphthalene by a dehydrogenation with tetrachloro-1,2-benzoquinone.[18] From the formolysis there was obtained also a 72% yield of 4-phenyl-1-butanol. In acetic acid, 4-phenyl-1-butyl bromobenzenesulfonate gave rise to an even smaller proportion of tetralin than in formic acid, the yield of tetralin being 4.9%.

For the solvolyses in which the products were examined, summarized in Table V, sufficient controls were run to establish that tetralin did not arise from the formate or acetate ester subsequent to its formation. Thus, 4-(2,4-dimethoxyphenyl)-1-butanol survived essentially quantitatively under the conditions for the formolysis. With 4-phenyl-1-butanol, no tetralin was observed after treatment in formic acid for the length of time involved in a solvolysis of the bromobenzenesulfonate, even when the formic acid solvent was acidified with toluenesulfonic acid. Similarly, no tetralin was observed to be formed from 4-phenyl-1-butyl acetate in acetic acid containing toluenesulfonic acid.

Dissection of k into k_Δ and k_s and Mechanism of Tetralin Formation.—By dissecting the solvolysis rate constants for the 4-aryl-1-butyl *p*-bromobenzenesulfonates into k_Δ, the rate constant for anchimerically assisted solvolysis, and k_s, the rate constant for anchimerically unassisted solvolysis, composition of solvolysis products can be connected quantitatively with observed rates. The dissection of rate constants is based on the k_s assigned to 4-phenyl-1-butyl *p*-bromobenzenesulfonate on the assumption that anchimerically assisted solvolysis leads only to tetralin and anchimerically unassisted solvolysis gives no tetralin. This assumes that any intermediate[19,20] in the anchimerically unassisted solvolysis of a simple primary arylsulfonate, such as 4-phenyl-1-butyl, would be too unstable and short-lived to lead to serious amounts of electrophilic attack on the benzene ring instead of collapsing to acetate or formate. The values assigned to k_Δ and k_s on this basis are listed in Table IV.

For the methoxyphenylbutyl esters, k_s is assumed equal to k_s for the unsubstituted 4-phenyl-1-butyl derivative, by analogy with the 3-aryl-1-propyl esters, where k_s is insensitive to methoxyl substitution. Subtracting k_s from the observed solvolysis rate constants leads to the derived values of k_Δ

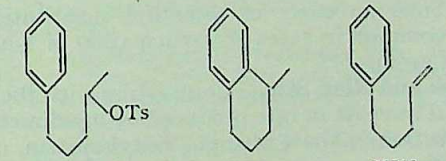
summarized in Table IV. These are, of course, much larger for the methoxyphenyl cases than for the unsubstituted phenyl derivative.

The assumption for the methoxy-substituted 4-phenyl-1-butyl esters, just as in the case of the 4-phenyl-1-butyl derivative, that k_Δ is connected with tetralin formation, allows one to calculate the expected product composition. The calculated values for per cent. tetralin in the product, namely, $100\,k_\Delta/(k_s + k_\Delta)$, are shown in Table V, along with the observed product compositions. It is apparent that the calculated and observed product compositions agree within experimental error, so that the underlying assumptions are at least semi-quantitatively valid.

The mode of formation of the observed tetralins from the methoxy-substituted 4-phenyl-1-butyl bromobenzenesulfonates is especially interesting, since the *ortho* and *para* methoxyl groups favor Ar_1-5 participation. It is reasonable to believe that k_Δ is predominantly connected with formation of a spiro-carbonium ion, VII in the case of solvolysis of the 4-(2,4-dimethoxy-phenyl)-1-butyl bromobenzenesulfonate. This must rearrange, as in the related dienone–phenol rearrangement,[21] probably to another intermediate VIII, finally leading to tetralin IX. In the present examples, no more direct evidence is available for the spiro-carbonium ion intermediate like VII, but such direct evidence is available in cases where, for example, C_δ of the original bromobenzenesulfonate is dimethylated.[2b]

Secondary Systems.—Two secondary arylsulfonates, 5-phenyl-2-pentyl (XII) and 5-(2,4-dimethoxyphenyl)-2-pentyl toluenesulfonates were examined for comparison with their primary analogs. As summarized in Table VI, the 2,4-methoxyl groups enhance formolysis rate in the 5-phenyl-2-pentyl system, but the factor is only 2.5 instead of *ca.* 10 observed in the primary case.

The products of formolysis of 5-phenyl-2-pentyl toluenesulfonate (XII), after lithium aluminum hydride reduction, were 46.6% 5-phenyl-2-pentanol and 47.8% hydrocarbon. The hydrocarbon contained 30% of olefin according to quantitative hydrogenation. Removal of olefin by reaction with osmium tetroxide left a hydrocarbon which was inert to potassium permanganate in acetone and analyzed correctly and possessed the correct physical properties for 1-methyltetralin (XIII). On this basis, the composition of solvolysis product may be restated as 35% tetralin, 50% alcohol and 15% olefin.



That the formation of the 1-methyltetralin (XIII) obtained in formolysis of 5-phenyl-2-pentyl toluenesulfonate is associated with the solvolysis reaction and it is not formed from reaction of formate ester or olefin subsequent to their formation is clear from control experiments. Under conditions of formolysis of the toluenesulfonate XII, 5-phenyl-2-pentanol yields no tetralin XIII. Similarly, the olefin produced in solvolysis of toluenesulfonate is quite inert to the solvolysis conditions. Even a sample of 5-phenyl-1-pentene (XIV), the straight chain olefin expected to be most reactive in tetralin formation, reacts only very slowly with formic acid. Even in the absence of added sodium formate, the 5-phenyl-1-pentene (XIV) in formic acid solution is only about one third converted to tetralin and formate ester in a ratio of 0.6:1 after a reaction time *ca.* 15 times that employed in solvolysis of the toluenesulfonate XII.

When it comes to dissecting the rate constant of solvolysis of the secondary toluenesulfonates into

(21) (a) See ref. 2b for other references; (b) a very closely related dienonephenol rearrangement is the following example studied in these Laboratories (R. Baird, unpublished work)

$2,4\text{-}(CH_3O)_2C_6H_3(CH_2)_3CHCH_3$ (OTs)	2.50	2894	5.43×10^{-5}	8.2×10^{-5}	1429	9111	1.51

[a] The value of the *p*-bromobenzenesulfonate divided by three. [b] Extrapolated from data at other temperatures. [c] Assuming products are the same at 25° as at 75°.

k_s and k_Δ, we cannot assume for the 5-phenyl-2-pentyl toluenesulfonate that tetralin formation is connected only with k_Δ, as we did for the 4-phenyl-1-butyl system. A carbonium ion intermediate[19] in the anchimerically unassisted formolysis of the secondary toluenesulfonate could well lead to substantial amounts of electrophilic attack on the benzene ring, resulting finally in tetralin formation. Thus, at least part of the tetralin formation could be connected with k_s. What has been done in writing down the values of k_s and k_Δ in Table VI for 5-(2,4-dimethoxyphenyl)-2-pentyl toluenesulfonate is to assume the rate constant of 5-phenyl-1-pentyl toluenesulfonate is entirely k_s, k_Δ being zero. On this basis, the k_s values are maximal, and k_Δ for 5-(2,4-dimethoxyphenyl)-2-pentyl toluenesulfonate is a minimum figure.

The k_Δ and k_s values for the secondary toluenesulfonates listed in Table VI are sufficiently clear to bring out the point that the α-methyl group which converts the primary to secondary arylsulfonates increases k_s more than k_Δ. This results in a lower k_Δ/k_s ratio for secondary arylsulfonate than for primary, aryl participation being considerably less dominant with secondary than primary arylsulfonate. Such an effect of α-methyl substitution is quite common in cases of participation of β-neighboring groups.[3,22]

Ar$_1$-*n* and Ring Size.—Contrasting with the substantial increase in rate produced by *o,p*-dimethoxy substitution in the 4-phenyl-1-butyl system, is the small increase produced in the case of 5-phenyl-1-pentyl bromobenzenesulfonate. In Table VII are compared the 5-phenyl-1-pentyl and 5-(2,4-dimethoxyphenyl)-1-pentyl bromobenzenesulfonates. By using the rate constant for the 5-phenyl-1-pentyl ester as k_s, one obtains an estimate for k_Δ only *ca.* 0.07 times k_s in the case of 5-(2,4-dimethoxyphenyl)-1-pentyl bromobenzenesulfonate. Thus, it is clear that rates associated with Ar$_1$-6 participation are much lower than those associated with Ar$_1$-5. Consequently, it will be more difficult to arrange conditions of structure and solvent so as to have Ar$_1$-6 participation dominate the rate-determining step of solvolysis of an arylsulfonate.[23]

In Table VIII are summarized relative k_Δ values for acetolysis and formolysis of ω-aryl-1-alkyl bromobenzenesulfonates for alkyl systems from ethyl to pentyl. In this comparison, k_Δ for 4-*p*-anisyl-1-butyl was taken as unity. Also summarized in Table VIII are the corresponding values of k_Δ/k_s. These orient one on the extent to which Ar$_1$-*n* participation dominates the solvolysis, while the relative k_Δ values are useful for outlining the variation of k_Δ with ring size or degree of methoxyl substitution.

[a] Rough values based on a k_Δ equal to the solvolysis rate constant.[9] [b] Based on a k_s equal to twenty times the rate constant for acetolysis of β-phenylethyl *p*-bromobenzenesulfonate.[9] [c] Based on a k_Δ three times k^0_{ext} for the *p*-sulfonate.[9] [d] Based on rate constant three times toluenesulfonate.[24] [e] Based on a k_s equal the value for the toluenesulfonate.[4] [f] Based on salt-enhanced rate constant.[9] to rate constant for acetolysis of β-phenylethyl *p*-bromobenzenesulfonate.[9]

The values in Table VIII reveal that both Ar$_1$-4 and Ar$_1$-6 participations compete very poorly in solvolysis of ω-aryl-1-alkyl arylsulfonates in acetic or formic acid solvents. In fact, the measured solvolysis rate constants of the corresponding bromobenzenesulfonates were so little greater than the k_s values, that the k_Δ values in Table VIII are very rough.

It is clear from the comparison in Table VIII that anchimerically assisted solvolysis is much more dominant with β-arylethyl than 4-aryl-1-butyl systems, rate of ionization with Ar$_1$-3 being much higher than the one with Ar$_1$-5 participation. The

sequence of rates of ionization with Ar$_1$-n participation as n varies is explicitly given in Table IX. From this it is clear that the sequence is $3 > 4 < 5 > 6$, both the 3:5 and the 5:6 ratios being of the order of 10^2.

TABLE IX

RELATIVE RATES OF Ar$_1$-n RING CLOSURES IN SOLVOLYSIS OF ω-ARYL-1-ALKYL BROMOBENZENESULFONATES AT 75°

Ar group	Solvent	Ring size, n: 3	4	5	6
4-$CH_3OC_6H_4$	AcOH	147	<0.2	1.00	
	HCOOH	161		1.00	
2,4-$(CH_3O)_2C_6H_3$	AcOH	262		1.00	0.014
	HCOOH	227		1.00	.007

Effect of Methoxy.—Reference to Tables IV and VIII reveals that the effects of methoxyl substitution in the benzene ring of 4-phenyl-1-butyl *p*-bromobenzenesulfonate on k_Δ tends to be less than with the 2-phenyl-1-ethyl system. The second methoxyl group (*ortho*) increases Ar$_1$-5 rate by a factor of 9 and Ar$_1$-3 by a factor of 13–16. The first methoxyl group (*para*) increases k_Δ in the 4-aryl-1-butyl system by a factor of only *ca.* 5–7, much smaller than in the case of Ar$_1$-3 rates. However, if the k_Δ for 4-phenyl-1-butyl *p*-bromobenzenesulfonate could be dissected into Ar$_1$-5 and Ar$_2$-6 components, the factor by which a *p*-methoxy group would be calculated to increase Ar$_1$-5 rate might be substantially larger than the value of *ca.* 5–7.

The factor by which a methoxyl group on the benzene ring facilitates electron-demanding reactions varies widely. In bromination,[25] for example, a *p*-methoxyl group increases rate by a factor of *ca.* 10^{10}. The relatively small effect of methoxyl in Ar$_1$-5 indicates a rather low degree of aryl involvement at the transition state configuration.

Experimental

3-*p*-Anisyl-1-propanol.—This alcohol was prepared in 44% yield by the reduction of *p*-methoxycinnamic acid[10] with lithium aluminum hydride, the acid being added to a stirred suspension of 1.5 moles of lithium aluminum hydride by means of a Soxhlet extractor.

3-(2,4-Dimethoxyphenyl)-1-propanol.—This material was prepared by addition of 46 g. of 2,4-dimethoxycinnamic acid[10] to an ether suspension of 12 g. of lithium aluminum hydride. The acid was added from a Soxhlet extractor, two days being required for the addition. The alcohol product, b.p. 144–145° (3.5 mm.), n^{25}D 1.5320, m.p. 36–38°, was obtained in 39% yield.

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22. Found: C, 67.16; H, 8.25.

4-Phenyl-1-butanol.—This material was prepared in high yield by lithium aluminum hydride reduction of γ-phenylbutyric acid.

Treatment of the alcohol with acetic anhydride and a few drops of pyridine for 1 hour on the steam-bath gave rise to 4-phenyl-1-butyl acetate, b.p. 120° (8.5 mm.), n^{25}D 1.4948.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39. Found: C, 74.73; H, 8.10.

4-*p*-Anisyl-1-butanol.—The reduction of 4-*p*-anisylbutyric acid[26] with lithium aluminum hydride gave rise to 4-*p*-anisyl-1-butanol, b.p. 125–130° (1.5 mm.), n^{25}D 1.5201, in 91.5% yield. A small sample, redistilled for analysis, had n^{25}D 1.5200.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.43; H, 9.05.

4-(2,4-Dimethoxyphenyl)-1-butanol.—The reduction of 4-(2,4-dimethoxyphenyl)-butyric acid[17] with lithium aluminum hydride afforded the alcohol, b.p. 157–161° (2.5 mm.), n^{25}D 1.5296, in quantitative yield.

Anal. Calcd. for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63. Found: C, 68.68; H, 8.40.

The *p*-nitrobenzoate of the alcohol prepared in the usual fashion, had the m.p. 52–53° after two recrystallizations from methanol.

Anal. Calcd. for $C_{19}H_{21}O_6N$: C, 63.50; H, 5.89. Found: C, 63.73; H, 6.01.

5-Phenyl-1-pentanol.—This material, b.p. 110–113° (3 mm.), n^{25}D 1.5149, was prepared from γ-phenylpropylmagnesium chloride and ethylene oxide. A b.p. of 151° (13 mm.) has been reported[11] for this alcohol.

ω-Aryl-1-alkyl *p*-Bromobenzenesulfonates.—The primary alcohols were converted to *p*-bromobenzenesulfonates by the low temperature method described previously,[9] the physical properties and analyses of the products being summarized in Table X.

γ-(2,4-Dimethoxybenzoyl)-butyric Acid.—To a mixture of 40 g. of glutaric anhydride and 50 g. of resorcinol dimethyl ether in 450 cc. of purified tetrachloroethane, cooled to 0°, was added 100 g. of anhydrous aluminum chloride in small portions with stirring. The mixture became purple and a viscous solid separated. After *ca.* 30 min. at 0°, ice and dilute hydrochloric acid were added. After working up the reaction mixture and recrystallizing the product from aqueous methanol, 18 g. of the desired acid was obtained. A small sample, recrystallized for analysis had a melting point of 106–107°.

Anal. Calcd. for $C_{13}H_{16}O_5$: C, 61.89; H, 6.39. Found: C, 61.61; H, 6.19.

5-(2,4-Dimethoxyphenyl)-valeric Acid.—The above keto acid (17 g.) was reduced by the Clemmensen method using 50 g. of zinc (amalgamated), 30 cc. of toluene, 30 cc. of water and 70 cc. of concd. hydrochloric acid. The mixture was refluxed for two days while 10 cc. of concd. hydrochloric acid was added every 6 hours. The product was extracted from the toluene phase with bicarbonate solution. Acidification of the bicarbonate extract gave the acid which was recrystallized from aqueous methanol to yield 5.5 g. of the acid, m.p. 95–98°. A small sample, recrystallized for analysis had m.p. 97–98.5°.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61. Found: C, 65.72; H, 7.63.

5-(2,4-Dimethoxyphenyl)-1-pentanol.—This alcohol, b.p. 144–145° (2 mm.), n^{25}D 1.5247, was obtained in 96% yield by the lithium aluminum hydride reduction of 5-(2,4-dimethoxyphenyl)-valeric acid.

Anal. Calcd. for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99. Found: C, 69.55; H, 8.79.

The *p*-bromobenzenesulfonate of the alcohol was obtained as a liquid, 90% pure according to the equivalent weight in acetolysis and formolysis.

1-Phenyl-4-pentyl *p*-Toluenesulfonate.—To a solution of 15 g. of 5-phenyl-2-pentanol,[11] b.p. 80–84° (1 mm.), n^{25}D 1.5108, in 75 ml. of dry pyridine was added 25 g. of *p*-toluenesulfonyl chloride. The mixture was kept below room temperature until the exothermic reaction was over, and then it was left at room temperature for another 2 hours. Working up the reaction mixture and evaporation of an ether solution of the product gave rise to an oil which was chromatographed on alumina. From the fraction eluted by benzene–pentane was obtained 9.5 g. of product, n^{25}D 1.5382, 93% pure by equivalent weight in formolysis.

1-(2,4-Dimethoxyphenyl)-4-pentanol.—4-(2,4-Dimethoxyphenyl)-butyric acid (16 g.) in 50 ml. of ether was added dropwise with stirring to a solution of methyllithium prepared from 25 g. of methyl iodide and 2.5 g. of lithium ribbon in 200 ml. of ether. After 30 minutes stirring, cold dil. hydrochloric acid was added. The ether phase was separated and washed with water and a sodium bicarbonate solution. After being dried, the ether solution was distilled, the fraction, b.p. 120–150° (2 mm.), being then reduced with lithium aluminum hydride. A 3.5-g. quantity of the alcohol, b.p. 135–139° (2 mm.), n^{25}D 1.5219, was obtained.

Anal. Calcd. for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99. Found: C, 69.58; H, 9.20.

[a] $n^{25}D$ 1.5694.

The *p*-toluenesulfonate of the alcohol was obtained as an impure liquid, $n^{25}D$ 1.5250, 70% pure according to the equivalent weight in formolysis.

Kinetic Measurements.—The procedure for the kinetic measurements was identical to that employed previously.[9]

Only with 3-(2,4-dimethoxyphenyl)-1-propyl *p*-bromobenzenesulfonate did the acetolysis fail to obey first-order kinetics strictly. The rate constant drifted down in a run, as is illustrated in Table XI. The initial rate constant was obtained from a plot of log $[(ROBs)_0/(ROBs)]$ *vs.* time.

Products of Formolysis of 4-(2,4-Dimethoxyphenyl)-1-butyl *p*-Bromobenzenesulfonate.—A mixture of 18.4 g. of 4-(2,4-dimethoxyphenyl)-1-butyl *p*-bromobenzenesulfonate and 3.40 g. of sodium formate in 900 cc. of dry formic acid was heated at 75° for six hours. The resulting solution was diluted with water and extracted with four 500-ml. portions of ether. The combined extracts were washed with water and aqueous sodium bicarbonate. After the extract was dried, the solvent was removed and the residue was reduced with 2 g. of lithium aluminum hydride in ether. The reduction product was extracted with dilute sodium hydroxide. The basic extract became colored orange, but only a negligible amount of material appeared when this extract was acidified. The reduction product yielded three fractions when it was chromatographed on 500 g. of alumina.

The first fraction was eluted with 5 liters of pentane. The tetralin product, b.p. 102–105° (2 mm.), $n^{25}D$ 1.5454, weighed 5.5 g. This material was inert to potassium permanganate in acetone. A sample, b.p. 105° (2 mm.), was analyzed.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39. Found: C, 75.14; H, 8.61.

This material crystallized after standing several months; m.p. 36.5–38°.

It formed a monobromide, m.p. 78–80°, when it was treated with bromine in carbon tetrachloride.

Anal. Calcd. for $C_{12}H_{15}O_2Br$: C, 53.15; H, 5.28. Found: C, 53.02; H, 5.51.

The dehydrogenation of 2 g. of the tetralin with 6 g. of chloranil in 20 ml. of xylene at reflux temperature for 15 hours as described by Arnold and Collins,[14] yielded 0.8 g. of the picrate of 1,3-dimethoxynaphthalene, m.p. 141–142°, undepressed by the synthetic material described below.

Anal. Calcd. for $C_{18}H_{15}O_9N_3$: C, 51.80; H, 3.62. Found: C, 51.84; H, 3.64.

A second fraction from the chromatography was eluted with four liters of ether. This material (0.8 g.) was also the tetralin mentioned above, b.p. 110° (3 mm.), $n^{25}D$ 1.5401, inert to potassium permanganate in acetone.

The third fraction was eluted with three liters of methanol. The product, 0.7 g., b.p. 130° (3 mm.), was converted into the *p*-nitrobenzoate. It was necessary to chromatograph the ester before it could be crystallized. Crystallization of the chromatographed product from methanol gave two fractions. The first fraction, m.p. 49–51°, mixed m.p. with authentic material 49–52°, weighed 0.8 g. The second fraction, m.p. 48–51°, mixed m.p. 48–51°, weighed 0.1 g.

In a control experiment, a solution of 2 g. of 4-(2,4-dimethoxyphenyl)-1-butanol in 150 ml. of 98–100% formic acid was heated at 75° for 15 hours. Working up in the manner described for the solvolysis reactions yielded 1.65 g. (82.5%) of recovered alcohol, b.p. 150–152° (2 mm.), $n^{25}D$ 1.5296.

In another control experiment, a solution of 0.5 g. of 4-(2,4-dimethoxyphenyl)-1-butanol in 30 cc. of 0.0315 *M* sodium formate in formic acid was heated at 75° for 10 hours. When the mixture was worked up as described for the solvolysis, 0.35 g. (70%) of the alcohol was recovered. This gave 0.40 g. (67%) of *p*-nitrobenzoate, m.p. 50–53°.

1,3-Dimethoxynaphthalene.—Ethyl 1,3-dihydroxy-2-naphthoate[15] (13 g.) was treated with a solution of diazomethane in 200 ml. of ether prepared from 15 g. of nitrosomethylurea. After the mixture was allowed to stand overnight, the ether was evaporated and the remaining oil was vacuum distilled. The fraction, b.p. 155–175° (2 mm.), weighing 11 g., was refluxed with 10 g. of sodium hydroxide in a mixture of 15 ml. of water and 15 ml. of ethanol overnight. The dark solution and solid was treated with water, and the product was extracted with ether. The product, b.p. 145–150° (3 mm.), was a dark colored oil weighing 2.8 g. The color was removed readily by chromatography on alumina, but the substance soon became colored again on standing. The purified product, $n^{25}D$ 1.6140, was analyzed.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43. Found: C, 76.79; H, 6.45.

The picrate of this substance crystallized from ether in the form of long orange-red needles, m.p. 140–141°.

Products of Formolysis of 4-*p*-Anisyl-1-butyl *p*-Bromobenzenesulfonate.—A solution of 8 g. of 4-*p*-anisyl-1-butyl *p*-bromobenzenesulfonate in 700 ml. of 0.03022 *M* sodium formate in dry formic acid, was heated at 75° for 42 hours. After dilution with water, the products were extracted with three portions of pentane. The oil remaining after the pentane was evaporated was reduced with 1 g. of lithium aluminum hydride. The product mixture was then chromatographed on 100 g. of alumina. The 7-methoxytetralin was eluted with 700 ml. of pentane. This substance, b.p. 76° (1.5 mm.), $n^{25}D$ 1.5414, weighed 1.65 g. and was inert to potassium permanganate in acetone. The b.p. of this compound has been reported as 103–105° (5.5 mm.)[17] and 129–131° (11 mm.).[16] The 4-*p*-anisyl-1-butanol was eluted with 600 ml. of ether. This product, b.p. 118–119° (1.5 mm.), $n^{25}D$ 1.5239, weighed 1.55 g.

Products of Formolysis of 4-Phenyl-1-butyl *p*-Bromobenzenesulfonate.—To a solution of 3.4 g. of dry sodium formate in 1000 ml. of dry formic acid (containing 0.31% water by Karl Fischer titration) heated to 75.0° was added 18.5 g. of the purified bromobenzenesulfonate. The solution was mixed well and left at 75.0° for 66 hours. The resulting solution was cooled, poured into 3 liters of water, and ex-

Digitized by Arya Samaj Foundation Chennai and eGangotri

tracted with 4 portions of pure pentane. The extracts were washed with water and aqueous sodium bicarbonate. After they were dried, the solvent was distilled off carefully through a Vigreux column, and the products were reduced with 2 g. of lithium aluminum hydride in ether. The reduced products were chromatographed on 500 g. of alumina. The pentane eluates yielded 1.10 g. (16.7%) of hydrocarbon, b.p. 101–103° (22 mm.), $n^{25}D$ 1.5388 (reported[27] for tetralin, b.p. 89° (12 mm.), $n^{25}D$ 1.5392). The infrared spectrum of the hydrocarbon was identical with that of pure tetralin. Also, an 80% yield of naphthalene, m.p. 75–77°, mixed m.p. 77–80°, was obtained from the hydrocarbon by dehydrogenation with tetrachloro-1,2-benzoquinone in benzene.[18]

Elution with methanol, concentration and distillation gave 5.4 g. (72.0%) of alcohol, b.p. 87–90° (1.5 mm.), $n^{25}D$ 1.5191 ($n^{25}D$ 1.5202 for pure 4-phenyl-1-butanol). The infrared spectrum of the alcohol was identical with that of 4-phenyl-1-butanol.

Treatment of 4-Phenyl-1-butanol with Acidic Formic Acid.—A solution of 2.0 g. of 4-phenyl-1-butanol and 0.6 g. of *p*-toluenesulfonic acid in 100 cc. of dry formic acid (0.31% water) was heated at 75.0° for 67 hours. Cooling and pouring into water gave rise to an oil which was extracted with three portions of pure pentane. The extracts were washed, concentrated and reduced with lithium aluminum hydride. Distillation of the product gave 1.7 g. (85%) of alcohol, $n^{25}D$ 1.5189, b.p. 124–127° (10 mm.), with no sign of any lower boiling tetralin.

Products of Acetolysis of 4-Phenyl-1-butyl *p*-Bromobenzenesulfonate.—A 20.0-g. quantity of pure 4-phenyl-1-butyl *p*-bromobenzenesulfonate was added to 1200 cc. of dry acetic acid already heated to 100.0°, and the solution was kept at this temperature for 101 hours. The cooled solution was poured into 3 liters of water and extracted with 5 portions of pure pentane. The extracts were washed, concentrated and reduced with lithium aluminum hydride. The reduced products were chromatographed on alumina. There was obtained 0.35 g. (4.9%) of tetralin, b.p. 75° (10 mm.), $n^{25}D$ 1.5370, and 6.85 g. (84.4%) of alcohol, b.p. *ca.* 100° (2 mm.), $n^{25}D$ 1.5205. The infrared spectrum of the tetralin product was essentially the same as that of pure tetralin except for the presence of 2 small additional bands at 960 and 680 cm.$^{-1}$. The alcohol product had an infrared spectrum identical with that of pure 4-phenyl-1-butanol.

In a control experiment, a solution of 11.0 g. of 4-phenyl-1-butyl acetate, 11.4 g. of *p*-toluenesulfonic acid and 1 cc. of acetic anhydride in 1200 cc. of dry acetic acid was kept at 100.0° for 140 hours. The solution was cooled, poured into water, and the products were extracted as before. The crude acetates were reduced with lithium aluminum hydride and the product distilled. The product, b.p. 120–123° (8.5 mm.), $n^{25}D$ 1.5202, weighed 8.2 g. (95%). There was no sign of any lower boiling tetralin.

Formolysis of 5-Phenyl-2-pentyl *p*-Toluenesulfonate.—A solution of 9.2 g. of the toluenesulfonate (93% pure) and 2.45 g. of dry sodium formate in 600 cc. of dry formic acid (0.31% water) was kept at 25.0° for 43.5 hours. The products were isolated in the usual way. Chromatography on 200 g. of alumina yielded two fractions, a hydrocarbon fraction, 2.05 g., b.p. 112–115° (25 mm.), $n^{25}D$ 1.5229, and an alcohol fraction, 2.20 g., b.p. 95–100° (1.5 mm.), $n^{25}D$ 1.5107. The alcohol had an infrared spectrum identical with that of 5-phenyl-2-pentanol.

The hydrocarbon fraction contained 30% olefin according to quantitative hydrogenation. The 1-methyltetralin was isolated from the hydrocarbon mixture by oxidizing the olefin with osmium tetroxide. For this purpose, 0.75 g. of the mixture was added to 1.0 g. of osmium tetroxide in 20 cc. of ether containing 2 drops of pyridine. After standing for 30 minutes, 150 cc. of pure methylene chloride and a solution of 2.5 g. of potassium hydroxide and 2. 5 g. of mannitol in 50 cc. of water was added. The two phase mixture was shaken in a shaking machine for two hours. The aqueous phase was separated and extracted again with methylene chloride. The combined extracts were washed with water, dried and concentrated under a Vigreux column. Vacuum distillation yielded 0.4 g. (53%) of 1-methyltetralin, b.p. 55° (1.5 mm.), $n^{25}D$ 1.5323 (reported[28] for 1-methyltetralin, b.p. 87–88° (7 mm.), $n^{25}D$ 1.5332). The material was inert to potassium permanganate in acetone. The infrared spectrum indicated a trace (*ca.* 1–2%) of alcoholic impurity.

Anal. Calcd. for $C_{11}H_{14}$: C, 90.35; H, 9.65. Found: C, 90.30; H, 9.46.

In a control experiment, a solution of 5.0 g. of the alcohol and 0.35 g. of sodium formate in 500 cc. of dry formic acid (0.14% water) was kept at 25.0° for 41 hours. The products were isolated as usual. Reduction with 1.5 g. of lithium aluminum hydride in ether gave 5.0 g. of alcohol, b.p. 117–120° (8 mm.), $n^{25}D$ 1.5108. There was no sign of any lower boiling material. An analogous treatment of 4.4 g. of alcohol in 500 ml. of formic acid without sodium formate for 27 days at 25° gave only 0.06 g. of a hydrocarbon fraction and 4.0 g. (91%) of alcohol, b.p. 145–148° (30 mm.), $n^{25}D$ 1.5106.

In another control experiment, a solution of 1.0 g. of the olefin–tetralin mixture obtained from solvolysis of 5-phenyl-2-pentyl *p*-toluenesulfonate was kept at 25.0° with 0.050 g. of pure sodium formate in 150 cc. of 98–100% formic acid for 42.5 hours. The products were isolated as usual and distilled. There was obtained 0.95 g. of product, $n^{25}D$ 1.5231, 26% olefin by quantitative hydrogenation. The infrared spectrum was nearly like that of the starting mixture except for weak bands at 1720, 1180 and 1110 cm.$^{-1}$, probably indicating a few per cent. of a formate ester.

Reaction of 5-Phenyl-1-pentene with Formic Acid.—A solution of 4.4 g. of 5-phenyl-1-pentene,[29] b.p. 77–78°, $n^{25}D$ 1.5019, in 500 ml. of 98–100% formic acid was kept at 25.0° for 27 days. The resulting solution was poured into water and extracted with 5 portions of pure pentane. The extracts were washed, dried, concentrated and reduced with lithium aluminum hydride. Chromatography yielded 3.2 g. (73%) of hydrocarbon, b.p. 106–108° (*ca.* 30 mm.), $n^{25}D$ 1.5054, and 1.0 g. (20%) of alcohol, b.p. 95° (2 mm.), $n^{25}D$ 1.5099. The hydrocarbon fraction was determined to be 16% tetralin by quantitative hydrogenation over palladium-on-charcoal.

Neighboring Carbon and Hydrogen. XXVIII. Ar_2-6 Participation in Solvolysis of Some ω-Aryl-1-alkyl Bromobenzenesulfonates[1,2]

BY RICHARD HECK AND S. WINSTEIN

RECEIVED NOVEMBER 10, 1956

In searching for Ar_2-participation in solvolysis, acetolysis and formolysis of suitably substituted ω-aryl-1-alkyl *p*-bromobenzenesulfonates have been studied. In the case of 4-aryl-1-butyl bromobenzenesulfonates, substantial rate enhancements result from introduction of one or two *m*-methoxyl groups into the benzene ring. These enhancements are ascribed to increased importance of Ar_2- assisted ionization in solvolysis. The product of formolysis of 4-(3,5-dimethoxyphenyl)-1-butyl *p*-bromobenzenesulfonate contains mainly 5,7-dimethoxytetralin, formate ester being a minor product. The product composition agrees within experimental error with that predicted from the k_Δ and k_s values obtained by dissection of the solvolysis rate constant by the method outlined in the previous paper. For Ar_2-*n* participation, the rate sequence is $5 \ll 6 \gg 7$, only Ar_2-6 being important in the present work. The observed sequence contrasts with that observed for Ar_1-*n*, for which $5 \gg 6$. This contrast may be understood by considering the respective transition states for the rate-determining steps. The comparison of rates of Ar_1- and Ar_2-assisted ionizations discloses that Ar_1-5 and Ar_2-6-assisted ionizations have nearly equal rates for equivalent degrees of activation of the benzene ring.

In this paper are presented more data bearing on anchimeric effects of aryl groups more distant than *beta*. In contrast with the ω-aryl-1-alkyl bromobenzenesulfonates stressed in the previous paper,[3] the compounds treated in the present manuscript were substituted so as to favor Ar_2- rather than Ar_1-participation in the rate-determining ionization step. The results obtained in the study of these compounds supply considerable orientation on the scope of Ar_2-participation and the comparison of such participation with the Ar_1-variety.

ω-Aryl-1-alkyl Systems.—The list of *p*-bromobenzenesulfonates examined in the present study is shown in Table I, which also summarizes their solvolysis rate constants.

The alcohols which were required for preparation of the bromobenzenesulfonates were obtained by a variety of methods. Of the propanols, 3-*m*-anisyl-1-propanol was prepared in fair yield by the reduction of *m*-methoxycinnamic acid with lithium aluminum hydride. 3-(3,5-Dimethoxyphenyl)-1-propanol was obtained by a lithium aluminum hydride reduction of 3-(3,5-dimethoxyphenyl)-propanoic acid, the latter being derived from the malonic ester synthesis on 3,5-dimethoxybenzyl chloride.

Of the butanols, 4-*m*-anisyl-1-butanol was prepared in poor yield from γ-*m*-anisylpropylmagnesium chloride and formaldehyde. 4-(3,4-Dimethoxyphenyl)-1-butanol was prepared by a lithium aluminum hydride reduction of 4-(3,4-dimethoxyphenyl)-butanoic acid, the latter being obtained by Clemmensen reduction of the Friedel–Crafts succinoylation product from veratrole.[4] The 4-(3,5-dimethoxyphenyl)-1-butanol was prepared by the reaction of β-3,5-dimethoxyphenylethylmagnesium bromide with ethylene oxide. The required bromide was obtained from a displacement reaction on the *p*-bromobenzenesulfonate of β-3,5-dimethoxyphenylethanol. The preparation of this material by way of 3,5-dimethoxyphenylacetic acid has been described previously.[5]

The pentanol, 5-(3,4-dimethoxyphenyl)-1-pentanol, was prepared by a Friedel–Crafts reaction between veratrole and glutaric anhydride,[6] followed by Clemmensen and lithium aluminum hydride reductions.

Kinetic Search for Ar_2-Participation.—All the substances investigated displayed good first-order behavior in acetolysis and formolysis. As regards enhancement of solvolysis rate by methoxyl substitution in the benzene ring, no substantial rate enchancement is observed with the ω-aryl-1-propyl esters, as was pointed out already in the previous paper.[3] This is true even for 3,5-dimethoxyl substitution.

In the 4-phenyl-1-butyl series, substantial rate enhancements are observed[2] on addition of *m*-methoxyl groups to the benzene ring. Thus, 4-*m*-anisyl-1-butyl *p*-bromobenzenesulfonate is 1.86 times as reactive, and the 4-(3,5-dimethoxyphenyl)-1-butyl ester I, 6.24 times as reactive, as the 4-phenyl-1-butyl derivative in formic acid at 75°. The rate comparisons are summarized in Table II. In line with the previous arguments,[3] the observed rate enhancements are ascribed to increased importance of Ar_2-participation in the case of solvolysis of the *m*-methoxyl-substituted derivatives.

The procedure for dissecting the solvolysis rate constant into k_Δ, the rate constant of anchimerically assisted ionization, and k_s, the rate constant of anchimerically unassisted solvolysis, which was applied previously,[3] may be employed on the present data. Using a k_s equal to that for 4-phenyl-1-butyl *p*-bromobenzenesulfonate,[3] one obtains the k_Δ and k_Δ/k_s values summarized in Table II. As in the case of Ar_1-participation,[2,3] two methoxyl groups suffice to make Ar_2-participation dominate formolysis of a 4-aryl-1-butyl ester. Just as for Ar_1-participation,[3] the importance of Ar_2-participation is greater in formic acid than in acetic acid solvent.

Since k_Δ is responsible for most of the formolysis rate constant of the 4-(3,5-dimethoxyphenyl)-1-butyl derivative I, the value for $\Delta S^\ddagger$ listed in Table I, namely, −15.8 e.u., is the value for Ar_2-6-assisted ionization. This is lower than the value[3] for Ar_1-5-assisted ionization, and not very different from the value for anchimerically unassisted formolysis.

Formation of Tetralin.—The products of formolysis of 4-(3,5-dimethoxyphenyl)-1-butyl p-bromobenzenesulfonate (I) were examined in the usual way.[3] Reduction of the crude formolysis products with lithium aluminum hydride and chromatography on alumina yielded a minor alcohol fraction and a major more easily eluted fraction. The alcohol yielded a p-nitrobenzoate which was shown by mixed melting point to be the p-nitrobenzoate of the parent alcohol, 4-(3,5-dimethoxyphenyl)-1-butanol (III).

The major fraction was a colorless liquid, inert to potassium permanganate in acetone. Dehydrogenation of this material with chloranil[7] produced 1,3-dimethoxynaphthalene (VI) which was characterized by mixed melting point of its picrate with the authentic material described previously.[3] Thus, the major solvolysis product was 5,7-dimethoxytetralin (V), the same substance obtained in formolysis of 4-(2,4-dimethoxyphenyl)-1-butyl p-bromobenzenesulfonate,[3] the isomer of I substituted so as to favor Ar_1-5 participation.

The products observed in formolysis of the 4-(3,5-dimethoxyphenyl)-1-butyl derivative I agree closely with those predicted on the basis of the k_s and k_Δ values in Table II, assuming k_s is associated with formation of formate II and k_Δ associated with formation of tetralin V. As is clear from Table III, the observed per cent. tetralin in the product agrees within experimental error with the value, 100 $k_\Delta/(k_\Delta + k_s)$, just as in the previous cases favoring Ar_1-participation.[3] The available facts, therefore, suggest that the formolysis of the 4-(3,5-dimethoxyphenyl)-1-butyl derivative I proceeds to the extent of 12% by the anchimerically unassisted process leading to formate II, and to the extent of 88% by anchimerically assisted ionization. Anchimerically assisted ionization must be very predominantly

[a] 0.0454 *M* ROBs; 0.0515 *M* NaOCHO; 12 hours at 75.0°.

Ar_2-Participation and Ring Size. Comparison with Ar_1.—The tendency for Ar_2-7 participation in formolysis was assessed roughly by measuring relative rates of formolysis of 5-phenyl-1-pentyl and 5-(3,4-dimethoxyphenyl)-1-pentyl *p*-bromobenzenesulfonates. While the latter substance is substituted to favor both Ar_2-7 and Ar_1-6 participations, it was easily available, and its rate could be used to set an upper limit on the rate enhancement due to Ar_2-7-participation. As is brought out in Table IV, any increase in rate due to 3,4-dimethoxyl substitution in the 5-phenyl-1-pentyl system is small. Consequently, the k_Δ calculated on the assumption that k_s is equal to the rate constant of the 5-phenyl-1-pentyl ester is also small.

TABLE IV

ANALYSIS OF RATES OF FORMOLYSIS OF 5-ARYL-1-PENTYL *p*-BROMOBENZENESULFONATES AT 75°

Compound	Rel. rate	$10^5\ k_s$	$10^5\ k_\Delta$	k_Δ/k_s
$C_6H_5(CH_2)_5OBs$	1.00	3.39		
$3,4\text{-}(CH_3O)_2C_6H_3(CH_2)_5$-OBs	1.03	3.39	0.11	0.03

As is brought out in Table V, the available data on relative rates of Ar_2-assisted solvolysis suggest the sequence of ring sizes, $5 << 6 >> 7$. With the ω-aryl-1-alkyl bromobenzenesulfonates of the type reported in the present article, only Ar_2-6 participation, not Ar_2-5 or Ar_2-7, has proved important.[8]

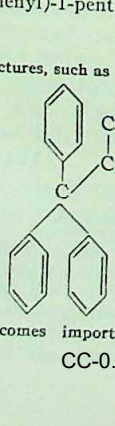
TABLE V

RELATIVE RATES OF Ar_2-*n* RING CLOSURES

Ar group	Solvent	Size of ring being formed 5	6	7
ω-(3-Methoxyphenyl)	HOAc	0.06[a]	1.00	
	HCOOH	..	1.00	<0.04[b]
ω-(3,5-Dimethoxyphenyl)	HCOOH	0.01[a]	1.00	

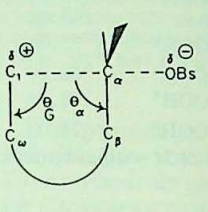
[a] Values calculated using the rate of 3-phenyl-1-propyl *p*-bromobenzenesulfonate as k_s. [b] The value obtained from 5-(3,4-dimethoxyphenyl)-1-pentyl *p*-bromobenzenesulfonate.

(8) For certain structures, such as

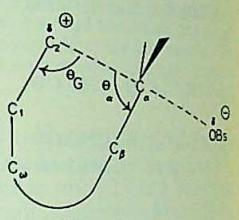


Ar_2-5 participation becomes important (P. Magee, unpublished work).

It is interesting that a maximum in rate is observed for $n = 6$ in the case of Ar_2-participation, whereas the rate sequence observed[3] for Ar_1 was $5 >> 6$. This contrast is relatively easy to understand by considering the transition states for the Ar_1- and Ar_2-assisted ionizations. These may be represented by VII and VIII, respectively, C_1 and C_2 denoting the respective carbon atoms of the neighboring phenyl group. The partial bonds between C_α and the leaving group, and between C_1 or C_2 and C_α in the transition state for the rate-determining step are symbolized by dotted lines. Also shown are the angles, θ_α and θ_G.



VII



VIII

In the transition states, the angle θ_α would have the value of 90° if the usual hybridization at C_α is assumed. In order to estimate θ_G, we should take into account the fact that the degree of involvement of the aryl group with C_α is quite small. For Ar_1, the low degree of involvement of aryl was clear from the relatively small effect of methoxyl substitution.[3] As is clear from Table II, methoxyl substitution has only a relatively small effect on rate in the case of Ar_2 also. This low degree of involvement of phenyl in the transition state suggests a value of θ_G close to 90°, the approach of C_α to C_1 or C_2 of the benzene ring being from a direction perpendicular to the plane of the benzene ring. Examination of models which employ a value of 90° for both θ_α and θ_G shows the transition state to be relatively strainless for Ar_1-5. However, it is quite strained in Ar_1-5, and becomes relatively comfortable when ring size is increased to Ar_2-6.

Comparing rates of Ar_1- and Ar_2-assisted solvolysis, the available data show that rates are comparable for Ar_1-5 and Ar_2-6 for equal degrees of activation of the benzene ring with methoxyl groups. This comparison is shown explicitly in Table VI.

TABLE VI

COMPARISON OF Ar_1-5 AND Ar_2-6 RING CLOSURES AT 75°

Compound	Main participation type	$10^5\ k_\Delta$ (sec.$^{-1}$) AcOH	HCOOH
$m\text{-}(CH_3O)C_6H_4(CH_2)_4OBs$	Ar_2-6	0.65	34.6
$p\text{-}CH_3OC_6H_4(CH_2)_4OBs$	Ar_1-5	0.53	33.0
$3,5\text{-}(CH_3O)_2C_6H_3(CH_2)_4$-OBs	Ar_2-6	..	181
$2,4\text{-}(CH_3O)_2C_6H_3(CH_2)_4$-OBs	Ar_1-5	4.89	312

From this table it is evident that Ar_1-5 is slightly slower than Ar_2-6 in the case of mono-methoxyl-substituted neighboring phenyl. On the other hand, Ar_1-5 is faster than Ar_2-6 for di-methoxyl-substituted neighboring phenyl. An amusing consequence of this is that the rate of formation of the tetralin V is smaller by the more direct Ar_2-6 route than it is by the less direct Ar_1-5 route from

4-(2,4-dimethoxyphenyl)-1-butyl *p*-bromobenzenesulfonate.[3]

Since a maximum in rate occurs at the 5-ring for Ar$_1$- and the 6-ring for Ar$_2$-participation, and since Ar$_1$-5-assisted ionization results in final formation of a six-membered ring, the present results help one understand the pronounced tendency toward closure of 6- rather than 5-membered rings in cyclodehydrations and related reactions.[9] For neighboring vinyl rather than aryl, closure of 6-rings is similarly favored.[10]

An interesting compound, not yet commented on, whose solvolysis rate was investigated, is 4-(3,4-dimethoxyphenyl)-1-butyl *p*-bromobenzenesulfonate. This material is substituted so as to favor both Ar$_1$-5 and Ar$_2$-6 participation. If both Ar$_1$-5 and Ar$_2$-6 participations were completely independent of each other, and if a second methoxyl (*meta* to the substitution spot) had no significant effect on rate, one could expect k_Δ for the 3,4-dimethoxyl case to equal approximately the sum of the k_Δ values for the 4-methoxyl and 3-methoxyl cases. Actually, k_Δ for the 3,4-dimethoxyl case exceeds the calculated value. For example, in formic acid, k_Δ is 8.02×10^{-5} sec.$^{-1}$, as shown in Table II, while the calculated sum of the separate k_Δ values is 6.76×10^{-5} sec.$^{-1}$. The lack of agreement could conceivably be due to a rate-enhancing effect of a *meta* methoxyl group on either Ar$_1$-5 or Ar$_2$-6 or both. Such an effect is observed in bromination of the benzene ring.[11] However, it is doubtful that the Ar$_1$-5 and Ar$_2$-6 participation reactions in hand are sufficiently electron-demanding to bring forth a rate-enhancing response from a *meta* methoxyl group. For example, in Ar$_1$-3 participation, which is even more electron-demanding than the present examples of Ar$_1$-5 and Ar$_2$-6, a *meta* methoxyl is rate-retarding.[5]

It seems possible that Ar$_1$-5 and Ar$_2$-6 participations are not completely distinct in cases such as the 4-(3,4-dimethoxyphenyl)-1-butyl derivative. Whether C_α is lodging onto C_1 or C_2 of the benzene ring, it seems likely that, in the transition state, there is some bonding interaction between C_α and C_2 in the case of Ar$_1$-5 and between C_α and C_1 in the case of Ar$_2$-6.

Experimental Part

3-*m*-Anisyl-1-propanol.—The reduction of *m*-methoxycinnamic acid[12] with lithium aluminum hydride by the usual method gave 3-*m*-anisyl-1-propanol, b.p. 135–140° (3.5 mm.), n^{25}D 1.5339, in 57.5% yield.

3-(3,5-Dimethoxyphenyl)-propanoic Acid.—To a solution of 3.6 g. of sodium metal in 200 ml. of anhydrous ethanol was added 39 g. of ethyl malonate, followed by 20 g. of 3,5-dimethoxybenzyl chloride.[13] After the mixture was refluxed overnight, most of the alcohol was distilled off, and the residue was mixed with cold dil. hydrochloric acid. The product was extracted with ether. The extract was washed with water, and the solvent was evaporated. The residue was refluxed for 4 hours with 25 g. of sodium hydroxide in 100 ml. of water and 50 ml. of ethanol. About 100 cc. of the solvent was distilled, and water was added to the residue. A trace of oil was extracted with ether and the aqueous solution was acidified. The crude malonic acid was heated to 150° until carbon dioxide evolution ceased, and then the product was distilled *in vacuo*. The acid, b.p. 177–178° (3 mm.), crystallized on standing. Recrystallization from a mixture of ether and petroleum ether gave 15.5 g. of material, m.p. 59–61° (reported[14] 61–62°).

3-(3,5-Dimethoxyphenyl)-1-propanol.—The reduction of 3-(3,5-dimethoxyphenyl)-propanoic acid with lithium aluminum hydride gave the desired alcohol, b.p. 145–150° (3 mm.), n^{25}D 1.5332, in 63% yield; the remainder of the unreacted acid was recovered.

Anal. Calcd. for $C_{11}H_{16}O_3$: C, 67.32; H, 8.22. Found: C, 66.83; H, 8.18.

The *p*-bromobenzenesulfonate of this alcohol was obtained as a viscous liquid, n^{25}D 1.5689, 93.3% pure as determined by equivalent weight measurements in acetic and formic acid, by the low temperature procedure previously described.[5]

4-*m*-Anisyl-1-butanol.—This alcohol, b.p. 112° (0.5 mm.), n^{25}D 1.5260, was prepared in poor yield by the action of the Grignard reagent from 3-*m*-anisylpropyl chloride, n^{25}D 1.5287, on formaldehyde.

4-(3,4-Dimethoxyphenyl)-butanoic Acid.—The Clemmensen reduction of 3-(3,4-dimethoxybenzoyl)-propanoic acid[4] gave 4-(3,4-dimethoxyphenyl)-butanoic acid, m.p. 56–58° after crystallization from a mixture of ether and pentane.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 64.27; H, 7.19. Found: C, 64.15; H, 6.99.

4-(3,4-Dimethoxyphenyl)-1-butanol.—The reduction of the above acid with lithium aluminum hydride gave impure 4-(3,4-dimethoxyphenyl)-1-butanol, b.p. 155–157° (3 mm.), n^{25}D 1.5343, in 30% yield. The remainder of the material was unreacted acid.

2-(3,5-Dimethoxyphenyl)-ethyl Bromide.—A solution of 50 g. of lithium bromide and 35 g. of 2-(3,5-dimethoxyphenyl)-ethyl *p*-bromobenzenesulfonate[5] in 500 cc. of pure acetone was refluxed for one hour. The acetone was distilled off, the residue was dissolved in water, and the bromide was extracted with ether. The extracts were washed with water, dried and distilled. The bromide, b.p. 125–128° (1.5 mm.), n^{25}D 1.5573, m.p. 24–26°, weighed 20.5 g.

Anal. Calcd. for $C_{10}H_{13}O_2Br$: C, 49.00; H, 5.34. Found: C, 49.03; H, 5.39.

4-(3,5-Dimethoxyphenyl)-1-butanol.—To a Grignard reagent prepared from 20 g. of 2-(3,5-dimethoxyphenyl)-ethyl bromide under dry nitrogen, an excess of ethylene oxide was added. The solution was refluxed for three hours and worked up with an ammonium chloride solution. Distillation gave 8 g. of forerun and 7 g. of still impure alcohol, b.p. 162–168° (2 mm.), n^{25}D 1.5297, n^{25}D 1.5290 after another distillation.

The residue from the above distillation could be distilled at high temperatures. Two recrystallizations from absolute ethanol yielded 2 g. of a substance, m.p. 100.5–101.5°, probably 1,4-di-(3,5-dimethoxyphenyl)-butane.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93. Found: C, 72.43; H, 7.63.

The *p*-nitrobenzoate of the above alcohol was prepared by the conventional pyridine method and chromatographed on alumina with 50% ether–pentane. Two recrystallizations from methanol gave the compound, m.p. 65–66°, in the form of small yellow needles. The mixed m.p. with 4-(2,4-dimethoxyphenyl)-1-butyl *p*-nitrobenzoate was 44–51°.

Anal. Calcd. for $C_{19}H_{21}O_6N$: C, 63.50; H, 5.89. Found: C, 63.65; H, 5.57.

5-(3,4-Dimethoxyphenyl)-pentanoic Acid.—The Clemmensen reduction of 4-(3,4-dimethoxybenzoyl)-butanoic acid[6] afforded a 50% yield of 5-(3,4-dimethoxyphenyl)-pentanoic acid. The substance, recrystallized twice from petroleum ether (b.p. 60–80°), formed colorless crystals, m.p. 75–76°.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61. Found: C, 65.79; H, 7.75.

5-(3,4-Dimethoxyphenyl)-1-pentanol.—A solution of 8 g. of the above acid in 400 ml. of ether was refluxed with 3 g. of

Preparation of Bromobenzenesulfonates and Kinetic Measurements.—The *p*-bromobenzenesulfonates of the various alcohols were prepared by the low temperature method described previously.[5] Physical properties and analyses of these derivatives are summarized in Table VII.

Kinetic measurements were carried out as described previously.[5]

Formolysis Products of 4-(3,5-Dimethoxyphenyl)-1-butyl *p*-Bromobenzenesulfonate.—A solution of 1.95 g. of the *p*-bromobenzenesulfonate was solvolyzed for ten hours at 75° in a solution of 0.35 g. of sodium formate in 100 ml. of anhydrous formic acid. The resulting solution was diluted with 700 ml. of water and extracted with 500 ml. of petroleum ether in three portions. The extracts were washed with water and a sodium bicarbonate solution. The solvent was carefully distilled off, and the residue was reduced with 2 g. of lithium aluminum hydride.

The reduced product was chromatographed on 50 g. of alumina. The first fraction was eluted with 500 ml. of pentane. This solution contained 0.67 g. of 5,7-dimethoxytetralin, b.p. 100° (1.55 mm.), $n^{25}D$ 1.5452. This material was dehydrogenated with 2 g. of chloranil in boiling xylene as described previously.[3,7] The 1,3-dimethoxynaphthalene formed gave 0.35 g. of pure picrate, m.p. 140–141°, mixed m.p. with the picrate obtained from the corresponding solvolysis product from 4-(2,4-dimethoxyphenyl)-1-butyl *p*-bromobenzenesulfonate,[3] 140–141°.

A second fraction from the chromatography was eluted with 700 ml. of ether. There was obtained from this fraction 0.10 g. of alcohol, $n^{25}D$ 1.5310, which formed 0.11 g. of a nitrobenzoate, m.p. 64.5–66°, mixed m.p. with 4-(3,5-dimethoxyphenyl)-1-butyl nitrobenzoate, 65–66°.

Reactivities of Several ω-Substituted Primary Alkyl Bromides with Tertiary Amines[1,2]

BY KATSUHIKO AKAGI, SHIGERU OAE[3,4] AND MASUO MURAKAMI

RECEIVED AUGUST 29, 1956

Rate constants, heats of activation and entropies of activation have been determined for a series of reactions between ω-substituted primary alkyl bromides and tertiary amines in two different solvents, *i.e.*, nitrobenzene and 50% ethanol. Alternation of reactivities was observed when nitrobenzene was used as a solvent, but no such phenomenon was observed when the solvent was 50% ethanol. The phenyl group showed little polar influence on the reactivities.

Our previous investigations[5] have been extended to the quaternization reactions of ω-substituted primary alkyl bromides with tertiary amines in two different solvents, *i.e.*, nitrobenzene and 50% ethanol, with the thought that these quaternization reactions might give a different trend from those of the reactions of the same bromides with thiosulfate ion, since it has been suggested[6] that the polar characteristic of the quaternization reaction is quite different.

Many studies of the quaternization reaction of alkyl halides with tertiary amines have been reported and our present experiments were carried out following the typical procedure used by Laidler and Hinshelwood[7] and later by Brown and Eldred.[8]

Experimental

The methods of preparations and purifications of all the organic halides have been described elsewhere.[5] The nitrobenzene was purified by partially freezing the fractionated material, which melted around 5.0–5.7°. The portions which melted from 5.5–5.7° were collected for use. Ethanol 50%, was made as reported in the previous paper.[5]

Investigation of Products.—It is known that primary alkyl halides gives quaternary ammonium salts in quantitative yield[9] and also that β-haloalkyl alcohols give quaternary ammonium chlorides in the reaction with trimethylamine.[10] No report has indicated any formation of olefin in the reaction of primary halide with tertiary amine.

In this study, the reaction products were investigated only in the case of β-bromoethyl ether in both 50% ethanol and in nitrobenzene, because among those studied kinetically this compound would be the most likely to give elimination products. The mixture of 1.53 g. of β-bromoethyl ethyl ether and 1.01 g. of triethylamine was placed in a 25-ml.

ampoule and was diluted either by 15 ml. of 50% ethanol or by 15 ml. of nitrobenzene and sealed. The sealed ampoules were heated at 80° for 144 hr. continuously to complete the reactions. Then the tubes were broken and the solvents were distilled very carefully in order to collect vinyl ethyl ether, but no trace of vinyl ethyl ether was obtained. Then the solvents were removed to complete dryness *in vacuo*, and from the 50% alcohol solution 2.45 g. of colorless crystalline solid (m.p. 87–90°) and from the nitrobenzene solution 2.48 g. of pale brown crystalline solid (m.p. 90–93°) were obtained in yields of 96.5 and 97.6%, respectively. After recrystallization from either ethanol–petroleum ether mixture or acetone–petroleum ether mixture the m.p. was 97–98°.

Anal. Calcd. for $C_{10}H_{24}ONBr$: Br, 31.5. Found: Br, 31.3.

Kinetic Studies.—Kinetic measurements and rate calculations were made by the procedure used by previous workers.[7,8] In this case, however, reaction was carried out in sealed tubes. Usually the concentration of the stock solutions was 0.20 *N*, so that on mixing equal volumes of the stock solutions the concentration would be 0.10 *N* with respect to both amine and alkyl bromide. After mixing, each 5-ml. of the well-cooled mixed sample was pipeted into a 10-ml. ampoule and sealed. The first tube was taken out for the initial concentration 15 minutes after all the sealed tubes were immersed in a well-controlled thermostat. At suitable time intervals, ampoules were taken out and placed in an ice–water mixture. Each ampoule was broken in standard 0.025 *N* hydrochloric acid and the excess acid was back-titrated with 0.025 *N* barium hydroxide using methyl red as the indicator. Calibration was made at each temperature in order to avoid large errors due to the expansion of the solutions at different temperatures. The rate constants were calculated using the second-order rate equation. Typical runs are given in Tables I, II and III.

Results and Discussion

The rate-constants, calculated as described, together with the heats of activation, $\Delta H^{\ddagger}$, and entropies of activation, $\Delta S^{\ddagger}$, for the reactions studied are listed in Tables IV, V and VI. The individual points used to calculate the rate constants result in an average deviation of approximately 1% or less throughout the experiments.

Table IV

Rate Constants for the Reaction of ω-Substituted Primary Alkyl Bromides with Triethylamine in Nitrobenzene

Benzene	$10^3 k_2$, l. mole^{-1} sec.$^{-1}$ 60.0°	70.0°	80.0°	$\Delta H^{\ddagger}$ at 70°, kcal./mole	$\Delta S^{\ddagger}$ at 70°, e.u.

When nitrobenzene was used as the solvent, alternation of reactivities was observed with the increase of methylene linkage in the reaction of these ω-substituted primary alkyl bromides with both triethylamine and trimethylamine. With ω-phenyl-substituted primary alkyl bromides the phenyl group showed little polar influence on reactivities and the reactivities were affected only by the change in the entropy changes. It is particularly interesting that even in the reaction of ω-ethoxy-substituted alkyl bromides with triethylamine, the changes in the heat of activation were found to be rather small compared to that in the reaction with thiosulfate ion.[5] This seems to indicate that the transition stage is nearer to the ideal symmetrical transition step, where the bond-fission requirements are equal to bond-forming requirements,[11]

(11) Probably such a reaction as those between alkyl halides and the same halide ion would pass through such a symmetrical transition stage.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

when the concept of Hammond[12] on the transition state is applied in our case. Thus, the bond-fission requirements in this case are less than those in the case of the reaction with thiosulfate ion. But in the reactions of ω-ethoxy-substituted alkyl bromides, the heat of activation decreased with the increase of the connecting methylene group as in the previous reactions with thiosulfate ion, although alternation of rates was observed in this case. The relatively small values of the heat of activations in spite of rather lower rates of reaction would probably be due to large contribution of solvation in the transition states. Solvation seems also to be responsible for the relatively large values of activation entropies.

However, in 50% ethanol solution, the rate sequence and other kinetic values of ω-ethoxyalkyl bromides were quite different from those in nitrobenzene. No alternation of rates was observed; instead, reactivity increased while heat of activation decreased with the increase of connecting methylene group between ethoxy group and halogen, as in the previous reactions with thiosulfate ion. It is known that in quaternization reactions both the heat and entropy of activation varies a great deal depending upon the solvent used.[13]

(12) G. S. Hammond, THIS JOURNAL, **77**, 334 (1955).

(13) J. W. Baker and W. S. Nathan, *J. Chem. Soc.*, 519, 1840 (1935).

For example, in the reaction of *p*-methylbenzyl bromide with pyridine the heat and entropy of activation in absolute acetone were 11.3 kcal. and −37.15 e.u., while those values in 90% ethanol were 15.4 kcal. and −22.5 e.u., respectively. Here also we found large differences of temperature coefficient values in two different solvents, *i.e.*, nitrobenzene and 50% ethanol. The differences in solvating power and in nature of solvation would be the responsible factor for these large changes from one solvent to another.[14]

Acknowledgment.—We wish to express our sincere thanks to the Ministry of Education for a Grant as well as the Grant-in-Aid for the Scientific Research and particularly to the Society of the Sigma Xi for the Grant-in-Aid which enabled us to purchase some chemicals from the United States. Our thanks are due both to Mr. Takuzo Fujino who kindly calibrated all our measuring apparatus and to Mr. Tsunehei Oki who carried out a part of the kinetic measurements.

(14) Both nitrobenzene and acetone have a rather highly negatively polarized oxygen atom in carbonyl and nitro group, which would easily solvate with positively charged quaternary nitrogen at the transition state, thus probably lowering the heat of activation; this strong solvation would also give relatively large negative values of entropy of activation. However, the oxygen atom in water or alcohol would not play such a large role.

Ozonolyses of 1,2-Dibenzoylpropene and 1,2-Dibenzoylethylene. Markownikoff's Rule and the Initial Attack of Ozone on an Unsaturated System[1]

BY PHILIP S. BAILEY AND SHEAFFERS S. BATH

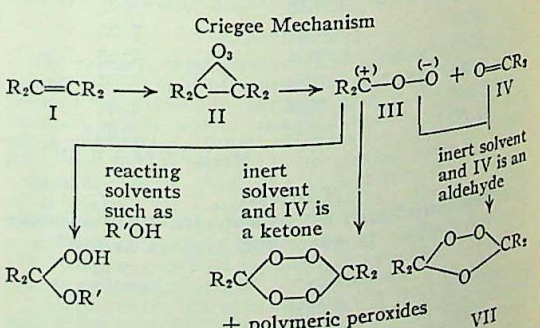
RECEIVED DECEMBER 8, 1956

The ozonolysis of 1,2-dibenzoylpropene in methanol furnishes direct evidence for the specificity previously noted in the attack of ozone on unsymmetrical olefins. The products were phenylglyoxal and α-hydroperoxy-α-methoxypropiophenone. The results are correlated with Markownikoff's rule and a mechanism is proposed which rationalizes the known facts concerning the initial attack of ozone on an unsaturated system. Decompositions of α-hydroperoxy-α-methoxypropiophenone and the corresponding hydroperoxide from the ozonolysis of 1,2-dibenzoylethylene in methanol are described.

The Criegee[2] mechanism for ozonolysis has been of tremendous importance in giving a better understanding of the course of the ozonolysis reaction, in particular, the character and fate of the most important intermediate in the reaction, the zwitterion III. It leaves in doubt, however, the nature of the initial attack of ozone on an unsaturated system and of the intermediates leading to the formation of the zwitterion III and the aldehyde or ketone IV.

Recent studies have shown that ozone, like hydrogen chloride and other unsymmetrical reagents, attacks unsymmetrical olefins in a specific manner.[3] This observation furnishes an important clue to the nature of the initial ozone attack.

Criegee Mechanism



The earlier examples of this specificity of ozone attack include isobutene (VIII), which produced an ozonide (XI) as the major product when ozonized in inert solvents, and camphene (XIV) which gave rearrangement products of zwitterion XV.[2c,3] This is, in the case of isobutene, that preferential

(1) A portion of this paper was presented at the International Ozone Conference, Chicago, Ill., November 28–30, 1956.

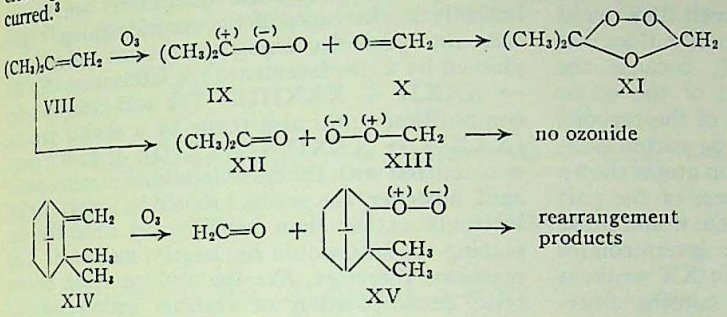
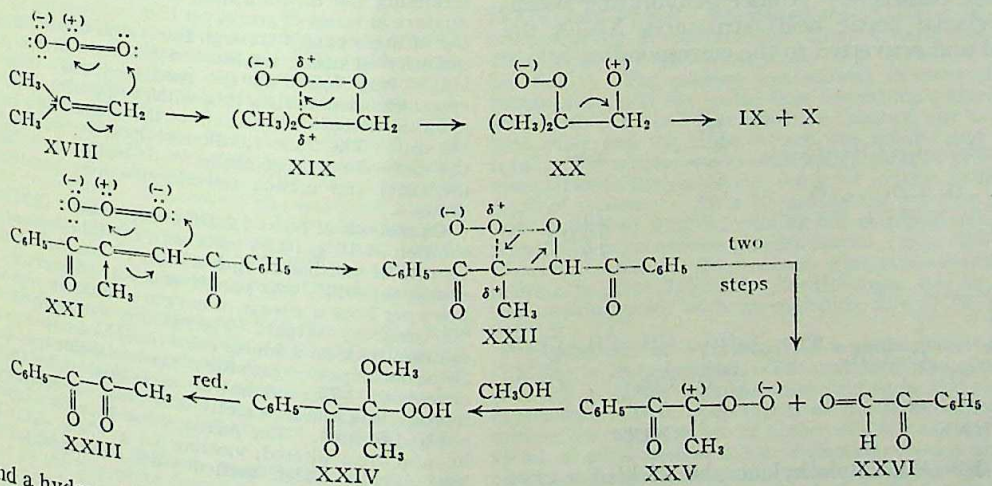
Digitized by Arya Samaj Foundation Chennai and eGangotri

cleavage of the double bond occurred to give zwitterion IX and formaldehyde, rather than zwitterion XIII and acetone.[3] This reasoning is based on Criegee's[2] finding that ozonides cannot be produced by interaction of a zwitterion and a simple ketone. In the case of camphene, preferential cleavage to zwitterion XV and formaldehyde occurred.[3]



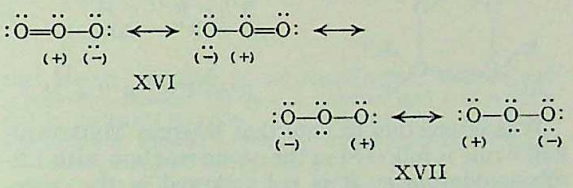
In the cases just discussed the evidence for the specificity of ozone attack was of an indirect nature. It would be much more conclusive if one could actually trap and identify the zwitterion preferentially formed. This has been done in the ozonolysis of *trans*-1,2-dibenzoylpropene (XXI) in methanol solution. The products were phenylglyoxal (XXVI) in 61% yield and α-hydroperoxy-α-methoxypropiophenone (XXIV) in 74% yield. The actual yields probably were much higher; both substances are difficult to isolate. The evidence for the structure assigned to XXIV, besides elemental analyses and the molecular weight determination, was the methoxyl group analysis, a positive lead tetraacetate test for a hydroperoxide,[4] the infrared spectrum which showed a strong carbonyl band at 5.9 μ and a hydroxyl band at 2.9 μ and reduction to 1-phenyl-1,2-propanedione (XXIII) in good yield. This reaction leaves no doubt concerning the specificity of ozone attack to produce preferentially phenyl glyoxal (XXVI) and zwitterion XXV, which was trapped through its reaction with methanol to give XXIV.



At first sight, as pointed out in the cases of isobutene and camphene,[3] these results seem to be in conflict with Markownikoff's rule, based on the usually assumed[5] electrophilic attack of the central carbon atom of the ozone molecule.

Meinwald[6] has pointed out, however, that the central oxygen atom of the ozone molecule cannot be electrophilic, since it has, in all of the structures (XVI and XVII) which make any appreciable contibution to the ozone molecule hybrid, its full quota of eight electrons. The electrophilic center in the ozone molecule, therefore, has to be a terminal atom as shown in contributing structures XVII.

On the basis of an initial terminal oxygen atom electrophilic attack and the assumption that the central oxygen atom completes the attack, the experimental results described can be correlated with Markownikoff's rule, as illustrated in the cases of isobutene (XVIII) and 1,2-dibenzoylpropene (XXI).



The experimental results also can be explained on the basis that the second step in the ozone attack involves the other terminal atom rather than the central atom, to give intermediates of type XXVII. Although these tructures could break down in two ways, it can be argued that they would break down preferentially to give zwitterions IX and XXV, because these zwitterions should be more stable than the other two possibilities through hyperconjugation with the methyl groups.

The intermediates with the four-membered ring

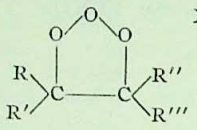
(XIX and XXII) are preferred by the present author for two reasons. First, they can break down in only one way, and this gives the required zwitterions (IX and XXV) and aldehydes (X and XXVI). Second, they explain better the easy cleavage of the double bond under the extremely mild conditions of the ozonolysis reaction. These structures (XIX and XXII) are formulated as activated complexes rather than real intermediates. As such they might be expected to be formed more readily than the more stable intermediates XXVII, because the length of the oxygen–oxygen bond of the ozone molecule is almost the same as that of the carbon–carbon double bond.[7] There would be partial positive charges on the oxygen and carbon atoms shown in structures XIX and XXII because of the partially formed and broken bonds. These would cause the election shift shown to produce intermediates such as XX. The positive charge in XX weakens the remaining carbon–carbon bond causing cleavage to IX and X and to XXV and XXVI.



XXVIIa, R = R′ = CH_3; R″ = R‴ = H

b, R = R″ = C_6H_5—C(=O)—; R′ = CH_3; R‴ = H

It is interesting to note that whereas Markownikoff's rule is followed in the ozone reaction with 1,2-dibenzoylpropene, it is not followed in the corresponding additions of hydrogen chloride and hydrogen bromide. Instead, in acetic acid solution the products are 3-chloro(or bromo)-4-methyl-2,5-diphenylfuran (XXX).[8–10] The reason for this appears to be that a complicated set of equilibria exists, part of which is shown below. The remainder is discussed elsewhere.[10] Under dehydrating conditions (glacial acetic acid) structures XXIX are trapped and converted to the corresponding furans (XXX).

trans-1,2-Dibenzoylethylene also yielded a crystalline methoxyhydroperoxide (XXXIa) upon ozonolysis in the presence of methanol. When this hydroperoxide and the one (XXXIb) from the ozonolysis of 1,2-dibenzoylpropene were heated in methanol or were treated with formic acid, sodium hydroxide or pyridine, decomposition occurred to give benzoic acid as the major product. In several instances spontaneous decompositions occurred when the ozonolysis reaction mixtures were evaporated to dryness before isolation of the hydroperoxides or when the impure hydroperoxides were allowed to stand. The pure crystalline hydroperoxides were stable at room temperature.

These decompositions to benzoic acid (and presumably methyl formate or acetate) are typical heterolytic cleavages of the peroxide group.[11] The base-catalyzed decomposition is most logically explained by a displacement type mechanism (XXXI → XXXII + XXXIII). The acid-catalyzed decomposition could also occur by a similar process (XXXIV → XXXII + XXXIII). If such a process occurred with the decompositions in warm methanol, however, the product should be largely methyl benzoate rather than benzoic acid since the displacing reagent would be, largely, methanol. This reaction, therefore, like the acid-catalyzed heterolytic decomposition of cumene hydroperoxide,[12] is best explained by a concerted rearrangement (XXXV → XXXVI → XXXII + XXXIII). This, of course, could also be the case with the acid-catalyzed decomposition. A similar rearrangement was found to occur during the ozonolysis of camphene in methanol.[3]

In two experiments small quantities of benzil were isolated. Products of this sort are typical of a competing homolytic cleavage of the peroxide group, involving changes such as shown in XXXV → XXXVII → XXXIX.

Experimental[13]

The ozonator used in this research was a Welsbach Corporation model T-23 laboratory apparatus. Oxygen dried to a dew-point of at least −60° was employed. The calculation of the quantity of ozone absorbed was done by determining the concentration of ozone in the oxygen–ozone mixture in terms of grams per liter, multiplying by the number of liters passed through the system and subtracting the quantity of ozone unabsorbed as shown in the potassium iodide trap following the reaction vessel. The reaction vessel was essentially a tube with the gas inlet at the bottom, a seal-in fritted disk just above the inlet and the outlet near the top. The *trans*-1,2-dibenzoylpropene was prepared by the method reported earlier.[14] It melted at 51–53°. The methanol and carbon tetrachloride were pure and anhydrous.

Ozonolysis of *trans*-1,2-Dibenzoylpropene (XXI).—Into a solution of 10 g. (0.04 mole) of *trans*-1,2-dibenzoylpropene, 15 ml. of methanol and 45 ml. of carbon tetrachloride, cooled to −40°, was passed at a rate of approximately 35 liters per hour a stream of oxygen containing approximately 6% ozone by weight. The reaction was stopped when the solution took on a bluish color (dissolved unreacted ozone). Some ozone passed into the potassium iodide trap during the ozonolysis. The amount of ozone used up by the reaction mixture was almost exactly 0.04 mole. A crystalline product had formed. The mixture was kept at −40° for 3–4 hr. and then filtered, yielding 5.8 g. (74% yield) of colorless crystals which melted with decomposition at 57°.

Several recrystallizations by the addition of petroleum ether (b.p. 60–68°) to an ethanol solution of the material gave a good recovery of material melting at 60–61°. The material is soluble in methanol, ethanol, acetic acid and benzene, and is insoluble in petroleum ether and carbon tetrachloride. It gave a negative hydroperoxide test with lead tetraacetate in acetic acid solution but a positive test in methanol solution.[4] The infrared spectrum, taken in chloroform, showed a broad hydroxyl band at 2.8–3.1 μ and a strong carbonyl band at 5.9 μ.

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.22; H, 6.16; active O, 8.1; methoxyl, 15.82; mol. wt., 196.2. Found: C, 61.51; H, 5.65; active O, 7.7; methoxyl, 15.48, 15.66; mol. wt., 199.

The filtrate from which the hydroperoxide was originally filtered was evaporated under vacuum. The residue was warmed over a steam-bath for a few minutes to decompose any remaining peroxide material, after which it was extracted with ether and sodium bicarbonate solution. The aqueous layer was acidified and filtered, yielding 0.6 g. of benzoic acid (m.p. 120–122°, no depression in mixture melting point with an authentic sample). The ether layer was washed and evaporated. The residue was extracted several times with hot water. That which did not dissolve was treated with excess phenylhydrazine under the usual conditions; 0.2 g. of material melting at 227–228° was obtained and shown to be the phenylosazone of benzil by the mixture melting point method.[15]

The water extract was evaporated and the residue was dried, leaving 3.7 g. (61%) of colorless crystals melting at 78–85°. The material was identified as the hydrate of phenylglyoxal[15] by treating it with phenylhydrazine under the usual conditions; the osazone was obtained (m.p. 150–152°), identification was by the mixture melting point method.[15]

Ozonolysis of *trans*-1,2-dibenzoylethylene (10 g.) was carried out by the procedure described in the preceding experiment. The crude hydroperoxide XXXIa weighed 4.6 g. (60% yield) and melted with decomposition at 63–65°. Recrystallization was by addition of petroleum ether (b.p. 60–68°) to a concentrated ethyl acetate solution of the material, followed by cooling to about −15°; the pure material melted with decomposition at 68–69°. The substance was soluble in acetic acid, methanol, ethanol and ethyl acetate, insoluble in petroleum ether, benzene and carbon tetrachloride. It gave a positive lead tetraacetate test[4] in methanol solution. The infrared spectrum, taken in chloroform, showed a broad hydroxyl band at 2.9–3.0 μ and a strong carbonyl band at 5.9 μ.

Anal. Calcd. for $C_9H_{10}O_4$: C, 59.33; H, 5.53, active O, 8.78. Found: C, 59.68; H, 5.45; active O, 7.8.

The filtrate also was worked up as described in the preceding experiment, yielding 1.6 g. of benzoic acid (m.p. 120–122°), 0.5 g. of benzil phenylhydrazone (m.p. 226–228°)[15] and 4 g. (63% yield) of phenylglyoxal hydrate (m.p. 80–85°), identified through the osazone (m.p. 150–152°).[15] Identifications were by the mixture melting point method.

Reduction of α-Hydroperoxy-α-methoxypropiophenone (XXIV) to 1-Phenyl-1,2-propanedione (XXIII).—To a cold mixture of 8 g. of sodium iodide, 5 ml. of acetic acid and 10 ml. of methanol was added, slowly, 1 g. of the hydroperoxide XXIV. The mixture was allowed to come to room temperature, and the iodine thus formed was reduced with sodium thiosulfate. The resulting mixture was extracted with ether and the ether extract was washed and evaporated. The residue was treated with a solution of 0.6 g. of semicarbazide hydrochloride, 0.6 g. of sodium acetate and 5 ml. of methanol. After 30 minutes the reaction mixture was cooled and filtered, yielding 0.8 g. (75% yield) of 1-phenyl-1,2-propanedione semicarbazone (m.p. 203–205°). Recrystallization of the material from ethanol raised the melting point to 211–212°. Identification was by a mixture melting point with an authentic sample (m.p. 211–212°).[16]

Reduction of α-Hydroperoxy-α-methoxyacetophenone (XXXIa) to Phenylglyoxal.—The reduction was carried out with 1.5 g. of the hydroperoxide just as in the preceding experiment. After evaporation of the ether extract containing the reduction product, the residue was treated with 10 ml. of ethyl alcohol, 2.5 g. of phenylhydrazine and 1 ml. of acetic acid, and the mixture was refluxed for 1–2 hr. The resulting solution was diluted with water and cooled, yielding 1 g. of phenylglyoxal osazone melting at 146–149°; recrystallized from ethyl alcohol, 0.8 g., m.p. 151–153°. Identification was by the mixture melting point method.[15]

Decompositions in Alcohols. (a) **α-Hydroperoxy-α-methoxyacetophenone (XXXIa).**—A solution of 1 g. of XXXIa in 10 ml. of methanol was refluxed for 30 min., after which time it was evaporated under vacuum. The residue was extracted with sodium bicarbonate solution and ether. The aqueous fraction was acidified with hydrochloric acid and partially evaporated and cooled, yielding

(15) The reported melting point of benzil phenylosazone is 225°. The reported melting point for phenylglyoxal hydrate is 91° and that for the phenylosazone is 152°. See R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," 4th Ed., John Wiley and Sons, Inc., New York, N. Y.

(16) O. Diels and A. v. Dorp, *Ber.*, **36**, 3183 (1903), report a melting point of 211°.

0.57 g. (85% yield) of benzoic acid melting at 121–122°; identification was by the mixture melting point method.

(b) α-Hydroperoxy-α-methoxypropiophenone (XXXIb).—A suspension of 5.6 g. of XXXIb in 20 ml. of ethanol and 10 ml. of petroleum ether (b.p. 60–68°) was allowed to stand at room temperature for 5 min., during which time an exothermal reaction occurred. The solution was evaporated and the residue was extracted with ether and sodium carbonate solution. Upon acidification of the aqueous extract and partial evaporation, 2.8 g. (80% yield) of benzoic acid (m.p. 120–122°) was obtained. Evaporation of the ether extract gave a small residue which was treated with phenylhydrazine in the usual manner, yielding 0.1 g. of benzil phenylosazone (m.p. 225–227°).[15] Identifications were by the mixture melting point method.

Decompositions in Formic Acid.—In each case 1 g. of hydroperoxide (XXXIa or b) was added to 10–20 ml. of cold formic acid. An exothermal reaction ensued in case of XXXIa. The solutions were then heated on a steam-bath for 30 minutes after which they were evaporated under vacuum. The residues melted at 120–122° and were identified as benzoic acid by the mixture melting point method. The yields were 0.6 g. (90%) from α-hydroperoxy-α-methoxyacetophenone (XXXIa) and 0.52 g. (84%) from the corresponding propiophenone (XXXIb).

Decompositions in Sodium Hydroxide Solution.—In each case 1 g. of hydroperoxide (XXXIa or b) was added to 15 ml. of 10% sodium hydroxide solution. An exothermal reaction occurred in the case of XXXIa. After a few minutes it was poured into excess dilute hydrochloric acid. In the case of XXXIb the reaction mixture stood overnight before it was poured into excess dilute hydrochloric acid. Upon evaporation of these solutions and recrystallization of the residues from water, yields of benzoic acid (m.p. 120–122°) of 79% from the hydroperoxyacetophenone (XXXIa) and of 72% from the hydroperoxypropiophenone (XXXIb) were obtained. Identifications were by the mixture melting point method.

Decomposition of α-Hydroperoxy-α-methoxyacetophenone (XXXIa) with Pyridine.—To 3.8 g. of the hydroperoxide was added 15 ml. of pyridine. An exothermal reaction ensued. The mixture was then heated over a steam-bath for 20 min., after which it was evaporated by a stream of air. The residue was dissolved in ether, the ether extract was washed thoroughly and then extracted with sodium carbonate solution. Upon acidification of the aqueous layer with hydrochloric acid 1.1 g. (43% yield) of benzoic acid was obtained (m.p. 120–122°). The ether layer was evaporated and the residue was treated with phenylhydrazine in the usual way. The product was benzil phenylosazone (0.14 g., m.p. 224–226°).[15] Identifications were by the mixture melting point method.

Cyclic Dienes. XX. 4-*n*-Octyl-1,2-dimethylenecyclohexane[1]

BY WILLIAM J. BAILEY AND WILLIAM A. KLEIN[2]

RECEIVED OCTOBER 15, 1956

A convenient synthesis of a 2-alkyl-1,3-butadiene was developed from a commercially available alkenylsuccinic anhydride as the starting material. Thus 2-*n*-octyl-1,3-butadiene was prepared in four steps including a pyrolysis of a diacetate in an over-all yield of 53%. This 2-octylbutadiene was then converted in five steps to 4-*n*-octyl-1,2-dimethylenecyclohexane in an over-all yield of 40%. The final step in the synthesis involved the pyrolysis of a diacetate in a 55% yield. The structures of the dienes were proved by ultraviolet and infrared absorption spectra and conversion to solid Diels–Alder adducts.

A series of substituted 1,2-dimethylcyclohexanes[3–6] has been prepared in this Laboratory in an effort to determine the correlation between the molecular structure and the physical properties of the corresponding polymers. One of the objectives was the determination of the reason for the fact that the all-*cis* poly-1,2-dimethylenecyclohexane was a high melting crystalline polymer while the closely related all-*cis* natural rubber was an excellent rubber.[7] Since a methyl group located in the 4-position had very little effect on the softening point of an all-*cis* polymer, it was of interest to determine what effect a large group located in the 4-position would have on the physical properties of a poly-1,2-dimethylenecyclohexane. It had been shown previously that, as the size of the *n*-alkyl group in poly-*n*-alkyl methacrylates[8] and poly-*n*-alkylstyrenes[9] was increased, the softening point was decreased until a maximum depression occurred when the alkyl group contained eight to ten carbon atoms. Higher homologs reversed this trend and the softening points began to rise, presumably because the long alkyl side chains were capable of increasing the crystallinity of the polymers by the formation of crystallites involving only these side groups. For these reasons the synthesis of 4-*n*-octyl-1,2-dimethylenecyclohexane (I) was undertaken with the hope that a less crystalline and therefore a more rubbery all-*cis* polymer could be produced.

Since one of the key intermediates in the projected synthesis of I was 2-*n*-octyl-1,3-butadiene (II), an effort was made to find a convenient route to this diene. Previous work in this Laboratory has shown that the pyrolysis of esters is an excellent method for the preparation of unsaturated compounds and that, if charring is avoided, highly strained dienes, such as 1,2-dimethylene-4-cyclohexene, an isomer of *o*-xylene, can be prepared completely free of its aromatic isomer.[10] Marvel and

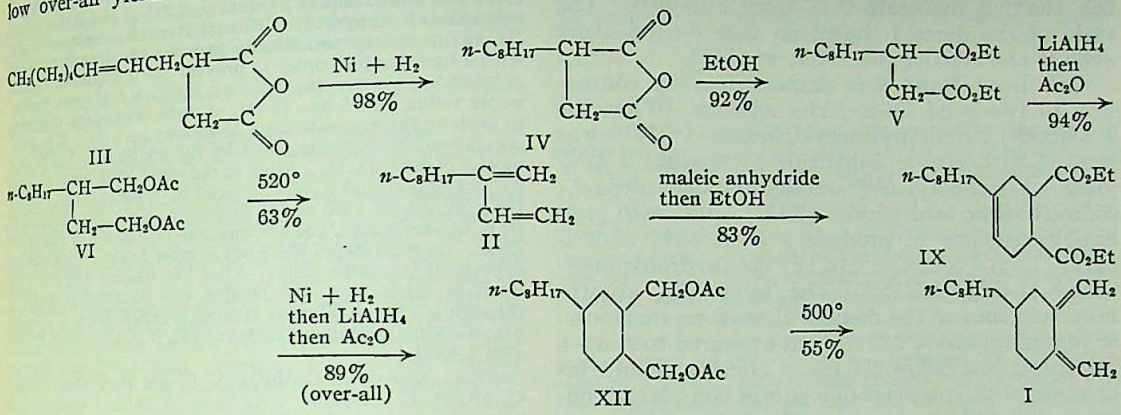
co-workers have developed a method for the synthesis of 2-alkylbutadienes involving the pyrolysis of a monoacetate as the final step; however, this procedure, which involves a Mannich reaction on an aldehyde, deamination, a Grignard reaction and esterification, is fairly long and gives a rather low over-all yield.[11] Overberger and co-workers also have developed a synthesis of 2-alkylbutadienes involving the pyrolysis of a diacetate as a final step; however, their starting material was prepared by a Stobbe condensation, esterification and catalytic reduction in only a fair over-all yield.[12] Since a series of alkenylsuccinic anhydrides, addition products of 1-olefins and maleic anhydride, are now commercially available,[13] it appeared that these adducts would make excellent starting materials for the preparation of 2-alkylbutadienes.

Thus the commercially available octenylsuccinic anhydride (III) was reduced catalytically to produce a 98% yield of *n*-octylsuccinic anhydride (IV) which was then esterified to give ethyl 3-carbethoxyundecylate (V) in a 92% yield. By a procedure which is essentially a one-step reductive acetylation with lithium aluminum hydride and acetic anhydride,[14] the ester V was reduced and the intermediate glycol in the reaction mixture was acetylated to yield the 3-acetoxymethylundecyl acetate (VI) in a 94% yield. An alternative procedure for the preparation of VI by the reductive acetylation of IV did not give as high a yield. Apparently the intermediate reduction products from IV were so insoluble that, even when the reduction was carried out for 96 hr., only a 78% yield of VI was obtained.

Pyrolysis of the diacetate VI at 520° was conducted by the dropwise addition of the liquid through a Vycor tube packed with Pyrex helices under such conditions that only 77% of two molar equivalents of acetic acid was liberated. Under these conditions little or no charring that could cause isomerization occurred. From the pyrolysis were obtained a 46% conversion to 2-*n*-octyl-1,3-butadiene (II) plus a 28% yield of a mixture of the two possible intermediate olefin acetates. The yield of II, based on unrecovered olefin acetate, was 63%. The over-all yield for the four-step synthesis of II from the commercially available III was 53%.



The diene II was characterized by conversion to two solid Diels–Alder adducts. Thus the 2-*n*-octyl-1,3-butadiene (II) plus maleic anhydride gave a 47% yield of 4-*n*-octyl-1,2,3,6-tetrahydrophthalic anhydride (VII), while treatment with 1,4-naphthoquinone produced a 67% yield of 2-*n*-octyl-1,4,4a,9a-tetrahydroanthraquinone (VIII). The ultraviolet absorption spectrum possessed a maximum ϵ of 20,400 at 226 mμ which indicated the presence of a pair of conjugated double bonds. Although the maximum is slightly higher than predicted from Woodward's rules,[15] it is in excellent agreement with that reported for 2-*n*-heptyl-1,3-butadiene.[12] The structure of II also was indicated by its infrared absorption spectrum which possessed strong bands at 722, 883–913, 986, 1367, 1443, 1619, 1789, 2245 and 2860 cm.$^{-1}$ and somewhat weaker bands at 757, 1015, 1066, 1111, 1155, 1195, 1232, 1298 and 1644 cm.$^{-1}$. The absence of a band in the 800 to 850 cm.$^{-1}$ region indicated that very little if any of the isomeric 3-methyl-1,3-undecadiene was present.

The 4-*n*-octyl-1,2-dimethylenecyclohexane was then prepared from II in five steps in an over-all yield of 40%, essentially by a procedure developed earlier for the ascending of a diene series by the addition of a cyclohexane ring.[3] The *n*-octylbutadiene II was treated with maleic anhydride and the solid adduct VII was not isolated, but the crude reaction mixture was esterified directly to produce an 83% yield of the diethyl ester IX. IX was catalytically reduced in a 96% yield to give the diethyl 4-*n*-octylhexahydrophthalate (X) which, in turn, was reduced nearly quantitatively to the glycol XI with lithium aluminum hydride. Acetylation with acetic anhydride produced a 95% yield of the 4-*n*-octylhexahydrophthalyl diacetate (XII).

The diacetate XII was pyrolyzed at 500° by dropwise addition to the apparatus described above under such conditions that only 54% of two molar equivalents of acetic acid was liberated. These rel-

atively mild conditions were chosen in order to prevent charring that could cause the formation of any polymerization inhibitors. Under these conditions a 26% conversion to the 4-*n*-octyl-1,2-dimethylenecyclohexane (I) was realized. In addition a 40% yield of a mixture of the two possible intermediate olefin acetates and a 13% recovery of the starting diacetate XII were obtained. The yield of the diene I, based on unrecovered olefin acetate and starting diacetate, was 55%.

The diene I also was characterized by conversion to two solid Diels–Alder adducts. Thus the 4-*n*-octyl-1,2-dimethylenecyclohexane (I) was treated with maleic anhydride to produce a 47% yield of 6-*n*-octyl-$\Delta^{9(10)}$-octahydronaphthalene-2,-3-dicarboxylic anhydride (XIII) and with 1,4-naphthoquinone to produce a 38% yield of 2-*n*-octyl-1,2,3,4,5,5a,6,11,11a,12-decahydronaphthacene-6,11-dione (XIV). The ultraviolet absorption spectrum of the diene I showed no maximum or minimum above 220 mμ but appeared to reach a maximum just below 220 mμ. This is a definite indication of the presence of a pair of non-planar conjugated double bonds exocyclic to a cyclohexane ring. Although this maximum is much lower than that predicted from Woodward's rules,[15] it is in excellent agreement with the maxima reported for similar cyclic dienes which have a pair of conjugated double bonds slightly askew.[3-5,10,16] For instance, 4-methyl-1,2-dimethylenecyclohexane also possesses no maximum or minimum above 220 mμ but appears to reach a maximum just below 220 mμ. Only when the two exocyclic double bonds are forced into the same plane, as in 2,3-dimethylenebicyclo[2.2.1]heptane, does the absorption maximum occur at longer wave lengths. The infrared absorption spectrum of the diene I also was very similar to that of closely related dienes. The strong absorption at 890 cm.$^{-1}$ indicated the presence of a terminal methylene group.

The polymers from these interesting dienes will be reported separately.

Experimental[17]

n-**Octylsuccinic Anhydride (IV).**—A solution of 368 g. (1.75 moles) of *n*-octenylsuccinic anhydride (III) (Humphrey–Wilkinson, Inc.) in 600 ml. of purified dioxane and 25 g. of W-5 Raney nickel catalyst were placed in a high pressure hydrogenation vessel. The hydrogenation was completed in 1 hr. at 100° and 160 atm. of hydrogen. After removal of the catalyst by filtration, the dioxane was removed by distillation under reduced pressure to yield 366 g. (98%) of *n*-octylsuccinic anhydride (IV), m.p. 62–64.5° (reported[8] m.p. 64–64.5°).

Ethyl 3-Carbethoxyundecylate (V).—A mixture of 3000 ml. of benzene, 1200 ml. of absolute ethanol, 775 g. (3.68 moles) of *n*-octylsuccinic anhydride (IV) and 10 ml. of concentrated sulfuric acid was heated under reflux until no further separation of an aqueous phase occurred (Dean–Stark trap). After the reaction mixture was washed with an aqueous sodium bicarbonate solution, the excess solvents were removed by distillation at atmospheric pressure through a 12-inch Vigreux column. The residue was fractionally distilled through the same column under reduced pressure to give 969 g. (92%) of ethyl 3-carbethoxyundecylate (V), b.p. 110° (0.07 mm.), n^{25}D 1.4350.

Anal. Calcd. for $C_{16}H_{30}O_4$: C, 67.10; H, 10.56. Found: C, 67.12; H, 10.26.

3-Acetoxymethylundecyl Acetate (VI). A. From *n*-Octylsuccinic Anhydride (IV).—To a slurry of 68.4 g. (1.8 moles) of lithium aluminum hydride in 2 liters of anhydrous ether was added slowly a solution of 315 g. (1.5 moles) of *n*-octylsuccinic anhydride (IV) in 2 liters of anhydrous ether. (It was necessary periodically to warm the dropping funnel with a heat lamp in order to prevent the precipitation of the anhydride.) After the reaction mixture had been heated under reflux for 96 hr., 75 ml. of water was added dropwise to destroy the excess lithium aluminum hydride. The complexes were then decomposed by the addition of 432 g. (7.2 moles) of acetic acid. Most of the ethyl ether was removed by distillation and it was replaced by *n*-butyl ether. After the addition of 1530 g. (15 moles) of acetic anhydride and 30 g. of acetic acid, the mixture was heated under reflux for 72 hr. It was filtered while hot in order to remove the heavy deposit of inorganic salts. After the solvent was removed by flash distillation, the residue was fractionally distilled through a 12-inch Vigreux column to yield 336 g. (78%) of 3-acetoxymethylundecyl acetate (VI), b.p. 118° (0.04 mm.), n^{25}D 1.4396.

Anal. Calcd. for $C_{16}H_{30}O_4$: C, 67.10; H, 10.56. Found: C, 67.39; H, 10.32.

B. From Ethyl 3-Carbethoxyundecylate (V).—To a cooled slurry of 160 g. (4.2 moles) of lithium aluminum hydride and 1.5 liters of dry ether was added slowly a solution of 962 g. (3.36 moles) of ethyl 3-carbethoxyundecylate (V) dissolved in 1.5 liters of dry ether. After addition had been completed, the reaction mixture was heated under reflux for an additional 72 hr. The excess lithium aluminum hydride was then destroyed by the dropwise addition of 100 ml. of water, and the complexes were decomposed with 1009 g. (16.8 moles) of acetic acid. The ethyl ether was replaced by *n*-butyl ether as described above, and the unisolated diol was heated under reflux for 120 hr. with 1500 ml. of acetic anhydride and 30 ml. of acetic acid. After the inorganic salts were removed by filtration of the hot mixture, the excess solvents were removed by flash distillation under reduced pressure. The residue was fractionally distilled through a 12-inch Vigreux column to yield 903 g. (94%) of 3-acetoxymethylundecyl acetate (VI), b.p. 127° (0.11 mm.), n^{25}D 1.4394.

2-*n*-Octyl-1,3-butadiene (II).—At the rate of 1.5 g. per minute, 100 g. (0.35 mole) of 3-acetoxymethylundecyl acetate (VI) was added dropwise to a vertical Vycor pyrolysis tube which was packed to a depth of 10 inches with 1/8-inch glass helices and heated externally at 520° by a FD 303 A Hoskins electric furnace as described previously.[18] The addition was conducted in an inert atmosphere by the introduction of a slow stream of oxygen-free nitrogen at the top of the tube. The pyrolysate was collected in a receiver cooled by a Dry Ice–cellosolve bath. (Titration of a 0.27-g. sample of the pyrolysate with standard sodium hydroxide solution indicated that 77% of two molar equivalents of acetic acid had been liberated.) Fractional distillation of the crude pyrolysate through a 6-inch, helix-packed column yielded 27 g. (46%) of 2-*n*-octyl-1,3-butadiene (II), b.p. 71° (4.3 mm.), n^{25}D 1.4514; and 22 g. (28%) of presumably a mixture of the two possible olefin acetates, 3-acetoxymethyl-1-undecene and 3-methylene-*n*-undecyl acetate. The yield of the diene II, based on the unrecovered olefin acetates, was 63%.

Anal. Calcd. for $C_{12}H_{22}$: C, 86.66; H, 13.34. Found: C, 86.66; H, 13.52.

4-*n*-Octyl-1,2,3,6-tetrahydrophthalic Anhydride (VII).—To a filtered solution of 1.60 g. (0.016 mole) of maleic anhydride in 50 ml. of dry benzene was added 3.5 g. (0.021 mole) of 2-*n*-octyl-1,3-butadiene (II). After the solution had been heated under reflux for 24 hr., the benzene was removed by distillation under reduced pressure to yield 2.36 g. (47%) of the crude adduct VII, m.p. 45–58°. Recrystallization from petroleum ether gave an analytically pure sample of 4-*n*-octyl-1,2,3,6-tetrahydrophthalic anhydride (VII), m.p. 51.3–51.8°. (A mixed melting point with maleic anhydride exhibited a large depression.)

2-*n*-Octyl-1,4,4a,9a-tetrahydroanthraquinone (VIII).—A solution of 1.58 g. (0.010 mole) of 1,4-naphthoquinone, 3.0 g. (0.018 mole) of 2-*n*-octyl-1,3-butadiene (II) and a few milligrams of N-phenyl-β-naphthylamine in 50 ml. of dry benzene was heated under reflux for 24 hr. The benzene was removed by distillation under reduced pressure to give 2.21 g. (67%) of the slightly impure adduct VIII, m.p. 84–86°. Recrystallization from ethanol produced analytically pure 2-*n*-octyl-1,4,4a,9a-tetrahydroanthraquinone (VIII), m.p. 85.8–86.4°.

Anal. Calcd. for $C_{22}H_{28}O_2$: C, 81.44; H, 8.70. Found: C, 81.65; H, 8.44.

Diethyl 4-*n*-Octyl-1,2,3,6-tetrahydrophthalate (IX).—After a filtered solution of 39.2 g. (0.40 mole) of maleic anhydride dissolved in 300 ml. of dry benzene and 50 g. (0.30 mole) of 2-*n*-octyl-1,3-butadiene (II) had been maintained at 55° for 20 hr., the unisolated adduct and excess maleic anhydride were esterified by the addition of 125 ml. of absolute ethanol and 1 ml. of concentrated sulfuric acid. The water formed in the esterification process was removed as the ternary azeotrope by means of a Dean–Stark receiver. After no more aqueous phase appeared in the distillate, the excess benzene and alcohol were removed by distillation through the Dean–Stark receiver. The residue, without further treatment, was fractionally distilled through a 12-inch Vigreux column to yield 84 g. (83%) of diethyl 4-*n*-octyl-1,2,3,6-tetrahydrophthalate (IX), b.p. 150° (0.15 mm.), $n^{25}D$ 1.4636.

Anal. Calcd. for $C_{20}H_{34}O_4$: C, 70.97; H, 10.13. Found: C, 71.01; H, 9.95.

Diethyl 4-*n*-Octylhexahydrophthalate (X).—A mixture of 114 g. (0.34 mole) of diethyl 4-*n*-octyl-1,2,3,6-tetrahydrophthalate (IX), 35 ml. of absolute ethanol and 6 g. of W-5 Raney nickel catalyst was added to a high pressure hydrogenation vessel. The hydrogenation was completed in 4 hr. at 100° and 170 atm. of hydrogen. After the catalyst was removed by filtration, the ethanol was removed by distillation under reduced pressure. The residue was fractionally distilled through a 6-inch, helix-packed column to yield 112 g. (96%) of diethyl 4-*n*-octylhexahydrophthalate (X), b.p. 149° (0.10 mm.), $n^{25}D$ 1.4562. (Similar results were obtained by the hydrogenation of IX in ethanol at 22° and atmospheric pressure by use of Adams catalyst, platinum oxide.)

Anal. Calcd. for $C_{20}H_{36}O_4$: C, 70.54; H, 10.66. Found: C, 70.70; H, 10.38.

4-*n*-Octylhexahydrophthalyl Alcohol (XI).—To a slurry of 14 g. (0.37 mole) of lithium aluminum hydride in 1 liter of anhydrous ether was added dropwise a solution of 96 g. (0.28 mole) of diethyl 4-*n*-octylhexahydrophthalate (X) in 100 ml. of ether. Near the end of the addition the reaction mixture became so viscous that it was necessary to add an additional 200 ml. of ether in order to facilitate stirring. After the reduction mixture had been heated under reflux overnight, the excess lithium aluminum hydride was destroyed by the dropwise addition of 50 ml. of water. A sufficient amount of 10% hydrochloric acid was added to the ice-bath cooled reaction mixture to cause the formation of two distinct layers. The clear ether layer was removed by decantation before the remainder of the salts was dissolved by additional dilute acid. The aqueous phase was extracted several times with ether, and these extracts were combined with the initial ether layer. After the ethereal solution had been dried with anhydrous potassium carbonate and sodium sulfate, the ether was removed by flash distillation under reduced pressure to give 70 g. (97%) of crude 4-*n*-octylhexahydrophthalyl alcohol (XI), m.p. 61–65°. Recrystallization of a small quantity from ether–petroleum ether gave an analytically pure sample, m.p. 64.0–64.6°.

Anal. Calcd. for $C_{16}H_{32}O_2$: C, 74.94; H, 12.58. Found: C, 74.77; H, 12.31.

4-*n*-Octylhexahydrophthalyl Diacetate (XII).—After a mixture of 104 g. (0.41 mole) of the crude 4-*n*-octylhexahydrophthalyl alcohol (XI), 250 g. of acetic anhydride and 30 g. of acetic acid was heated under reflux in a 1-liter flask for 24 hr., the excess acetic acid and acetic anhydride were removed by distillation under reduced pressure through a 12-inch Vigreux column. The residue was distilled through the same column to yield 132 g. (95%) of 4-*n*-octylhexahydrophthalyl diacetate (XII), b.p. 140° (0.03 mm.), $n^{25}D$ 1.4605.

Anal. Calcd. for $C_{20}H_{36}O_4$: C, 70.54; H, 10.66. Found: C, 70.35; H, 10.49.

4-*n*-Octyl-1,2-dimethylenecyclohexane (I).—By the use of the pyrolysis apparatus described for the preparation of II, 36 g. (0.105 mole) of 4-*n*-octylhexahydrophthalyl diacetate (XII) was pyrolyzed at 500° at the addition rate of 1.5 g. per minute. A few milligrams of antioxidant, N-phenyl-β-naphthylamine, was added to an ether solution of the pyrolysate. Removal of the acetic acid by extraction with water and titration of an aliquot of these washings with standard sodium hydroxide solution indicated that 54% of two molar equivalents of acetic acid had been eliminated. After the ether solution was dried over anhydrous sodium sulfate, most of the ether was removed by distillation through a 6-inch, helix-packed column. The residue was then fractionally distilled through the same column to yield 6.2 g. (26%) of the light yellow 4-*n*-octyl-1,2-dimethylenecyclohexane (I), b.p. 79° (0.11 mm.), $n^{25}D$ 1.4707; 11.8 g. (40%) of presumably a mixture of the pair of intermediate olefin acetates, 1-methylene-2-acetoxymethyl-4-*n*-octylcyclohexane and 1-acetoxymethyl-2-methylene-4-*n*-octylcyclohexane, b.p. 106–118° (0.09 mm.), $n^{25}D$ 1.4645; and 4.5 g. (13%) of recovered diacetate XII. The yield of I, based on unrecovered olefin acetates and XII, was 55%.

Anal. Calcd. for $C_{16}H_{28}$: C, 87.19; H, 12.81. Found: C, 87.47; H, 12.80. Calcd. for $C_{18}H_{32}O_2$: C, 77.09; H, 11.50. Found: C, 76.80; H, 11.27.

6-*n*-Octyl-$\Delta^{9(10)}$-octahydronaphthalene-2,3-dicarboxylic Anhydride (XIII).—After a mixture of a filtered solution of 0.59 g. (0.006 mole) of maleic anhydride in 50 ml. of dry benzene and 1.59 g. (0.007 mole) of 4-*n*-octyl-1,2-dimethylenecyclohexane (I) had been allowed to stand at 25° for 2 hr., it was heated under reflux for 15 hr. The benzene was partially removed by distillation under reduced pressure and the precipitate which formed was removed by filtration and was washed with 30–60° petroleum ether. The crude adduct XIII weighed 0.90 g. (47%) and had a melting range of 89–95°. Two recrystallizations from 60–80° petroleum ether gave analytically pure 6-*n*-octyl-$\Delta^{9(10)}$-octahydronaphthalene-2,3-dicarboxylic anhydride (XIII), m.p. 103.8–105°.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.41; H, 9.64.

2-*n*-Octyl-1,2,3,4,5,5a,6,11,11a,12-decahydronaphthacene-6,11-dione (XIV).—A mixture of 1.72 g. (0.008 mole) of 4-*n*-octyl-1,2-dimethylenecyclohexane (I), 0.95 g. (0.006 mole) of 1,4-naphthoquinone and 50 ml. of dry benzene was heated under reflux for 15 hr. After the benzene was partially removed by evaporation of the solution on the steam-bath, the resulting precipitate was removed by filtration and was washed with hot ethanol. The yield of the crude light tan adduct XIV, m.p. 141–144°, was 0.87 g. (38%). Recrystallization from 60–80° petroleum ether gave analytically pure 2-*n*-octyl-1,2,3,4,5,5a,6,11,11a,12-decahydronaphthacene-6,11-dione (XIV), m.p. 145.8–146.6°.

Preparation and Polymerization of Unsaturated Quaternary Ammonium Compounds. VIII. A Proposed Alternating Intramolecular–Intermolecular Chain Propagation[1]

BY GEORGE B. BUTLER AND RUDOLPH J. ANGELO

RECEIVED NOVEMBER 23, 1956

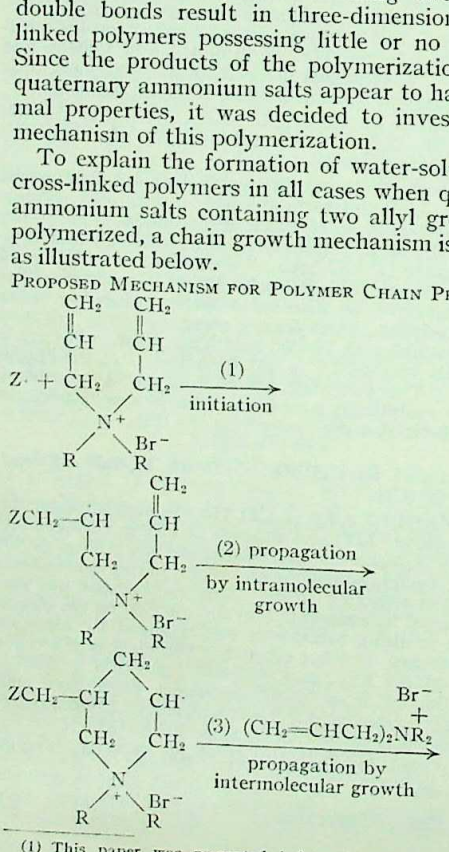
A mechanism is proposed for the polymerization of certain allyl unsaturated quaternary ammonium salts which involves an alternating intramolecular–intermolecular chain propagation leading to the formation of chains of piperidine rings. This mechanism is supported by results obtained using suitable monomers, by studies of solvent, initiator and oxygen effects and by hydrogenation evidence. An estimation of the molecular weight of the polymers has been made.

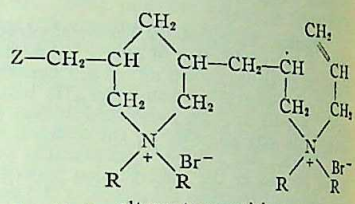
Previous work[2–6] carried out in this Laboratory on the free radical initiated polymerization of allyl or substituted allyl quaternary ammonium derivatives showed that infusible and water-insoluble polymers were obtained only from monomers containing three or more allyl groups. Polymers from monomers containing only two allyl groups were non-cross-linked, since they were completely soluble in water. Monomers containing only one allyl group did not undergo polymerization.

These results are contrary to the accepted views that monomers containing one double bond result in linear polymers possessing some degree of solubility, while monomers containing two or more double bonds result in three-dimensional, cross-linked polymers possessing little or no solubility. Since the products of the polymerization of allyl quaternary ammonium salts appear to have abnormal properties, it was decided to investigate the mechanism of this polymerization.

To explain the formation of water-soluble, non-cross-linked polymers in all cases when quaternary ammonium salts containing two allyl groups were polymerized, a chain growth mechanism is proposed as illustrated below.

PROPOSED MECHANISM FOR POLYMER CHAIN PROPAGATION





R = alkyl radical
Z· = free radical

alternate repetition of (2) and (3) → polymer

This would involve a free radical attack on one of the double bonds, followed by cyclization with the remaining favorably situated double bond within the same molecule; the resulting cyclic radical then attacks another molecule of monomer, and repetition of the process results in a growing chain.

In a somewhat related case, Simpson, *et al.*,[7] studied the structure of polydiallyl phthalate at the gel point and, by calculations from values of residual unsaturation and degree of polymerization, concluded that at the gel point about 40% of the reacted monomer units was used up in cyclization reactions and were, therefore, not available for further cross-link formation. In a later publication[8] these authors analyzed several other polydiallyl esters in a similar way, but only in the above case did cyclization appear to occur to any great extent. Such an intramolecular cyclization in the case of diallyl phthalate would lead to ten-, eleven-, twelve-membered, or even larger, rings. Such cyclizations are much less likely to occur than those we propose which lead to six-membered rings.

Through use of suitable monomers, studies of solvent, initiator and oxygen effects, hydrogenation studies and estimation of molecular weight, evidence has been obtained to support this proposed mechanism.

Experimental

Diallyldiethylammonium Bromide.—Allyl bromide, 60.5 g. (0.5 mole), was added to 50.0 g. (0.44 mole) of N,N-diethylallylamine dissolved in 100 ml. of acetone; the N,N-diethylallylamine had a boiling point of 110° and $n^{25}D$ 1.4198; Libermann and Paal[9] report the boiling point as 110–113°. Upon addition of the bromide, the mixture became cloudy and crystals began to form. The product was washed and decanted several times with cold acetone, filtered and dried in a vacuum desiccator. White, hygroscopic crystals, 87 g. (84% yield), m.p. 155° (closed capillary), were formed and were recrystallized from acetone–absolute ethanol.

Anal. Calcd. for $C_{10}H_{20}NBr$: Br, 34.15. Found: Br, 34.12.

Diallyldimethylammonium bromide and triallylbutylam-

monium bromide were prepared as described in previous papers.[2,5]

Polydiallyldiethylammonium Bromide.—Twenty drops of 60% *t*-butyl hydroperoxide (approximately 0.012 g./drop) was added to a solution of 8.0 g. of diallyldiethylammonium bromide and 4.0 ml. of water. The mixture was allowed to remain open to the atmosphere in an oven at 60° for 48 hr. The resulting white hygroscopic product was ground to a fine powder and dried for several days in a vacuum desiccator. Eight grams of product, melting with considerable decomposition at 346–354°, was obtained. The product was quite soluble in water and ethanol and gave an immediate halogen test when treated with $AgNO_3$ solution.

Anal. Calcd. for $C_{10}H_{20}NBr$: C, 51.30; H, 8.20; N, 5.98; Br, 34.15. Found: C, 51.35; H, 8.32; N, 5.50; Br, 33.90.

Polydiallyldimethylammonium Bromide.—Twenty-five grams of the salt, 12.5 g. of water and 20 drops of *t*-butyl hydroperoxide were mixed and allowed to stand overnight at room temperature. The solution was then placed in an oven at 70° for 72 hr. when a white opaque, brittle mass resulted. This polymer was hygroscopic and soluble in water. After grinding and drying *in vacuo*, the m.p. was 348–352°.

Polydiallylamine Hydrochloride.—Ten grams of diallylamine hydrochloride (recrystallized from acetone–ethanol three times, m.p. 164–165°) was dissolved in 5 ml. of water and treated with 25 drops of 60% *t*-butyl hydroperoxide solution. The mixture remained in an open beaker at 60° for three days. Ten grams of polymeric product was obtained which was insoluble in water and ethanol. The wash ethanol on treatment with acetone showed only a faint cloudiness which indicated there was very little unreacted diallylamine hydrochloride present. After soaking in an acetone–ethanol mixture or absorbing moisture from the atmosphere, the product exhibited elastic properties. This was the only monomer in this study with two allyl groups to show characteristics of cross-linking upon polymerization.

Hydrogenation.—An infrared absorption band at 6.10 μ indicated some degree of unsaturation in the water-soluble polymers obtained from diallyldiethyl- and diallyldimethylammonium bromides. Quantitative hydrogenation of weighed samples of polydiallyldiethylammonium bromide over Adams catalyst at atmospheric pressure resulted in an average absorption of 0.193 mole of hydrogen per mole of monomer unit in the polymer.

Solvent interaction during the polymerization might affect the nature of the polymer. If a chain radical could react with a solvent radical in preference to a monomer molecule, the degree of polymerization would be reduced. Thus it might be possible to have a monomer molecule containing several unsaturated groups and yet obtain a polymer of a low degree of polymerization and slight cross-linking. The following experiments were carried out varying the solvent and solvent concentration. (a) A mixture of 3.0 g. of triallylbutylammonium bromide, 3.0 ml. of water and 6 drops of 60% *t*-butyl hydroperoxide solution was heated at 60° for 76 hr. A hard, water-soluble solid was obtained. The product was dissolved in 10 ml. of water, 10 drops of initiator was added and the mixture heated for an additional week at 60°. The product was still water soluble. (b) A mixture of triallylbutylammonium bromide (2 g.), 4 drops of initiator and 2.0 ml. of water was allowed to react at 100° for 38 hr. The product was again water soluble. (c) Two grams of triallylbutylammonium bromide, 2 drops of initiator and 0.08 ml. of water were allowed to react at 100° for 38 hr. The resulting hard, glassy product was soaked in hot water, filtered and dried; 1.7 g. (85% yield) of water-insoluble product was obtained. The procedure was that of Bunch,[10] who reported a 52.5% yield. (d) Three grams of diallyldiethylammonium bromide, 10 drops of initiator and 0.3 ml. of water were allowed to react at 100° for 38 hr. The product was water soluble. (e) Three grams of diallyldiethylammonium bromide, 10 drops of initiator and 50 drops of dimethylformamide were allowed to react at 100° for 38 hr. The product was water soluble.

Initiator Effect.—Various initiators were tried with monomers containing one and two double bonds to see whether *t*-butyl hydroperoxide is unique in its property of yielding non-cross-linked polymers with monomers containing two allyl groups.

One gram each of triethylallylammonium bromide and diallyldiethylammonium bromide were dissolved in 1.0 ml. of water and reacted for one week at 60° with 0.05 g. each of *t*-butyl hydroperoxide, di-*t*-butyl peroxide and benzoyl peroxide.

The lack of cross-linking was indicated by the water solubility of the products. Polymerization took place only in the reaction of diallyldiethylammonium bromide with *t*-butyl hydroperoxide. In the other cases, the starting monomers were recovered and identified.

In an attempt to evaluate the initiating property of 2,2′-azoisobutyronitrile, this initiator was treated with hexaallylethylenediammonium dibromide, since it was thought that an easily isolated, insoluble product would be obtained if polymerization occurred. The monomer (5 g.), dissolved in 10 ml. of dimethylformamide, was allowed to react with varying amounts of initiator for two weeks at 60° in an open vessel. These results are recorded in Table I (a to f).

TABLE I

Initiator, %	Weight of H_2O insoluble product	Remarks
(a) 0.1	Soluble	Light viscous liq. after 2 wk.
(b) 0.5	Soluble	Light viscous liq. after 2 wk.
(c) 1.0	Soluble	Viscous liq. after 2 wk.
(d) 2.0	0.75 g.	Heavy viscous liq. after 2 wk.
(e) 5.0	3.28 g.	Gelatinous after 12–15 hr., flexible solid 2 wk.
(f) 10.0	4.37 g.	Gelatinous after 6 hr.; brittle solid at 2 wk.
(g) 1.0	Soluble	Hot acetone–insol. portion, m.p. 295–300°
(h) 5.0	Soluble	M.p. 305–307°
(i) 10.0	Soluble	M.p. 306–307°

The effect of this initiator on the polymerization of diallyldiethylammonium bromide was determined in a similar manner. Two grams of diallyldiethylammonium bromide, dissolved in 10 ml. of dimethylformamide, was allowed to react with varying amounts of azo initiator at 75° for fifteen days. The product was water soluble in every case. Unreacted monomer was separated from the reaction product by extraction with hot acetone. Results are given in Table I (g to i).

Effect of Oxygen.—The following experiment, along with the molecular weight estimation, demonstrated the inhibiting effect of oxygen; a mixture of 8.0 g. of diallyldiethylammonium bromide, 4.0 ml. of water and 33 drops of 60% *t*-butyl hydroperoxide solution (approximately 0.012 g./drop) was allowed to react for 76 hr. at 60–65°. The reaction was carried out in an oxygen-free, dry nitrogen atmosphere. Eight grams of hygroscopic product was obtained after drying for several days in a vacuum desiccator. The product decomposed over a wide range and melted with decomposition at 355–360°, and was soluble in water but relatively insoluble in ethanol, forming some gel. The degree of solubility of this product in ethanol differed from that of the polydiallyldiethylammonium bromide, which was prepared open to the atmosphere.

Identical experiments, carried out quantitatively, open to the atmosphere, and under pure nitrogen, gave weight increments which showed that hydroxyl radical interaction from the solvent was not appreciable and could be neglected.

It was also considered that the formation of peroxide or hydroperoxide linkages might account for the utilization of some of the monomer double bonds during the polymerization. However, infrared spectra of the above products showed no absorption bands at 870 and 840 cm.$^{-1}$, which are characteristic of peroxide[11] and hydroperoxide,[12] respectively. Polarographic determinations[13] of polydiallyldiethylammonium bromide (prepared open to the atmosphere

and under nitrogen) gave no indication of a peroxide or hydroperoxide wave.

Estimation of Molecular Weight.—A crude approximation of the degree of polymerization was obtained as shown in Table II. This estimation involves the following assumptions: (1) Only the *t*-butoxide radical is to be considered as an initiating fragment. This assumption is probably valid, considering work carried out on the decomposition of *t*-butyl hydroperoxide in the gaseous and liquid phase.[14-17] In all cases cited, fission of the O–O linkage to produce *t*-butoxide and hydroxyl radicals was proposed to account for the formation of the reaction products. (2) The increase in weight during polymerization is due only to incorporation of initiator fragments. (3) The means of chain termination is either by combination or by disproportionation.

The polymerization reaction products were freed from any unreacted monomer by extraction with hot acetone. Samples of the reaction products were extracted in a fine filter funnel until a constant weight was obtained upon vacuum drying.

Discussion of Results

Free radical catalyzed polymerization of quaternary ammonium salts containing only two allyl groups affords only water soluble, non-cross-linked polymers.

The polymers showed some unsaturation by their infrared absorption at 6.10 μ. Quantitative hydrogenation indicated that one free double bond was left for every five monomer units in the polymer chain. Linear intermolecular chain growth would have used five double bonds per five monomer units, leaving four double bonds unaccounted for in the polymerization. It appears probable that much of the unsaturation is used up in the formation of an intramolecular cyclic structure, since cross-linking does not occur to any significant extent. Under these circumstances, the suggested mechanism appears to be the obvious mode of chain propagation.

It appears that the solvent affects the polymerization to some extent, since the attempted polymerizations of triallylbutylammonium bromide at 60 and 100° indicated that the amount of water as solvent is rather critical in obtaining an insoluble product. Diallyldiethylammonium bromide did not yield a water-insoluble product under any circumstances, again showing that at least three allyl groups per molecule of quaternary ammonium salt are required to produce an insoluble product. Diallylamine hydrochloride was the only monomer with two double bonds that produced a water-insoluble product upon polymerization. This compound, however, is not a quaternary ammonium salt and steric considerations suggest that it would be less likely to favor cyclizations of the type proposed.

It was found that *t*-butyl hydroperoxide or 2,2'-azoisobutyronitrile would initiate the polymerization of allyl quaternary ammonium derivatives. Table I indicates that the effective amount of azo initiator is between 5 and 10%, which is higher than the effective initiator ratio of *t*-butyl hydroperoxide.

The polymerization appeared to be somewhat sensitive to oxygen, since the degree of polymerization of the product polymerized under nitrogen was higher than that prepared open to the atmosphere; this greater degree of polymerization also was evident from the different solubilities in ethanol. Chemical, infrared and polarographic analyses did not however, show the presence of peroxide linkages. It is likely that oxygen affects the rate of initiation rather than the formation of different polymers.

Since the soluble polymers are polyelectrolytes, a molecular weight determination of the products, as such, was very difficult. The usual molecular weight determinations, which are dependent on the colligative properties of polymer molecules in solution, were not useful since the degree of ionic dissociation of the polyelectrolytes was unknown. An attempt was made to convert polydiallyldiethylammonium bromide to the polyhydroxide form, degrade this product by the loss of ethylene and water and measure the molecular weight of the resulting polytertiary amine. Although the polyelectrolyte was degraded, a molecular weight determination of the product obtained could not be carried out because of the extreme insolubility of the product. A crude approximation of the molecular weight was obtained by polymerizing accurately weighed amounts of monomer and catalyst, determining weight increments, extracting unreacted monomer and by various assumptions arriving at a degree of polymerization. By assuming that the chain termination process is by disproportionation or combination, the data indicate the degree of polymerization to be from 15 to 30 for the product polymerized open to the atmosphere and 25 to 50 for the product polymerized under nitrogen.

This low degree of polymerization agrees with the results of Bartlett and Altschul[18] who found the degree of polymerization of allyl acetate to be

from 13 to 14 and attributed this low degree of polymerization to resonance stabilization of the monomer by transfer of the α-hydrogen atom to a chain radical. Later work by these authors[19] showed that this was the case.

Consideration of the proposed cyclic intramolecular polymerization of diallyl phthalate by Simpson, Holt and Zeite[7] and the degradative chain transfer in the polymerization of allyl acetate by Bartlett and co-workers[18,19] leads to the belief that the polymerization of allyl quaternary derivatives is affected by both factors. Cyclic intramolecular polymerization, greatly influenced by chain termination caused by α-hydrogen transfer, could account for the soluble, non-cross-linked, low molecular weight and unsaturated polymers obtained in this work.

This study has provided evidence that a suggested alternating intramolecular–intermolecular chain propagation occurs when unsaturated quaternary ammonium salts are polymerized and shows that a polymer of average degree of polymerization of approximately 25 or 50 is obtained when diethyldiallylammonium bromide is polymerized under nitrogen with *t*-butyl hydroperoxide as catalyst. It also shows that this chain propagation mechanism is followed by an average of four-fifths of the monomer units entering the chain, leaving an average degree of unsaturation in the polymer equivalent to one-fifth double bond per monomer unit in the chain.

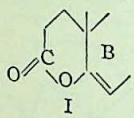
Rearrangement in the Addition of Grignard Reagents to Enol Lactones

BY KENNETH D. ZWAHLEN,[1] W. J. HORTON AND GEORGE I. FUJIMOTO

RECEIVED DECEMBER 6, 1956

Grignard reagents add to the acyl portion of enol lactones with rearrangement of this acyl carbon to the β-olefinic carbon atom. Further addition of Grignard reagent is subject to steric considerations. Such rearrangements were found in the case of a model steroid enol lactone and also in the addition of Grignard reagents to vinyl acetate and isopropenyl acetate.

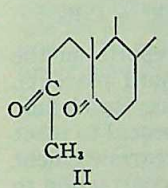
The addition of methylmagnesium halide to enol lactones derived from steroids (I) has been a useful method for the synthesis of Δ^4-3-keto steroids containing C^{14} at position 4[2] and for the closure of the A ring in the synthesis of steroids.[3]



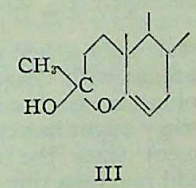
I

An intermediate in this process has been assigned various structures (II,[2a] III,[2c] with phenylmagnesium bromide IV).[4] Structure II for the intermediate from the enol lactone derived from cholestenone, however, is not identical with II from an independent source.[2c,5]

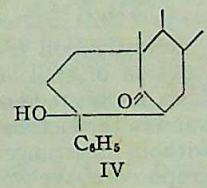
The present investigation was undertaken in order to test whether a structure of type IV would satisfy the requirements for the intermediate obtained when the enol lactone from cholestenone was combined with methylmagnesium halide.[6] For this purpose a model V of a steroid enol lactone was studied.



II



III



IV

Model V, when treated with methylmagnesium iodide or phenylmagnesium bromide, gave VI and VII, respectively. The structure of VII was confirmed by an independent synthesis (formulas V–X). Reduction of VII with lithium aluminum hydride gave VIII, thus adding support for VII. This diol formed a cyclic sulfite ester IX which enables the assignment of an $8\beta,11\alpha$-configuration. These reactions are not easily explainable on the basis of the hemiketal structure (type III).

The reaction of V to yield VI (or VII) involves the migration to an olefinic carbon atom. Such migrations occur when Grignard reagents are added to the simplest enol esters. Methylmagnesium iodide, added to isopropenyl acetate (XI), gave 2,4-dimethyl-2,4-pentanediol (XIII), identical with material prepared as reported.[7] Similarly, ethyl-

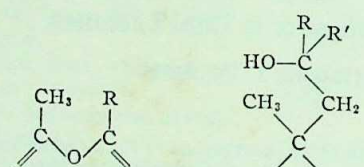
magnesium bromide, added to vinyl acetate (XII) gave 3-methyl-3,5-heptanediol (XIV).[8] In both cases the product obtained may be understood if the rearrangement proposed above is followed by further addition of Grignard reagent to the carbonyl group liberated from its enolic form.



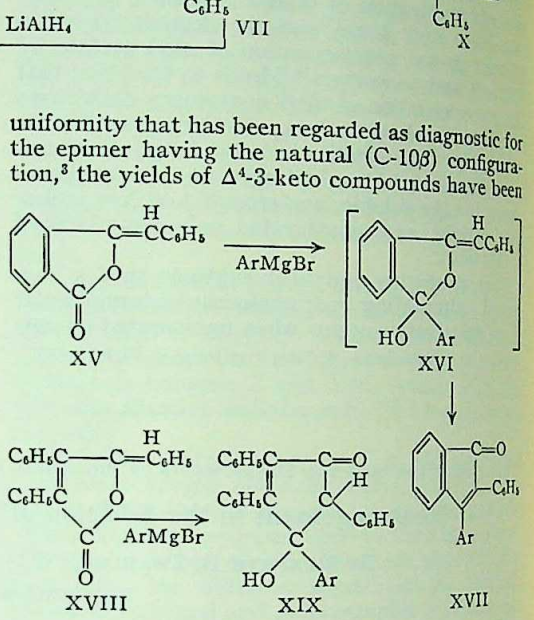
XI, R = CH_3
XII, R = H

XIII, R = R′ = CH_3
XIV, R = H; R′ = C_2H_5

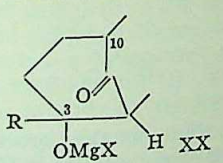
Investigation reveals only a few reports on the reaction of enol lactones with Grignard reagents. A six-membered enol lactone containing the olefinic bond in the lactone ring[9] might be expected to react without rearrangement since the rearrangement proposed above would require a ring contraction to a four-membered ring. Benzalphthalide (XV) gave XVII when treated with arylmagnesium bromides.[10a] The analogous reaction with benzaldiphenylmaleide[11] (XVIII) gave a colorless intermediate. The properties of the intermediate were satisfied by assigning to it a hemiketal structure (type III or XVI) and XVI was suggested[11] for the intermediate from XV which could not be isolated.

We propose that all of the properties found for the intermediate from XVIII would also be expected of the structure XIX which would arise if the Grignard–enol lactone rearrangement occurred. The single exception is the recovery of unchanged intermediate on treatment with phenylmagnesium bromide, a behavior which might be expected if XIX were highly enolic.

If the addition or non-addition of Grignard reagent to XX depended on steric factors, it would account for the experience of those employing this procedure for the synthesis of steroids. With a uniformity that has been regarded as diagnostic for the epimer having the natural (C-10β) configuration,[3] the yields of Δ^4-3-keto compounds have been



good, whereas the yields with the epimer having the C-10α-configuration have been poor. Variation in experimental conditions and in amounts of the methyl Grignard reagent did not improve this result.[3a] It, appears likely therefore, that akin to our reaction with V to yield VI, further addition of methyl Grignard reagent in the steroid synthesis work gave rise to a diol which could not dealdol with base and hence could not close again to the desired Δ^4-3-keto compound. In the natural series, steric factors prevented further Grignard addition to the carbonyl bridge, thus yielding a β-hydroxyketone which was converted by base to a Δ^4-3-keto compound. Our isolation of VII suggests that further addition of Grignard reagent in this case must be controlled by the configuration at C-8 (methanocycloöctabenzene numbering) since V is composed only of enantiomorphs.



The model compound V was obtained by lactonization of XXII which in turn was obtained from known[12] 1-methyl-2(1H)-3,4-dihydronaphthalenone (XXI) by alkylation with ethyl β-bromopropionate. Excess of methylmagnesium iodide at room temperature gave VI (42%). The analytical data clearly indicated that two moles of

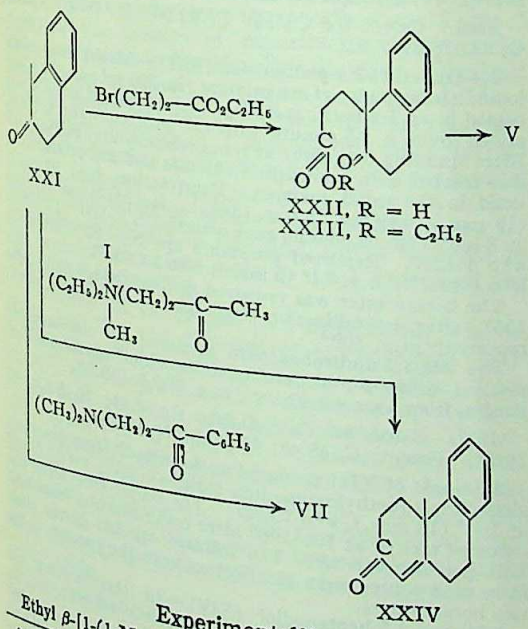
the Grignard reagent had been acquired as opposed to three moles if a structure such as II had been available. An attempt to prepare the diketone similar to II by the addition of the methiodide of 1-diethylamino-3-butanone to XXI[13] failed because cyclization occurred to XXIV as shown by analytical data, ultraviolet absorption at 236 mμ and strong absorption at 5.97 μ (carbonyl group).

The addition of phenylmagnesium bromide to V gave VII (33%) identical with the product from XXI and β-dimethylaminopropiophenone. The identity of these materials was shown by their infrared and ultraviolet absorption curves. The carbonyl group was demonstrated by the preparation of an oxime and a 2,4-dinitrophenylhydrazone. The reduction of the carbonyl with lithium aluminum hydride to VIII, the formation of a cyclic sulfite ester IX and the dehydration of VII to an olefin X which contains a carbonyl group are reactions consistent with the proposed structure for VII. Catalytic hydrogenation of X gave a product whose analysis indicated that one mole of hydrogen had been added, but this material gave no 2,4-dinitrophenylhydrazone and was inert to Huang-Minlon reduction. By Clemmensen reduction, dihydro-X gave an oil, $C_{20}H_{20}$, according to the analytical data. The rearrangement which seems to take place was not investigated.

This work was supported in part by research grants from the National Cancer Institute, National Institutes of Health, United States Public Health Service, and from the American Cancer Society upon recommendation of the Committee on Growth of the National Research Council. The award of a fellowship and financial assistance by the Eastman Kodak Co. are gratefully acknowledged.



Experimental[14]

Ethyl β-[1-(1-Methyl-2-oxo-1,2,3,4-tetrahydronaphthyl)]-propionate (XXIII).—2(1H)-3,4-Dihydronaphthalenone was prepared according to a published procedure[15] in 68% yield, b.p. 132° (14 mm.), reported[12b] 139° (18 mm.). It was alkylated with methyl iodide[12a] to yield XXI in 50% yield, b.p. 134° (14 mm.), reported[12b] b.p. 137–138° (18 mm.). When the unreacted and the dimethylated compounds were not removed,[12b] lower yields were obtained in the subsequent reactions.

In an atmosphere of nitrogen 39.0 g. (0.238 mole) of XXI was added over a 30-minute period with stirring to 9.2 g. (0.236 mole) of powdered potassium in 500 ml. of benzene. The reaction was refluxed for 1 hr., cooled and 50.0 g. (0.275 mole) of ethyl β-bromopropionate was added dropwise. The reaction was refluxed for 1 hr. and allowed to stand overnight. After acidification with dilute sulfuric acid and addition of water, the benzene layer was separated, the aqueous layer was extracted with ether and the ether–benzene solution was washed with 5% sodium bicarbonate and with water. The solvents were removed at reduced pressure and the residue was rapidly distilled. The fraction b.p. 140–160° (0.5 mm.) (33.7 g.) was redistilled. The fraction b.p. 133–136° (0.2–0.3 mm.) (28.4 g., 48%) was a pale yellow viscous liquid. A portion redistilled for analysis boiled at 133–134° (0.2 mm.), $n^{26}D$ 1.5250.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 73.50; H, 7.70.

The semicarbazone crystallized from aqueous ethanol melted at 123.5–125°.

Anal. Calcd. for $C_{17}H_{23}O_3N_3$: C, 64.33; H, 7.30; N, 13.24. Found: C, 64.42; H, 7.22; N, 13.08.

The bicarbonate-soluble acid XXII obtained (88%) by saponification in aqueous alcoholic sodium hydroxide was a light yellow oil which was used without further purification.

The semicarbazone of the acid crystallized from absolute ethanol and melted at 189–190° (gas evol.) when inserted at 170° and heated 3° per minute.

Anal. Calcd. for $C_{15}H_{19}O_3N_3$: C, 62.27; H, 6.62; N, 14.52. Found: C, 62.02; H, 6.64; N, 14.00.

β-[1-(1-Methyl-2-hydroxy-1,4-dihydronaphthyl)]-propionic Acid Lactone (V).—A solution of 22.2 g. of XXII and 2 g. of *p*-toluenesulfonic acid in 75 ml. of acetic anhydride and 100 ml. of benzene was allowed to stand at room temperature overnight. After addition of 1 g. of sodium acetate the solvents were removed *in vacuo* at room temperature. The residue was combined with benzene, the salts were removed by filtration and the solution was distilled to yield 17.7 g. (87%), b.p. 155–162° (0.6 mm.). The distillate crystallized slowly to a pale yellow solid, m.p. 98–100°. The analytical sample sublimed at 95° (bath temperature) (0.2 mm.), m.p. 99–102°.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.17; H, 6.70.

The compound was hygroscopic and hydrolyzed unless stored in a desiccator.

8,11-Dihydroxy-5,8,11-trimethyl-5,6,7,8,9,10-hexahydro-5,9-methanocycloöctabenzene (VI).—Methylmagnesium iodide (from 1.3 g. (54 mmoles) of magnesium) in 25 ml. of ether was treated with 2.00 g. (9.5 mmoles) of V in 50 ml. of ether. After 3 hr. at room temperature 100 ml. of saturated ammonium chloride was added, the layers were separated and the water layer extracted with ether. The combined ether layers, washed with water and dried over calcium sulfate, were distilled *in vacuo*. The residual pale yellow oil weighed 2.2 g. Chromatographed on 200 g. of acid-washed alumina, the acetone eluate weighed 0.97 g. (42%), m.p. 130–135°. Crystallized from benzene–petroleum ether and then several times from dilute methanol, the material melted at 143–145°, softening at 141°.

Anal. Calcd. for $C_{16}H_{22}O_2$: C, 78.00; H, 9.00. Found: C, 78.23; H, 8.82.

4a-Methyl-4,4a,9,10-tetrahydro-2(3H)-phenanthrone (XXIV).—The methiodide from 11 g. of 1-diethylamino-3-butanone was prepared by the addition of 11 g. of methyl iodide in small portions over a 30-minute period while cooling in an ice-bath. It was then allowed to stand in the ice-bath for 1 hr. and for 45 minutes at room temperature. A solution of 12.4 g. of XXI in 75 ml. of benzene was added, the air in the flask was replaced by nitrogen and a solution of 4.76 g. of potassium in 75 ml. of absolute ethanol was added

over a 5-minute interval with cooling. After 1.5 hr. in the ice-bath with occasional swirling followed by 30 minutes of refluxing, the cooled mixture was acidified with dilute sulfuric acid and diluted with water. The benzene layer was separated, the aqueous layer was extracted with ether and the ether–benzene solution was washed with water, 5% sodium bicarbonate and finally with water. After drying over sodium sulfate the solvents were distilled *in vacuo* and the residue distilled, b.p. 130–160° (0.5 mm.), 5.60 g. (34%). The material crystallized from benzene–petroleum ether, m.p. 90–91°, $\lambda_{max}^{ethanol}$ 236 mμ (log ε 4.23), strong infrared absorption at 5.97 μ indicating an α,β-unsaturated carbonyl group.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.86; H, 7.60. Found: C, 84.89; H, 7.56.

8-Hydroxy-5-methyl-11-oxo-8-phenyl-5,6,7,8,9,10-hexahydro-5,9-methanocycloöctabenzene (VII). (a).—Phenylmagnesium bromide (from 0.27 g. of magnesium) in 25 ml. of ether was added during 1 hr. with constant stirring to a suspension of 2.0 g. of V in 25 ml. of ether with cooling in an ice-bath. Stirring was continued for 30 minutes and then the mixture was refluxed for 1 hr. and allowed to stand overnight. The product was isolated according to the procedure with methylmagnesium iodide above and the pale yellow oil obtained crystallized when benzene and petroleum ether were added. The product weighed 0.87 g. (33%), m.p. 173–174°. Crystallized from benzene–petroleum ether, it melted at 178–179° and at 180–182° on admixture with the material obtained below. The infrared and ultraviolet spectra of the two products were identical.

(b).[16]—Thirty-nine grams (0.2 mole) of β-dimethylaminopropiophenone hydrochloride[17] in 400 ml. of ethyl alcohol at the boiling point was treated with 32 g. (0.2 mole) of XXI and then with 16 g. (0.4 mole) of sodium hydroxide in 80 ml. of water added in one portion. After 15 minutes refluxing, the solution was cooled in an ice-bath, acidified with hydrochloric acid and concentrated to one-third its volume by distillation from a steam-bath at reduced pressure. The waxy solid was filtered, washed with water and dried. Two crystallizations from benzene–petroleum ether gave 24.0 g. (41%) of crystals, m.p. 169–175°. Repeated crystallization from benzene–petroleum ether yielded material, m.p. 184.5–186°.

Anal. Calcd. for $C_{29}H_{29}O_2$: C, 82.16; H, 6.90. Found: C, 82.15; H, 6.90.

The oxime, crystallized from aqueous dioxane–ethanol, melted at 248–251° with slight darkening.

Anal. Calcd. for $C_{29}H_{21}O_2N$: C, 78.15; H, 6.89; N, 4.56. Found: C, 77.82; H, 6.72; N, 4.9.

The 2,4-dinitrophenylhydrazone from aqueous ethanol melted at 214–218°.

Anal. Calcd. for $C_{35}H_{24}O_5N_4$: C, 66.09; H, 5.12; N, 11.86. Found: C, 66.50; H, 5.21; N, 11.51.

8,11-Dihydroxy-5-methyl-8-phenyl-5,6,7,8,9,10-hexahydro-5,9-methanocycloöctabenzene (VIII).—A solution of 2.92 g. (10 mmoles) of VII in 200 ml. of anhydrous ether was added slowly to a slurry of 0.4 g. of lithium aluminum hydride in 50 ml. of ether. After 3 hr. a slight excess of water was added, the ether was decanted and the residual salts were washed with chloroform. On removal of the solvents 2.8 g. of colorless solid, m.p. 170–188°, remained. Crystallization from acetone gave 2.0 g. (68%), m.p. 178–184°, and further purification from acetone gave VIII, m.p. 197–198°.

Anal. Calcd. for $C_{29}H_{22}O_2$: C, 81.59; H, 7.53. Found: C, 81.66; H, 7.35.

The Cyclic Sulfite Ester IX from VIII.—The diol VIII (2.0 g.) suspended in 50 ml. of anhydrous ether and 1.6 g. of pyridine was cooled in an ice-bath and a solution of 1.2 g. of thionyl chloride in 25 ml. of ether was added over a 30-minute period with stirring. Stirring was continued for 2 hr. while the reaction mixture came to room temperature. The pyridine hydrochloride was filtered and washed well with ethyl acetate. Evaporation of the ether–ethyl acetate solution gave 1.8 g. of colorless crystals which decomposed below 150° with gas evolution. Crystallization from benzene–petroleum ether and then repeatedly from acetone gave IX, m.p. 142–143° dec., if inserted at 120° and heated 3° per minute.

Anal. Calcd. for $C_{29}H_{20}O_3S$: C, 70.56; H, 5.92; S, 9.42. Found: C, 70.28; H, 5.88; S, 9.55.

5-Methyl-11-oxo-8-phenyl-5,6,9,10-tetrahydro-5,9-methanocycloöctabenzene (X).—After 40 hr. refluxing of a solution containing 24 g. of VII in 750 ml. of acetic acid and 125 ml. of hydrochloric acid, the solution was distilled under reduced pressure on the steam-bath. A benzene solution of the residue was washed with water, 5% sodium bicarbonate and finally with water. The dried benzene was then distilled at reduced pressure and the residue was distilled. The fraction b.p. 160–175° (0.5 mm.) was a pale yellow extremely viscous oil (16.9 g., 75%). The analytical sample boiled at 168° (0.4 mm.).

Anal. Calcd. for $C_{29}H_{18}O$: C, 87.55; H, 6.61. Found: C, 87.21; H, 6.59.

The 2,4-dinitrophenylhydrazone was obtained from ethyl acetate–ethanol as orange crystals, m.p. 206–206.6°. From chloroform–ethanol yellow crystals were obtained, m.p. 150° (gas evol.), with solidification and remelting at 205–206°.

Anal. Calcd. for $C_{35}H_{22}O_4N_4$: C, 68.71; H, 4.88; N, 12.33. Found: C, 68.50; H, 4.96; N, 12.32.

When a solution of 7.0 g. of X in 75 ml. of absolute ethanol with 500 mg. of platinum oxide was shaken under hydrogen at slightly above atmospheric pressure, one mole of hydrogen was consumed in 20 minutes and hydrogenation stopped. The product, isolated after removal of the catalyst, solidified when benzene and petroleum ether were added. It was crystallized once from aqueous ethanol (5.2 g., m.p. 135–139°) and repeated crystallization brought the melting point to 147.8–149°.

Anal. Calcd. for $C_{29}H_{20}O$: C, 86.91; H, 7.29. Found: C, 86.86; H, 7.17.

This dihydro-derivative of X failed to react with 2,4-dinitrophenylhydrazine and was recovered unchanged from hydrazine–sodium hydroxide treatment according to Huang-Minlon.[18]

On Clemmensen reduction of 4.0 g. of the dihydro-derivative of X, an oil (2.1 g.), b.p. 160–175° (0.6 mm.), was obtained. The sample for analysis boiled at 168° (0.5 mm.).

Anal. Calcd. for $C_{29}H_{20}$: C, 92.26; H, 7.74. Found: C, 92.37; H, 7.22.

2,4-Dimethyl-2,4-pentanediol (XIII).—Methylmagnesium iodide (from 23 g. of magnesium) in 500 ml. of ether was cooled in an ice-bath, and 40 g. of isopropenyl acetate was added over a 45-minute interval with constant stirring. After standing overnight at room temperature, the mixture was treated with ammonium chloride and the product isolated in the usual manner. The fraction, b.p. 102–104° (19 mm.), weighed 28.6 g. (54%). Redistillation through an 8-inch Vigreux column gave material, b.p. 100° (17 mm.), $n^{20}D$ 1.4327. Reported constants are b.p. 89° (5 mm.), $n^{20}D$ 1.4327[7a]; b.p. 64° (2 mm.), $n^{20}D$ 1.4378.[7b]

The borate ester was prepared as described,[7a] m.p. 103–105°, after crystallization from benzene–petroleum ether; reported[7a] m.p. 102°.

The bis-3,5-dinitrobenzoate prepared by the excellent method using *p*-toluenesulfonyl chloride[19] gave colorless needles from aqueous ethanol, m.p. 166.5–168.2°.

Anal. Calcd. for $C_{21}H_{20}O_{12}N_4$: C, 48.46; H, 3.87; N, 10.77. Found: C, 48.43; H, 3.83; N, 10.88.

A sample of XIII prepared as described[7c] from diacetone alcohol and methylmagnesium iodide (in 34% yield) boiled at 100° (18 mm.), $n^{20}D$ 1.4327. The borate ester from this material melted at 104–106° after crystallization from benzene–petroleum ether. The infrared spectra of the diols from each source were identical as were the spectra of the two borate esters.

3-Methyl-3,5-heptanediol (XIV).—In the manner described above, vinyl acetate (0.4 mole) was added to 1 mole of ethylmagnesium bromide. The product boiled at 120–122° (19 mm.) (34%). The sample obtained on fractionation through an 8-inch Vigreux column boiled at 117° (16

The Beckmann Rearrangement in Liquid Sulfur Dioxide. II.[1] Rearrangement by Halogen

BY NIICHIRO TOKURA, RYUZO ASAMI AND RITSURO TADA

RECEIVED JUNE 27, 1956

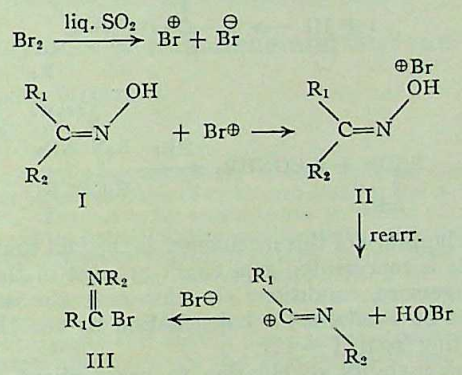
The Beckmann rearrangement of ketoximes may be effected by bromine and iodine in liquid sulfur dioxide at room temperature. Chlorine and sulfuryl chloride are without effect, but the addition of a small quantity of bromine (0.02:1 mole ratio) to these reagents leads to rearrangement. The oximes studied were those from cyclohexanone, cyclopentanone, acetophenone and benzophenone; in the case of aromatic oximes the reaction products were brominated or chlorinated amides. A possible mechanism is discussed.

Previous work has shown that the Beckmann rearrangement may be carried out in liquid sulfur dioxide at room temperature with sulfur trioxide,[1,2] with thionyl chloride and with a variety of phosphorus compounds.[1] It now has been found that the rearrangement may also be effected in sulfur dioxide solution by bromine, by iodine and by chlorine or sulfuryl chloride in the presence of small amounts of bromine (1:1:0.02 mole ratio for oxime:chlorine:bromine). Chlorine and sulfuryl chloride did not induce rearrangement when they were used without added bromine.

Rearrangements of the oximes of cyclohexanone, cyclopentanone, acetophenone and benzophenone were studied under varying conditions. Table I contains the results of experiments with cyclohexanone oxime in liquid sulfur dioxide. The best results were obtained with a 1:1 mole ratio of bromine to oxime (58 and 64% yield of ε-caprolactam for reaction periods of 1 and 24 hr., respectively) and with chlorine and sulfuryl chloride containing a small amount of bromine (67–72% yield of lactam). The yield of amide was not increased by increasing amounts of bromine, but a decrease in the bromine to oxime ratio to 0.5:1 decreased the yield of amide to 39%.

The bromine procedure (1:1 mole ratio, 1 hr. at 20°) and the chlorine–bromine procedure (1:1:0.02 mole ratio for oxime:chlorine:bromine, 1 hr. at 20°) were applied to the oximes of cyclopentanone, acetophenone and benzophenone. The results are given in Table II. Amides from acetophenone oxime and benzophenone oxime were halogenated under these conditions. Halogenation evidently occurred after the rearrangement reaction, since the products from benzophenone oxime were those to be expected from the halogenation of benzanilide.

The mechanism of the rearrangement is thought to be



This mechanism requires a 1:1 mole ratio of bromine to oxime for complete reaction. The formation of an amide from the intermediate III may occur during the reaction or at the time of addition of water to the reaction mixture. An alternate

TABLE I

ACTION OF HALOGEN ON CYCLOHEXANONE OXIME IN LIQUID SO_2[a]

Reagent	Molar ratio of oxime to halogen	Lactam formed, yield, %

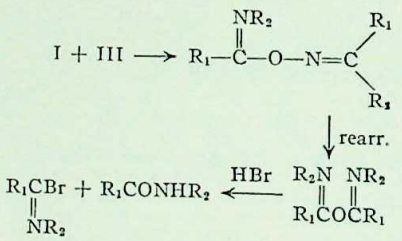
Acetophenone	Cl_2,Br_2	1:1:0.02	Acetanilide	32.5
			p-Chloroacetanilide	22.3
			N-Benzoyl-*o*-chloroaniline	28.4
Benzophenone	Cl_2,Br_2	1:1:0.02	N-Benzoyl-*p*-chloroaniline	51.7

[a] Reaction carried out at 20° for 1 hr. in liquid SO_2.

possibility also must be considered. From the work of Stephen and Staskun,[3] it is likely that III and the oxime might also react to form an intermediate in the Stephen–Staskun proposal for the Beckmann rearrangement. Thus



An advantage of this mechanism is the fact that the amide is represented as a direct product of the rearrangement condition. In this case the amide would be available for halogenation by the HOBr resulting from II → III.

The inability of chlorine to bring about rearrangement of an oxime under these circumstances may be due to a failure to form $Cl^{\oplus}$. The catalytic effect of bromine, when used with chlorine, can be ascribed to the regeneration of $Br^{\oplus}$ in the following way

$$Cl_2 + HOBr \longrightarrow ClBr + HOCl$$

$$ClBr \xrightarrow{\text{Liq. } SO_2} Cl^{\ominus} + Br^{\oplus}$$

The effect of bromine and water on the rearrangement reaction was also investigated. It is known that the reaction of bromine and water in liquid sulfur dioxide is[4]

$$Br_2 + 2H_2O + SO_2 \longrightarrow 2HBr + H_2SO_4$$

The hydrogen bromide remains in solution, but the sulfuric acid forms an insoluble lower layer. A mixture prepared in this way was not effective in bringing about the rearrangement of cyclohexanone oxime.

From the fact that the hydroxyl of the oxime undergoes reaction with a halogen in liquid sulfur dioxide, the hydroxyl of a substituted alcohol –C–OH should also undergo substitution with a halogen by the same procedure. Data on such a reaction will be published at later date.

Acknowledgment.—The authors wish to thank a reviewer for his help and Emeritus Prof. Dr. R. Hara for his interest and encouragement in this investigation. The authors are indebted to Miss Y. Endo for the microanalyses, to the Befu Chemical Industries Co. for donation of the liquid sulfur dioxide used in this research and to the Ministry of Education of Japan for a grant.

Experimental

Reagents.—Oximes were made by reaction of the appropriate ketone and hydroxylamine according to the references indicated; the oximes were cyclohexanone oxime[5] (m.p. 89–90.5°), cyclopentanone oxime[6] (m.p. 56.5–57°), acetophenone oxime[7] (m.p. 59.5–60.5°) and benzophenone oxime[8] (m.p. 141.5–142°).

Liquid sulfur dioxide was used as a solvent. Commercial material was used after filtration. It was found unnecessary to redistil the liquid or to dry it with sulfuric acid or phosphorus pentoxide.

The chlorine was distilled before use. Bromine was dried with sulfuric acid in the usual way. The iodine was washed with water and dried before use. The sulfuryl chloride was distilled (b.p. 66.5–67.5° (760 mm.)).

Apparatus and General Procedure.—Glass pressure vessels (300-ml. capacity) equipped with metal joints were used. Liquid sulfur dioxide was added to the oxime, with ice-cooling of the vessel, and a solution of the halogen or other reagents in sulfur dioxide was then added. Reverse addition was used for iodine reactions, since this material is sparingly soluble in sulfur dioxide. Chlorine solutions were best prepared by the addition of chlorine to sulfur dioxide.

Rearrangement of Cyclohexanone Oxime (Table I).—To a solution of 25 g. (0.22 mole) of cyclohexanone oxime in 100 ml. of sulfur dioxide there was added 100 ml. of sulfur dioxide containing the reagents indicated in Table I in various molar ratios. After the indicated time at 20° (usually 1 hr.), water was added with chilling and the solvent was allowed to evaporate. The residue was neutralized with 25% sodium hydroxide solution, and the products were extracted with chloroform. The chloroform was removed (reduced pressure) and the mixture was distilled under reduced pressure to yield cyclohexanone (b.p. 55–65° (35–36 mm.)), unchanged oxime (b.p. 95–115° (10–11 mm.)) and ε-caprolactam (b.p. 120–130° (7–8 mm.)). The ε-caprolactam was recrystallized from ether to yield a product with m.p. 67–68°. This was hydrolyzed with 15% sodium hydroxide solution and benzoylated to ε-benzoylaminocaproic acid,[9] m.p. 80–80.5°, for identification purposes (a mixed m.p. with an authentic sample was not depressed).

Yields obtained with a variety of reagents and conditions are in Table I.

Rearrangement of Ketoximes (Table II).—A solution of 35.5 g. (0.22 mole) of bromine in 100 ml. of sulfur dioxide was added to a solution of 22 g. (0.22 mole) of cyclopentanone oxime in 100 ml. of sulfur dioxide. After 1 hr. at 20°, the reaction mixture was treated as in the previous set of experiments. From the chloroform extract there was obtained by distillation 8.2 g. (37.2%) of δ-valerolactam, collected at 130–140° (15–16 mm.). This material, m.p. about 30°, was converted for identification into 1,3-dioxo-2-isoindolinevaleric acid[10] by treatment with phthalic anhydride; the m.p. and mixed m.p. with an authentic sample was 117–118°.

When this reaction was repeated with a chlorine–bromine mixture (1:0.02 mole ratio), the yield was 52.2% of δ-valerolactam, collected at 130–140° (15–16 mm.) and identified as before.

For acetophenone oxime, the reaction was carried out in the following way. A solution of 16 g. (0.1 mole) of bromine in 50 ml. of sulfur dioxide was added to a solution of 13.5 g.

(0.1 mole) of acetophenone oxime in 50 ml. of sulfur dioxide. After the reaction period, the sulfur dioxide was removed as usual and the residue was treated with 25% sodium hydroxide solution. The products were extracted with ether; the ether solution was dried and evaporated to yield 14.8 g. of material. Trituration with ether gave 7.9 g. of soluble material and 6.9 g. of colorless residue, m.p. *ca.* 155°, which was recrystallized from benzene to give a crystalline product with m.p. 164–165.5°, not depressed on mixture with authentic *p*-bromoacetanilide.

When the reaction was repeated on the same scale with a chlorine–bromine mixture, a yield of 14.5 g. of crude mixed products was obtained. This was triturated with benzene–ligroin (6.3 g. was soluble) to give 7.9 g. of colorless residue. Fractional crystallization from water gave 4.4 g. of material melting at about 100° and 3.8 g. of material melting at about 165°. Each fraction was crystallized from benzene; the products were identified as acetanilide (m.p. and mixed m.p. 113–114°) and *p*-chloroacetanilide (m.p. and mixed m.p. 171–172.5°).

The reaction with benzophenone oxime (19.7 g., 0.1 mole) was carried out in the usual way in 100-ml. total volume of sulfur dioxide. The yield of 18.7 g. of crude product was triturated in ether (4.4 g. of soluble material) to give 14.3 g. of orange powder, m.p. 201–202°. The m.p. was not depressed on mixture with authentic N-benzoyl-*p*-bromoaniline.

When a chlorine–bromine mixture was used with 0.1 mole of benzophenone oxime, crude product amounted to 20.3 g. This was triturated with benzene, and the benzene solution yielded 6.6 g. of N-benzoyl-*o*-chloroaniline, m.p. and mixed m.p. 99–101° after recrystallization from ethanol. The benzene-insoluble residue was fractionally crystallized to give 12 g. of N-benzoyl-*p*-chloroaniline, m.p. and mixed m.p. 187–188.5°, and an unidentified material (1.7 g.) with m.p. 150–152°.

Satisfactory nitrogen analyses were obtained for all reaction products.

Reactions with Bromine–Water Mixture.—When a bromine–water mixture was used in sulfur dioxide with cyclohexanone oxime, a rearrangement did not occur (Table I). Cyclohexanone and cyclohexanone oxime were recovered. For the reactions in Table I, the recovery of oxime was 74.0 and 87.6%.

The Synthesis and Identification of Block Polymers of Butadiene and Styrene

BY R. J. ORR AND H. LEVERNE WILLIAMS

RECEIVED NOVEMBER 21, 1956

A method of synthesizing polymeric dihydroperoxides in which the hydroperoxy groups are terminal has been evolved. The monomers are polymerized in emulsion at 12.8° using sufficiently large quantities of complexed iron(II) and *p*-diisopropylbenzene dihydroperoxide that mutual termination is dominant. The molecular weight of the polymeric dihydroperoxide is controlled by adjusting the emulsifier, the dihydroperoxide and the iron(II) sulfate concentrations. The residual hydroperoxide group on the polymer is protected from reaction by the short residence time in the aqueous phase. Such polymers after purification will initiate polymerization of a second monomer. The iodine monochloride adduct of butadiene–styrene copolymers is insoluble in carbon tetrachloride for high-butadiene polymers and soluble for low-butadiene polymers. This permitted verification that the polymers produced by initiating styrene polymerization with polybutadiene dihydroperoxide were not mixtures of polystyrene and polybutadiene but were composed of chemically linked blocks of polymers of the two compositions. This was supported by fractionation experiments which indicated that some bound styrene could not be extracted after cross-linking such a polymer. Evidence is presented that such results do not arise from chain transfer.

Introduction

Active interest in the field of block and graft polymers is comparatively recent, stimulated by the potential economic value of some novel product. While methods of grafting are numerous, since they depend only on placing side chains randomly along the main chain, the methods of forming block polymers are few due to the restriction on the location of the points of union of the blocks in the molecule. Several reviews[1–3] summarize methods. The methods have the defect that if they are simple and commercially feasible they offer little control over the structure of the final polymer. The problem of exerting control over the process and product seems to be the major difficulty.

It is important to establish by analytical methods the structure of the polymer postulated from kinetic reasoning. Fractionation of the product of the reaction may be tedious, and success in separating differing polymers depends on the difference in solubilities of the polymers. There is little difference between the solution properties of polybutadiene and polystyrene, so that this approach offers little promise, although some workers report successful fractionations of similar polymer mixtures.[4]

During the course of the study of the decomposition of hydroperoxides by iron(II), *p*-diisopropylbenzene dihydroperoxide was used.[5] This gave a free radical which underwent little side reaction relative to reaction with monomer. Considering the theories of emulsion polymerization as outlined by Harkins[6] and Smith and Ewart[7] suggested that sufficiently rapid decomposition of hydroperoxide might result in appreciable amounts of mutual termination according to the mechanism

$$\text{HOOROOH(aq)} + \text{Fe(II)} \longrightarrow \text{HOORO}\cdot\text{(aq)} + \text{Fe(III)}$$

$$\text{HOORO}\cdot\text{(aq)} + \text{M(aq)} \longrightarrow \text{HOOROM}\cdot\text{(aq)} \xrightarrow{(n-1)\text{M}} \text{HOOROM}_n\cdot\text{(oil)}$$

$$\text{HOOROM}_n\text{(oil)} + p\text{M(oil)} \longrightarrow (\text{HOOROM}_{n+p})\text{(oil)}$$

$$\text{HOOROM}_n\text{(oil)} + \text{HOOROM}_{n+p}\text{(oil)} \longrightarrow \text{HOOROM}_{2n+p}\text{OOROOH}$$

This would be much more likely with diisopropyl benzene dihydroperoxide than other hydroperoxides since at the high steady state concentrations of hydroperoxy free radicals in the aqueous phase necessary to bring about rapid initiation of polymerization there would be less chance that the free radical would undergo side reactions with iron(II) or with the parent dihydroperoxide. If the residence time of the initiating radical in the aqueous phase be sufficiently short, then little opportunity of reaction of the remaining hydroperoxide group with the water-soluble iron(II) would occur, and a polymeric dihydroperoxide would be formed. Once this is formed, the polymeric hydroperoxide groups would be protected from decomposition by isolation from the water-soluble iron(II). Such a polymer when mixed with another monomer and heated should be capable of forming diradicals which would give rise to block polymer.

Experimental Methods.—The diisopropylbenzene dihydroperoxide (DHP) was obtained in solution in acetone. It was reported as being mostly *para*, although some of the *meta* form may have been present. The product was contaminated with an oil-soluble hydroperoxide, probably diisopropylbenzene monohydroperoxide. No attempt was made to remove it. The compound (DHP) was insoluble in hydrocarbons, probably due to the lipophobic nature of the hydroperoxide groups. The solubility in carbon tetrachloride was less than 0.085%. The solid dihydroperoxide was added to the 7-ounce reaction bottle initially followed by the emulsifier solution and high boiling monomers. The activator (an aqueous solution of iron(II) pyrophosphate) was added. Premature reaction was minimized by the separation of the activator from the dihydroperoxide. Excess volatile monomer was added last and allowed to evaporate to the correct weight to expel residual air. The beginning of agitation of the reaction was taken as zero time. The recipe was composed of 5 parts of potassium fatty acid soap and 320 parts of water per 100 parts of monomer. The large amount of water was necessary to accommodate the catalyst and activator. Reaction temperature was 12.8°.

Experimental

(a) **Molecular Weight of Polymeric Dihydroperoxides.**—The obvious method of controlling molecular weight of the polymeric dihydroperoxide is by changing the rate of free radical production by varying the activator and catalyst concentration in the recipe. The results are in Table I for a 72/28 butadiene/styrene ratio. The branching constants (k') were measured from the slope of the plot of ln η_{rel} *versus* c according to the Mead–Fuoss equation. These compare favorably at the lower molecular weights with those observed for polystyrene.[8]

The polymeric dihydroperoxides were soluble in benzene except when prepared with 0.2 and 0.5 part DHP. The intrinsic viscosity was determined on the soluble fraction of these, which accounts for the decrease in the value of k' from that obtained for the polymer prepared with 1.0 part of dihydroperoxide. The experiments were done using 5.3 parts of emulsifier and conducting the reaction to 100% conversion which was reached by 17 hr. Assuming mutual termination to be responsible for molecular weight control, then the molecular weight at any given rate of free radical production should be dependent on the ratio of the number of particles containing growing chains to the total number of particles. If this ratio be dependent on emulsifier concentration, molecular weight should be dependent on emulsifier concentration. This was investigated. The results are in Table II.

TABLE I

MOLECULAR WEIGHT CONTROL BY ACTIVATOR–CATALYST SYSTEM

Parts DHP	$[\eta]$	k'
0.2	1.64	0.50
0.5	1.01	.53
1.0	0.84	.58
3.0	.83	.46
5.0	.78	..
6.0	.52	.41
7.0	.74	..
10.0	.61	.31

TABLE II

MOLECULAR WEIGHT CONTROL BY VARIATION OF EMULSIFIER CONCENTRATION

100% Conversion in 17 hours; DPH, 10 parts; FESO·7H$_2$O/DHP/K$_4$P$_2$O$_7$,1/1/1

Parts emulsifier	$[\eta]$
7	0.4
10	0.7
15	1.0
20	1.0

(b) **Effect of Monomer Structure on Polymeric Dihydroperoxide Formation.**—Several monomers were polymerized in the preceding recipe containing 10 parts of DHP and DHP/FeSO$_4$·7H$_2$O/K$_4$P$_2$O$_7$ = 1. Those for which intrinsic viscosity data were obtained are in Table III.

TABLE III

FORMATION OF POLYMER DIHYDROPEROXIDES FROM VARIOUS MONOMERS

Initial monomer composition	$[\eta]$
Styrene	0.7
72% butadiene/28% α-methylstyrene	.8
Butadiene	.6
72% isoprene/28% styrene	.7
72% butadiene/28% *p*-chlorostyrene	.7
72% butadiene/28% vinylpyridine	.3

Other butadiene-containing polymers were prepared with a 72/28 charge ratio of butadiene to acrylonitrile, acrylamide or methyl methacrylate using gel as a criterion for molecular weight changes. The latter two pairs gave gel-free, low molecular weight polymers at 100% conversion. With the first-mentioned pair, it was necessary to reduce the proportion of acrylonitrile in the charge to 5% before the resulting polymer was soluble in benzene or methyl ethyl ketone. On replacing the anionic emulsifier with dodecylamine hydrochloride and reducing the *p*H to 4.5 with acetic acid, a polymer soluble in methyl ethyl ketone with an intrinsic viscosity of 0.3 in this solvent was obtained. This is believed to be related to a tendency[9] of hydroperoxides to react with acrylonitrile at high *p*H.

(c) **Stability of Polymeric Dihydroperoxides.**—When purifying butadiene-containing polymeric dihydroperoxides, the dry polymer cross-linked easily even after precipitation 3 or 4 times from benzene solution, due to the reactive nature of the polymeric dihydroperoxides. The polymers could be stored as 10% solutions in benzene or toluene at 50° without change of the intrinsic viscosity for at least 72 hr.

A characteristic behavior of the polymeric dihydroperoxides containing butadiene was the tendency for reaction of the double bounds when stored in carbon tetrachloride solution as shown by Fig. 1. After about 50% reaction of the double bonds (as measured by an iodine monochloride titra-

(8) J. A. Manson and L. H. Cragg, *J. Polymer Sci.*, **29**, 481 (1958).

Digitized by Arya Samaj Foundation Chennai and eGangotri

tion), the polymer began to precipitate. This cannot be due to cross-linking since reaction of less than 5% of the double bonds by such a process should yield 100% gel. It appears reasonable that addition of carbon tetrachloride imparting solvent resistance to the polymer is occurring. To confirm if this were the case, reaction of double bonds of mercaptan-modified polymers in the presence of free hydroperoxide was studied by iodine monochloride titration. It was necessary to treat the remaining hydroperoxide by shaking with aqueous iron(II) sulfate or to carry out a blank titration without polymer since the hydroperoxide reacted with iodine monochloride. With a saturated solution of dihydroperoxide, no reaction of double bonds occurred in 8 days at 50°. With diisopropylbenzene monohydroperoxide higher concentrations of hydroperoxide were attainable. There was an initial reaction of about 4% of the double bonds at 50° in 30 hr. after which time the double bond analysis became constant.

(d) **Initiation by Polymeric Dihydroperoxides.**—Polymeric dihydroperoxides will be formed if the residence time of the hydroperoxy terminated radical in the aqueous phase is sufficiently short that reaction with iron(II) sulfate cannot occur. If this is the case, the polymeric dihydroperoxide should initiate polymerization. To test this the polymer was dissolved in a benzene solution of monomer to give a solution 5.5% polymer and 55% monomer which was heated to 50° for 17 hr. According to Smets and Woodward,[10] the presence of benzene suppresses the formation of branched chains. Since care had to be exercised that the polymerization of the second monomer did not result from peroxidic impurities in the polymer, all polymers were purified by reprecipitation from benzene solution with methanol. In all instances, one precipitation was sufficient to reduce the hydroperoxide concentration in the polymer so that subsequent extraction with methanol did not remove sufficient hydroperoxide to detect by iodimetric methods. Removal of hydroperoxide reflects the insolubility of the free dihydroperoxide in benzene compared with methanol. At least one more purification step was applied to the polymer. Some data on the effect of the number of purifications on the activity of the polymer are in Table IV.

TABLE IV

EFFECT OF PURIFICATION ON POLYMERIZATION ACTIVITY AT 50°

Polymer type	No. of purifications	Increase in total polymer present, %
72/28 Bd/Sty	2	38
	4	10
Polystyrene	2	228
	3	166

The polymer retains initiating activity after concentrations of free hydroperoxide sufficiently large to be detected have disappeared. The difference in activity between the polymeric dihydroperoxides suggests that different structures for the dihydroperoxides must be assigned. This would not be so if free hydroperoxides were catalyzing the reaction. Under comparable condition it was found that a 0.7% solution of dihydroperoxide would polymerize styrene equivalent to only 44% of the total polymer. This amount of hydroperoxide is detectable by iodimetric analysis.

To investigate the factors affecting the activity of the polymeric dihydroperoxide, a series of polymeric dihydroperoxides of varying composition was prepared and chain-extended with a series of monomers with the results shown in Table V. The polymers were purified twice. The value at 1100% polymer increment indicates that polymerization had proceeded till the monomer supply was exhausted. Those reactions which proceeded only at 100° were preaged 17 hr. at 50°. While the data in this table may be affected by the tendency of the polymeric dihydroperoxide to lose activity during purification, there seems to be an inverse correlation between the polarity of the monomer–polymer pair and the reactivity. Experiments containing monomeric dienes proved to be exceptions since they were less reactive than monovinyl compounds.

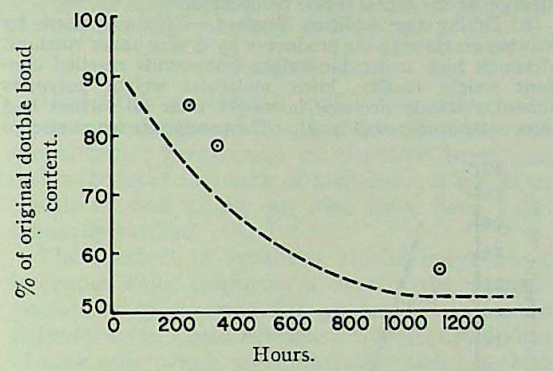

Fig. 1.—Double bond disappearance of polybutadiene dihydroperoxide in CCl_4 at 25°.

(e) **Effect of Iodine Monochloride on Copolymers and Their Mixtures.**—Consideration was given to methods other than fractional precipitation to prove that the polybutadiene chains were chemically linked to polystyrene units. Kemp and Peters[11] utilized iodine monochloride analyses for butadiene in a copolymer. This added quantitatively to the double bond in the polymerized butadiene in dichlorobenzene solution. It was noted that when carbon tetrachloride was used as a solvent, iodine monochloride consumption gave reproducible values for the bound butadiene and that a voluminous white precipitate formed with polymers richer in butadiene. Since no reaction between polymers of monovinyl compounds and iodine monochloride occurred, it was felt that this would be a method for analyzing polymeric mixtures in which one substituent was a polymer or copolymer of a diene.

(f) **Determination of Iodine Monochloride Consumption.**—Since the addition product may weigh nearly four times as much as the polymer from which it is formed, the importance of a precise determination of the iodine monochloride consumption is obvious; 0.05 molar solution iodine monochloride was added to 0.12 g. of polybutadiene or its equivalent so as to give an amount of iodine monochloride 100% in excess of the theoretical requirement. After the reaction proceeds to completion, the residual iodine monochloride was titrated with 0.1 *N* sodium thiosulfate to a starch endpoint. With 100% excess, no changes in iodine monochloride reacted occurred between 15 minutes and 1 hr. so that the titration could be made after 15 minutes. A polymer was prepared in a conventional recipe with a charge ratio of 72/28 butadiene/styrene. It was possible to determine the butadiene content (and hence the iodine monochloride

content of the precipitate) as 75.28 ± 0.15% based on 12 determinations.

(g) **Filtration of the Addition Product.**—Filtration of the addition products for high molecular weight polymers proved much easier than for low molecular weight compounds. The latter plugged the pores of sintered glass filters and necessitated the use of ground glass as a filtration aid. The precipitate particles were trapped in a thick pad of ground glass over the fritted disk. The precipitate adhered to the walls of the flask if there was water in the reaction flask. Each experiment was done using two identical samples, since filtration could not be done with the sample intended for back titration of the excess iodine monochloride.

(h) **Drying the Addition Product.**—This was done by drawing air through the product or by drying under vacuum. Although high molecular weight compounds reached constant weight readily, lower molecular weight polymers showed a steady decrease in weight after all solvent had apparently vanished (Fig. 2). The precipitate may undergo

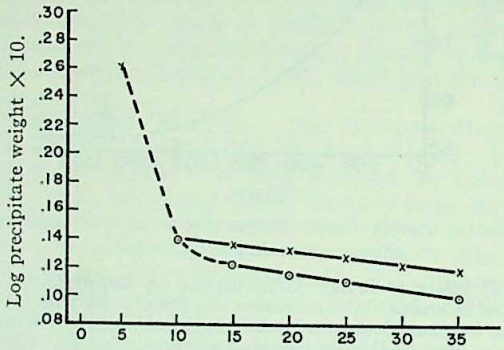

Fig. 2.—Dependence of weight of ICl addition product on drying time for low molecular weight polybutadiene.

some thermal change. By choosing the point of inflection in the weight *vs.* time curve as the correct weight, it was possible to account for all polymer present within ±2%. The precision could be improved to that characteristic of analysis of high molecular weight polymers on a relative scale. To determine the amount of styrene which had been blocked onto the ends of a polybutadiene chain, the weight–time curve of the block polymer precipitate was compared with that curve derived from a precipitate of an equal amount of the original polybutadiene. The difference was nearly independent of time. For higher molecular weight products it was possible to recover 99.5% ± 0.6% of the total for four polymer samples.

(i) **Effect of Styrene Content on Precipitation.**—Polymers were prepared from varying charge ratios, and the effect of styrene content on the tendency to precipitate was investigated. The results are in Table VI. It is interesting that the total change in solubility occurs over a region of less than 10% bound styrene.

Table VI

Influence of Styrene Content on Recovery of Precipitate

Styrene, %	[η]	Theor. ppt., %
0	0.6	100
25	1.5	99.7
40	1.5	100.2
50	1.5	Cloudy
70	1.5	Clear

(j) **Analysis of Mixtures of Polymers and Copolymers of Butadiene and Polystyrene.**—A 75/25 butadiene/styrene copolymer was mixed with twice its weight of polystyrene. The butadiene-containing portion was precipitated with iodine monochloride. Complete recovery of this portion could be made in this fashion when the volume of CCl_4 present was 600 cc. When only 300 cc. was used, it was difficult to wash the precipitate free of polystyrene. The precision of determinations in a volume of 600 cc. is that predicted from the reproducibility of each step in the process, indicating no significant absorption of polystyrene on the precipitate. Polystyrene, when mixed with polybutadiene, showed no effect on recovery up to 4/1 ratio.

(k) **Effect of Various Solvents.**—Carbon tetrachloride was the only suitable solvent found for this precipitation. No precipitation occurred in benzene, chlorobenzene, ether, pentane, ethylene dichloride, chloroform or ethanol–carbon tetrachloride mixes. Addition of the ICl to the double bond occurred in all instances.

(l) **Study of Chain Extension Step by Iodine Monochloride Technique.**—Two aspects were considered: (i) The tendency of the iodine monochloride adduct to become soluble in CCl_4 when chain extension was great. (ii) The degree to which it was possible to recover in this adduct all of the polymer formed when chain extension was little.

In each series polybutadiene dihydroperoxide was dissolved in benzene, styrene added to the solution and the temperature raised to 50°. In one series, designed for low amounts of chain extensions, the polymer concentration was 2.34% and the polymer/styrene ratio either 85/15 or 50/50. At the required degree of chain extension, the sample containing styrene and its styrene-free control were cooled and the benzene and residual styrene removed by evaporation from aliquots and replaced with CCl_4. Precipitation, when combined with the ICl reaction by an aliquot from which the residual styrene had not been removed, permitted calculation of percentage polymer relative to total polymerization. For higher chain extensions the styrene/polymer ratio was 10, in about 5.5% solution of polymer in benzene–styrene. The polymer was coagulated, purified by reprecipitation and analyzed. After precipitation, all samples of the addition product showed continuous decrease of weight on drying, a characteristic noted previously for polybutadiene. The weight difference between the precipitate of the chain-extended sample and the polybutadiene control was found to be independent of drying time. This weight difference must be equivalent to the weight of styrene bound to the ends of the polybutadiene chain. The precision involved in the determination will be double that of the weighing and filtering processes which was determined as ±0.1%.

Figure 3 shows the percentage recovery of the polymer in the addition product against the total amount of polymerized styrene in the polymer. This is compared with the curve to be expected if subsequent polymerization were formation of polystyrene.

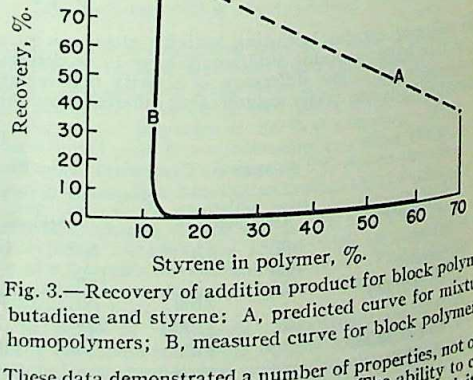

Fig. 3.—Recovery of addition product for block polymers of butadiene and styrene: A, predicted curve for mixtures of homopolymers; B, measured curve for block polymer.

These data demonstrated a number of properties, not only of the process but also of the product. The ability to convert polybutadiene to a polymer which did not precipitate upon addition of iodine monochloride permitted no interpretation other than the elimination of polybutadiene as a separate chemical entity. Previous experiments indicated that up to a 4-to-1 ratio of polystyrene to polybutadiene did not interfere with the recovery of the addition product. The maximum ratio of polystyrene to polybutadiene in the above was 1/1. Such interference could not result from polystyrene. During the initial portion of the reaction the polymerized styrene in the addition product was recovered to be quantitative after the bound

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

styrene reached about 6%. After this, the amount of addition product and the recovery of the polymer decreased and reached zero at about 10% bound styrene. This indicates that some of the polymer chains contained sufficient styrene to make the iodine monochloride addition product soluble. This effect was also noted with random copolymers in increasing the styrene content, but not until about 50% bound styrene had been reached. The average bound styrene content necessary to make the addition product soluble showed that styrene had a much greater effect when blocked onto the ends of a polymer than when copolymerized randomly. The tendency of the incoming styrene to make the addition product soluble made any estimate of the amount of styrene polymerizing to the homopolymer unrealistic. The possibility of forming graft polymers by chain transfer between a polystyrene radical and polybutadiene was checked by polymerizing a similar amount of styrene with diisopropylbenzene dihydroperoxide in 2.75% polybutadiene solution to give an apparent 95% chain extension. By removal of the gelled fraction and purification of the sol fraction, it was established by the iodine monochloride technique that all the polymerized butadiene present was in the form of polybutadiene. This corresponds with the conclusions drawn by Smets and Woodward.[10]

(m) **Chain Extension of Polybutadiene Dihydroperoxide with Methyl Methacrylate and Analysis of Products.**—In an attempt to obtain more precise results on the rate of homopolymer formation, polybutadiene was chain extended with methyl methacrylate. It was possible to show a minimum of 200% weight increase in the polymer precipitated with iodine monochloride. However, interpretation of these results was complicated by the ability of iodine monochloride to precipitate polymethyl methacrylate from carbon tetrachloride solution, even though there was no chemical reaction between the polymer and iodine monochloride. This method of investigating chain extension may have limitations for polar–non-polar monomer–polymer pairs.

(n) **Fractionation of Butadiene–Styrene Block Copolymers.**—Polybutadiene, twice purified, was chain extended with styrene as in the preceding experiments. A film was cast from solution and allowed to stand in air at 45° for 72 hr. This polymer was found to be partly gelled. The gel portion was loose and swelled in benzene. Benzene was added until the gel had imbibed its maximum and allowed to come to equilibrium before the soluble fraction was removed. Several extractions were carried out until the extract showed no evidence of dissolved polymer. The sol fraction contained large quantities of bound butadiene as evidenced by reaction with iodine monochloride. The swollen gel fraction was pressed into a film and dried. Refractive index of the film indicated 14% bound styrene which was unextractable. This styrene must have been bound directly to the butadiene in a block and cannot be considered to indicate the total amount of block polymer present, since this will consist of the higher end of the molecular weight distribution which may or may not contain the same proportion of active polymers as does the lower end of the distribution. The film of block polymer was not subjected to quantitative measurements, but it differed from a normal copolymer with 14% bound styrene. It was hard and stiff and not rubbery, which may be a result of a higher second-order transition point.

(o) **Intrinsic Viscosity Changes During Chain Extension.**—The change in intrinsic viscosities during chain extension was investigated. A polymeric dihydroperoxide composed of 72% butadiene and 28% styrene increased in intrinsic viscosity from 0.61 to 1.20 when styrene was blocked on the ends to give a polymer containing 35% styrene. Any polystyrene formation will tend to increase the intrinsic viscosity of the resultant mixture since the intrinsic viscosity of bulk polymerized polystyrene was found to be about 3.0. However, if this be neglected, as the analytical data indicate to be reasonable, then it is possible to calculate the Staudinger K and α values for a block polymer.

The Staudinger equation for the molecular weight of GR-S types at 50° is: $\eta = 5.25 \times 10^4 M^{0.667}$.[12]

Considering the above polymer and postulating that the total number of molecules in the system did not change, then if the system were always monodisperse, the molecular weight would increase from 7.6×10^4 to 1.1×10^5. Each styrene block has a molecular weight of 1.7×10^4 or approximately 1700 styrene units. α does not differ markedly for GR-S and styrene in solution being 0.69 for polystyrene.[13] If α for the block polymer be taken as that of polystyrene, then the Staudinger formula is $4.9 \times 10^4 M^{0.69}$.

Conclusions

This work provides a qualitative confirmation of the mechanisms assigned to emulsion polymerization. Predictions which have been made on the basis of the work of Harkins and Ewart and Smith as well as on our own have been experimentally verified.

The method of synthesis of the polymeric dihydroperoxides conforms to one of the more important requirements for preparing any active polymer to be chain extended, that is, the isolation of such polymers from conditions which may result in destruction of some of the active centers. This is accomplished since the polymeric dihydroperoxide becomes oil-soluble so quickly that there is no significant reaction with the iron(II) sulfate. If this is not done, subsequent deactivation of such active centers will give rise to an inactive polymer and result in contamination of the product. The fact that little of this exists is confirmed by the disappearance of insoluble ICl adduct characteristic of high styrene polymers. The use of the iodine monochloride technique allows rapid analysis of the polymers resulting from non-polar monomer polyperoxide pairs. The method does not appear to be applicable to non-polar–polar pairs, but other methods such as turbidimetric titration[14] exist which are useful.

Acknowledgments.—Helpful discussions were held with Dr. L. A. McLeod of Polymer Corporation Limited and Dr. M. H. Jones of Ontario Research Foundation. R. Wunder was technical assistant. The sample of dihydroperoxide of diisopropylbenzene was supplied by Hercules Powder Co. The authors thank Polymer Corporation Limited for permission to publish this data. Alkylation of Diphenylmethane with Alkyl Halides by Sodium Amide. Substitution *versus* β-Elimination. Relative Acidities of Diphenylmethane and Ammonia

BY CHARLES R. HAUSER AND PHILLIP J. HAMRICK, JR.[1]

RECEIVED JANUARY 7, 1957

Diphenylmethane was metalated by sodium amide in liquid ammonia and ether, and the resulting sodium diphenylmethide was alkylated with alkyl halides to produce excellent yields of hydrocarbons having the benzhydryl group. The method is superior to other methods of synthesis of such hydrocarbons. Sodium diphenylmethide shows a strong affinity for the carbon nucleus producing largely the alkylation product even with β-phenylethyl chloride which has been shown to undergo predominantly β-elimination with other strong bases. Potassium diphenylmethide yields some styrene with this halide. Sodium diphenylmethide was unaffected by *t*-butyl chloride. Evidence is presented that diphenylmethane is a stronger acid than ammonia in liquid ammonia.

Reactions of diphenylmethane involving one of its active methylene hydrogens have generally been effected through the intermediate formation of an ether suspension of potassium diphenylmethide. This red intermediate has been prepared by adding the hydrocarbon to potassium amide in liquid ammonia, and then replacing the ammonia with ether.[2] For example, the resulting suspension has been carbonated to form diphenylacetic acid in 91% yield (equation 1).[3,4]

$$(C_6H_5)_2CH_2 \xrightarrow[\text{liq. } NH_3]{KNH_2} (C_6H_5)_2CHK \xrightarrow[2,\ CO_2\\ 3,\ \text{acid}]{1,\ \text{ether}} (C_6H_5)_2CHCOOH \quad (1)$$

Although ether is a suitable medium for many reactions of carbanions, liquid ammonia is sometimes an even better medium. Thus certain alkylations of sodio- or potassiophenylacetonitrile have been realized in better yields in a mixture of liquid ammonia and ether than in ether alone.[5]

In the present investigation alkylations and aralkylations of sodium diphenylmethide with alkyl and aralkyl halides were effected in a mixture of liquid ammonia[6] and ether to form hydrocarbons having the benzhydryl group. The reaction may be illustrated with benzyl chloride which formed hydrocarbon I in 99% yield (equation 1).

$$(C_6H_5)_2CH_2 \xrightarrow[\text{liq. } NH_3]{NaNH_2} (C_6H_5)_2CHNa \xrightarrow[\text{ether}]{C_6H_5CH_2Cl} (C_6H_5)_2CHCH_2C_6H_5 \quad (2)$$
$$\text{I}$$

Similarly, benzhydryl and α- and β-phenylethyl chlorides gave hydrocarbons II, III and IV in yields of 96, 97 and 88%, respectively. The last two yields were based on slightly impure products which are low melting solids.

$$(C_6H_5)_2CHCH(C_6H_5)_2 \qquad (C_6H_5)_2CHCHC_6H_5 \qquad (C_6H_5)_2CHCH_2CH_2C_6H_5$$
$$\text{II} \qquad\qquad \text{III} \qquad\qquad \text{IV}$$

The purely aliphatic halides, isopropyl chloride, and 2-ethylbutyl and *n*-octyl bromides, produced hydrocarbons V, VI and VII in yields of 86, 94 and 99%, respectively.

$$(C_6H_5)_2CHCH(CH_3)_2 \qquad (C_6H_5)_2CHCH_2CH(C_2H_5)_2 \qquad (C_6H_5)_2CH(CH_2)_7CH_3$$
$$\text{V} \qquad\qquad \text{VI} \qquad\qquad \text{VII}$$

These results are summarized in Table I. This method is convenient to carry out. The diphenylmethane is added to an equivalent of sodium amide in liquid ammonia, followed by an equivalent of the halide in ether. The metalation of the hydrocarbon occurs immediately, and the alkylation of the resulting sodium diphenylmethide takes place rapidly (see Experimental).

TABLE I

ALKYLATIONS OF SODIUM DIPHENYLMETHIDE WITH HALIDES TO FORM HYDROCARBONS

Halide	Hydrocarbon	Yield, %
Benzyl chloride	I	99
Benzhydryl chloride	II	96
α-Phenylethyl chloride	III	97
β-Phenylethyl chloride	IV	88
Isopropyl chloride	V	86
2-Ethylbutyl bromide	VI	94
n-Octyl bromide	VII	99

This procedure is more convenient than the related earlier method involving the preparation of sodium diphenylmethide from benzhydryl methyl ether and sodium in ethyl ether (equation 3).[7,8]

$$(C_6H_5)_2CHOCH_3 \xrightarrow[\text{ether}]{Na} (C_6H_5)_2CHNa \xrightarrow{RX} (C_6H_5)_2CHR \quad (3)$$

Not only is diphenylmethane more readily available than benzhydryl methyl ether, but the con-

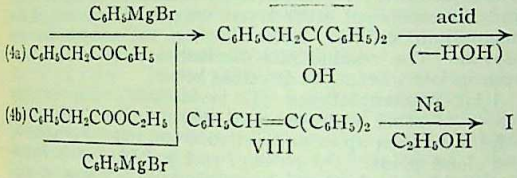
version of the hydrocarbon to the sodio derivative can be accomplished in much less time than that of the ether. In fact the ether was shaken with finely divided sodium for two days.[8] Moreover, the yields of hydrocarbons III and IV were 97 and 88%, respectively, by our method, and only 42 and 65%, respectively, by the earlier method.[8] However, the earlier method has been reported to produce hydrocarbon V in quantitative yield.[7]

The present method also appears preferable to known indirect methods, the most widely employed of which involves the synthesis of the corresponding olefin, and its reduction or hydrogenation. The olefins have generally been obtained by the dehydration of carbinols which usually have been synthesized by appropriate Grignard reactions. For example, olefin VIII, which was reduced to form hydrocarbon I, was synthesized by the action of phenylmagnesium bromide on the appropriate ketone[9] or ester[10] (equations 4a and 4b). No yields were reported.



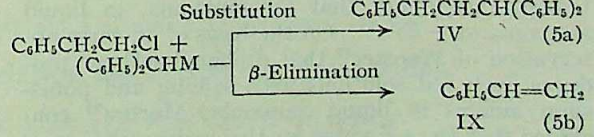
Similarly hydrocarbons III[10] and V[11] have been synthesized through the corresponding olefins and carbinols which were obtained from Grignard reactions. The yield for the former hydrocarbon was not given but that for the latter was reported to be good.

Hydrocarbon II has been prepared in this Laboratory by the reduction of tetraphenylethylene which was synthesized through the selfalkylation of benzhydryl chloride by means of sodium amide in liquid ammonia.[12] The over-all yield was good, but the present alkylation method is more convenient.[13]

Substitution *versus* β-Elimination.—It is rather remarkable that even β-phenylethyl and isopropyl chlorides and 2-ethylbutyl bromide underwent predominantly the substitution type of reaction with sodium diphenylmethide to form alkylation products (Table I), since such halides generally exhibit largely β-elimination with strong bases to yield the corresponding olefins.[14] For example, β-phenylethyl bromide is converted by ethanolic sodium ethoxide at 25° to styrene in almost quantitative yields (93–96%).[15] Although the low temperature (−33°) at which the reactions with sodium diphenylmethide were carried out should favor substitution,[16] the more strongly basic nature of this reagent compared to sodium ethoxide might be expected to more than compensate for the influence of temperature and to produce appreciable β-elimination. Apparently sodium diphenylmethide shows less tendency to attack the β-hydrogen of an alkyl halide than would be anticipated from its basic strength.[17]

The lack of appreciable tendency for sodium diphenylmethide to effect β-elimination was further demonstrated by its failure to react with *t*-butyl chloride which generally undergoes this type of reaction with bases.[18] Thus, in contrast to the halides listed in Table I, this halide failed to react with sodium diphenylmethide in liquid ammonia and ether, the red color of this reagent remaining even after four hours in the presence of two equivalents of the halide. That no appreciable amount of the sodium diphenylmethide had reacted was shown by the addition of benzhydryl chloride which produced the corresponding hydrocarbon II in 94% yield. Not only did the *t*-butyl chloride fail to react with the sodium diphenylmethide but apparently no appreciable amount of it underwent ammonolysis with the ammonia since much of the tertiary halide was recovered.

Since the potassium amide in liquid ammonia is known to effect relatively more β-elimination than sodium amide with certain halides,[19] it seemed likely that potassium diphenylmethide would effect relatively more β-elimination than sodium diphenylmethide under similar conditions. In agreement with expectation, potassium diphenylmethide converted β-phenylethyl chloride to styrene in 18% yield, although even the potassium reagent underwent mainly (70%) alkylation to form hydrocarbon IV. The influence of the metallic cation of the two courses of reaction may be illustrated by equations 5a and 5b.



M = Na; yields 88% of IV, trace of IX
M = K; yields 70% of IV, 18% of IX

Relative Acidities of Diphenylmethane and Ammonia.—The fact that the yield of the alkylation product of sodium diphenylmethide with benzyl chloride or certain other halides was essen-

(17) This tendency for sodium diphenylmethide to react at the α-carbon atom rather than at the β-hydrogen of the halides, together with the high rate at which these substitutions occur (see Experimental), suggests the mutual activation of both components through coordination of the sodium with the halogen leading to a low energy transition state.

tially quantitative indicates that the equilibrium of the acid–base reaction between equivalents of diphenylmethane and amide ion in a mixture of liquid ammonia and ether is far on the side of the diphenylmethide ion (equation 6). Otherwise

$$(C_6H_5)_2CH_2 + \bar{N}H_2 \underset{\longleftarrow}{\xrightarrow{\text{liq. } NH_3}} \underset{\text{(red)}}{(C_6H_5)_2\bar{C}H} + NH_3 \quad (6)$$

the amide ion present in the equilibrium mixture might be expected to react with the halide. For example, benzyl chloride is rapidly converted by the amide ion in liquid ammonia to stilbene (equation 7).[12] This reaction is accompanied by the production of violet color.[12]

$$2C_6H_5CH_2Cl \xrightarrow[\text{liq. } NH_3]{NaNH_2}$$

$$C_6H_5CH_2\underset{\displaystyle Cl}{\underset{|}{C}}HC_6H_5 \xrightarrow[\text{liq. } NH_3]{NaNH_2} C_6H_5CH{=}CHC_6H_5 \quad (7)$$

The possibility that an appreciable concentration of amide ion is present at equilibrium but that the diphenylmethide ion reacts more rapidly with the halide than the amide ion was eliminated by a competitive experiment. Thus, the addition of an equivalent of benzyl chloride to a mixture of one equivalent each of sodium diphenylmethide and sodium amide gave only a 35% yield of the alkylation product, hydrocarbon I. The main product was stilbene (62%), the violet color associated with its formation being observed (equation 7).

These results lead to the conclusion that diphenylmethane is a considerably stronger acid than ammonia.[20] This conclusion might appear to be at variance with reported pK values for diphenylmethane and ammonia which are 35[21] and 33,[22] respectively. On the basis of these values the hydrocarbon would be expected to be ionized by an equivalent of the amide ion to the extent of only about 10%. However, these values should probably not be compared since the value for diphenylmethane was determined in ether at room temperature,[21] and that for ammonia, in liquid ammonia at −55°.[22] On the basis of an early observation of Wooster[23] that diphenylmethane produces deep red solutions with sodium and potassium amides in liquid ammonia, Morton[24] concluded that the pK value for this hydrocarbon may be considerably lower than the reported value of 35.

Finally it should be mentioned that, in contrast to diphenylmethane, di-*p*-methoxyphenylmethane (X) is evidently a weaker acid than ammonia (equation 8). Thus, although the addition of

$$\underset{\text{X}}{(p\text{-}CH_3OC_6H_4)_2CH_2} + NaNH_2 \underset{\longleftarrow}{\xrightarrow{\text{liq. } NH_3}} (p\text{-}CH_3OC_6H_4)_2CHNa + NH_3 \quad (8)$$

compound X to an equivalent of sodium amide in liquid ammonia produced a red color, only about one-twentieth of an equivalent of benzyl chloride was required to change this color to the purple color associated with stilbene formation. On adding an equivalent of the halide, an 89% yield of stilbene was obtained, and 94% of X was recovered.

Experimental[25]

Alkylations and Aralkylations of Diphenylmethane (Table I).—To a stirred suspension of 0.1 mole of sodium amide in 200 ml. of anhydrous liquid ammonia[3] was added 16.8 g. (0.1 mole) of diphenylmethane in 100 ml. of dry ether. The red color of sodium diphenylmethide appeared immediately. After 10 minutes, 0.1 mole of the halide in 100 ml. of dry ether was added rapidly. Benzyl chloride, benzhydryl and α-phenylethyl chlorides decolorized the red solution as soon as all the halide solution was added. The other halides listed in Table I required a few minutes to discharge the red color. When no color remained the liquid ammonia was removed on the steam-bath to produce a suspension of salt in ether. An additional 100 ml. of ether was added and the mixture cooled. Water (100 ml.) was added to dissolve insoluble salts and the ether layer was separated. The aqueous layer was extracted twice with 50 ml. of ether and the combined ether layers were dried over anhydrous magnesium sulfate. After filtering, the solvent was removed. The residue was distilled or recrystallized from appropriate solvents as described below.

1,1,2-Triphenylethane (I) crystallized when the last traces of ether were removed under suction. The crude solid was taken up in warm ethanol and water was added to the cloud point. On cooling, 15.4 g. (99%) of the hydrocarbon was obtained which melted at 55–56°, reported m.p. 54°[9] and 56°.[7]

1,1,2,2-Tetraphenylethane (II) precipitated from the ether in the reaction mixture. The solid was filtered from the ether and water layers. The ether layer was then separated and the ether removed to obtain more solid. The combined crude solids were dissolved in excess hot benzene and the benzene solution was filtered. The clear filtrate was heated to remove excess solvent and ethanol was added from time to time. When white solid began to separate, the hot solution was allowed to cool. The yield of pure hydrocarbon was 32 g. (96%), melting at 214–215°. A mixed melting point with an authentic sample[26] (m.p. 214–215°) showed no depression.

1,1,2-Triphenylpropane (III) was taken up in hot ethanol (75 ml.) and filtered. Water was added until the solution was cloudy, and a few drops of ethanol were then added to clarify the solution. On standing, white cubic crystals separated. A total of 26 g. (97%) of the compound was obtained from the original crystallization and from the mother liquor. The crude solid melted at 68–71°. Two crystallizations from aqueous ethanol gave pure material, m.p. 73–75°, reported[10] m.p. 73–75°.

1,1,3-Triphenylethane (IV) was obtained from the residue remaining after attempted isolation of styrene by distillation in the presence of a few crystals of hydroquinone. Only a few drops of distillate were obtained at 50 mm. which decolorized bromine in carbon tetrachloride, but no styrene dibromide was obtained. The viscous residue was taken up in 50 ml. of ethanol and filtered. Cooling gave 24 g. (88%) of IV melting at 41–45°. Two recrystallizations from ethanol gave pure IV, m.p. 47°, reported[8] m.p. 47°.

1,1-Diphenyl-2-methylpropane (V) distilled at 126–127° at 5 mm. to produce 18 g. (86%) of V (reported b.p. 158–159° at 19 mm.[7] and 285–286° at 760 mm.[11]), $n^{25}D$ 1.5551, reported[11] $n^{16}D$ 1.560.

Anal. Calcd. for $C_{16}H_{18}$: C, 91.37; H, 8.63. Found: C, 91.35; H, 8.43.

1,1-Diphenyl-2-ethylpentane (VI) was distilled to give 23.7 g. (94%) of the product, b.p. 157–158° at 5 mm., $n^{25}D$ 1.5415.

(20) These results evidently are not due merely to physical factors. Indeed, essentially complete metalation of diphenylmethane occurs in spite of the fact that sodium amide is partly in suspension while sodium diphenylmethide dissolves in the medium, and also in spite of the mass action effect of the solvent, ammonia.

Attempted Alkylation with *t*-Butyl Chloride.—To a stirred solution of 0.1 mole of sodium diphenylmethide in 250 ml. of liquid ammonia and 100 ml. of ether was added 9.3 g. (0.1 mole) of freshly distilled *t*-butyl chloride in 100 ml. of ether. A Dry Ice–acetone reflux condenser was fitted to the flask. After two hours the red color of sodium diphenylmethide remained. An additional 0.1 mole of *t*-butyl chloride in 100 ml. of ether was added and ammonia was refluxed an additional two hours. Finally 0.1 mole of benzhydryl chloride in 100 ml. of ether was added, the red color being discharged. The reaction mixture was worked up as described above for hydrocarbon II. The ether solution was distilled after solid 1,1,2,2-tetraphenylethane was filtered off. Ether and *t*-butyl chloride were difficult to separate, but 12.5 g. of *t*-butyl chloride was recovered. The residue after distillation was solid 1,1,2,2-tetraphenylethane. The combined solids were recrystallized from benzene and ethanol to give 31.5 g. (94%) of the hydrocarbon, m.p. and mixed m.p. 214–215°.

Reaction of Potassium Diphenylmethide with β-Phenylethyl Chloride.—To a stirred solution of 0.1 mole of potassium amide[3] in 200 ml. of anhydrous liquid ammonia was added 16.8 g. (0.1 mole) of diphenylmethane in 100 ml. of anhydrous ether. To the resulting deep red solution was added after 10 minutes 14.05 g. (0.1 mole) of β-phenylethyl chloride in 100 ml. of anhydrous ether. The red solution turned gray after 7 minutes. The ammonia was removed on the steam-bath, and water and ether were added. The ethereal layer was dried and, after adding a few crystals of hydroquinone, the solvent was removed. The residue was distilled at 50 mm. to give 1.9 g. (18%) of styrene, b.p. 70–71°; styrene dibromide, m.p. and mixed m.p. 72–73°, reported[27] m.p. 72–73°. The residue remaining after removing styrene yielded 3.85 g. of recovered diphenylmethane, b.p. 105° at 5 mm. The residue was taken up in 30–60° petroleum ether, filtered and methanol was added. There was obtained 18 g. (70%) of 1,1,3-triphenylpropane, m.p. 47°, on cooling in a Dry Ice–acetone-bath.

Competitive Experiment of Sodium Diphenylmethide and Sodium Amide with Benzyl Chloride.—To 0.11 mole of sodium amide in 200 ml. of anhydrous liquid ammonia was added with stirring 9.24 g. (0.055 mole) of diphenylmethane in 100 ml. of dry ether. After 10 min. 6.96 g. (0.055 mole) of benzyl chloride in 50 ml. of dry ether was added rapidly. The red color of sodium diphenylmethide remained until ammonia was removed on the steam-bath. The red color faded to become purple when only ether remained. After cooling the reaction mixture, 100 ml. of water was added. The purple color was discharged and the ether layer was separated. The aqueous layer was extracted with two 50-ml. portions of ether and the combined ether layers were dried and filtered. Ether was removed from the filtrate and the residue was dissolved in 75 ml. of ethanol. A few drops of water clouded the solution which was clarified by adding a small amount of ethanol. On standing overnight in a refrigerator white crystals of stilbene separated. The solid was recrystallized from ethanol to give 2.5 g. (62%) of stilbene, m.p. 123–125°, reported[28] 125°. A mixed m.p. with an authentic sample (m.p. 124–125°) showed no depression. The mother liquor was treated with more water and cooled in a Dry Ice–acetone-bath. Crude 1,1,2-triphenylethane (I) crystallized to give 5 g. (35%) of the product, m.p. 51–56°. It was recrystallized from ethanol, m.p. 55–56°, reported m.p. 56°[7] and 54°.[9]

Attempted Benzylation of Sodium Di-*p*-methoxyphenylmethide.—To a stirred suspension of 0.05 mole of sodium amide in 250 ml. of anhydrous liquid ammonia was added with stirring 11.4 g. (0.05 mole) of di-*p*-methoxyphenylmethane in 100 ml. of ether. A red color developed and after 15 minutes 6.33 g. (0.05 mole) of benzyl chloride in 50 ml. of ether was added. The red color was discharged when only a small fraction of the halide solution was added. A purple color was produced when the remaining halide was added. After 15 minutes solid ammonium chloride (4 g.) was added and ammonia was removed on the steam-bath. More ether (100 ml.) was added and then 100 ml. of water. The ether layer was separated and the aqueous layer was extracted with two 50-ml. portions of ether. The ether solvent was removed to give an oil which was taken up in ethanol. Stilbene (4.0 g., 89%) was obtained by alternately adding water and cooling in a Dry Ice–acetone-bath. The pure product melted at 124° after crystallization from methanol and chloroform. A mixed melting point with an authentic sample (m.p. 124–125°) showed no depression. Water was added to the remaining solution to precipitate unchanged di-*p*-methoxyphenylmethane (10.7 g., 94%).

Reactions of Amines. II. Degradation via Tertiary Amine Oxides[1]

BY HENRY E. BAUMGARTEN, FRANK A. BOWER[2] AND TED T. OKAMOTO[3]

RECEIVED JANUARY 18, 1957

Degradative sequences (see chart) for amines derived from acids related to the naphthenic acids are described that include as an important step the pyrolysis of a *t*-amine N-oxide. Evidence is offered indicating that in the pyrolysis of *t*-amine N-oxides the direction of elimination may follow the Hofmann rule.

One of the most attractive procedures for the degradation of naphthenic acids in structural studies is the conversion of the acids into the amines of one less carbon atom by the Schmidt reaction.[4,5] The utility of this procedure is lessened somewhat, however, by the apparent unavailability of entirely satisfactory, unambiguous processes for the further degradation of the resultant amines. Of the reactions previously used, the Hofmann degradation[4] to the olefin is reasonably unambiguous but, as carried out by von Braun,[6] requires an undue amount of manipulation with a resultant relatively low yield of olefin (20–35%). The reaction of naphthenylamines with nitrous acid[7] to give olefins and alcohols has been shown to lead to extensive rearrangements of the Demjanov type, and the amine phosphate degradation to the olefin has been found also to proceed with considerable

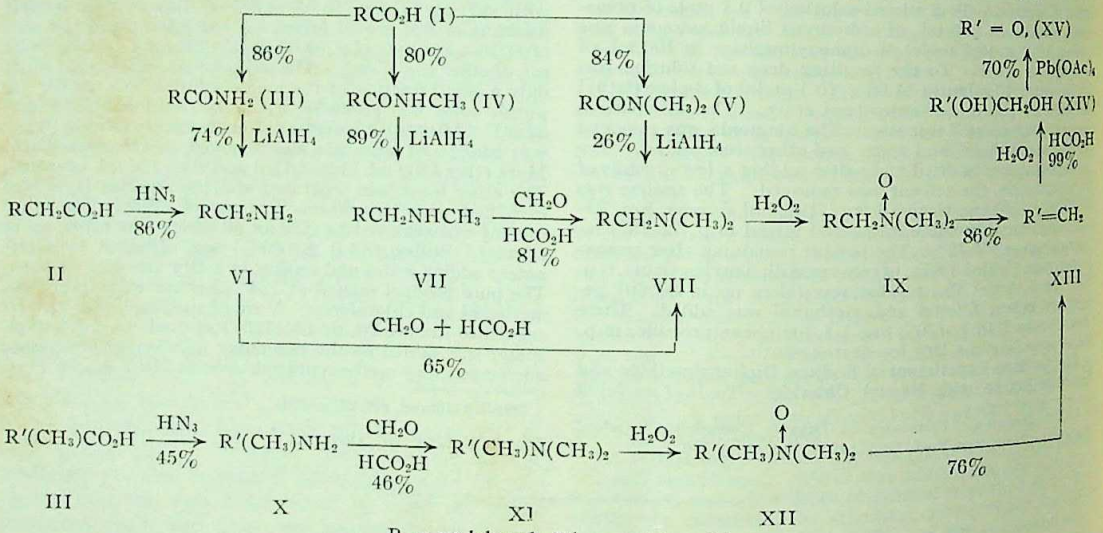
rearrangement.[8] This communication is the first of a series to be devoted to the study of the degradation of naphthenylamines (and other types) to olefins of the same number of carbon atoms by various procedures, both old and new. Of the procedures studied to date that described here based upon the pyrolysis of tertiary amine oxides, recently rediscovered and elegantly applied by Cope and co-workers,[9] has been most satisfactory and will be used in future papers as a standard for comparison.

For use as model compounds in these studies three acids were selected, cyclohexanecarboxylic acid (I), cyclohexaneacetic acid (II) and 1-methylcyclohexanecarboxylic acid (III). At the time this work was started both I and II were commercially available and III was synthesized readily in 81% over-all yield by condensation of butadiene with methacrylic acid,[10] followed by catalytic hydrogenation of the intermediate, 1-methyl-3-cyclohexenylcarboxylic acid.



R = cyclohexyl; R′ = cyclohexylidene

The individual steps required for the degradation of I to cyclohexene in about 52% over-all yield, *via* the successive application of the Schmidt reaction,[11] the Eschweiler–Clarke reaction[12] and the Cope amine oxide pyrolysis,[9] have already been described. In the chart several alternative degradations of I as well as degradations of II and III are outlined.

The key sequence in the chart is the degradation of II. Application of the Schmidt reaction to II gave cyclohexylmethylamine (VI) in 86% yield. Methylation of VI *via* the Eschweiler–Clarke procedure (formaldehyde and formic acid) gave dimethylcyclohexylmethylamine (VIII) in 65% yield. From oxidation of the latter with hydrogen peroxide an 89% yield of crude dimethylcyclohexylmethylamine oxide (IX) was obtained. Pyrolysis of the oxide at 115–160° under reduced pressure gave an 86% yield (based on VIII) of methylenecyclohexane (XIII), free from any detectable amounts of isomerization products (based on infrared spectra).

An attractive degradation of I based on that of II was developed as outlined in the flow sheet. Conversion of I, *via* treatment of the acid chloride with ammonia or the appropriate amine, into cyclohexanecarboxamide (III), N-methylcyclohexanecarboxamide (IV) and N,N-dimethylcyclohexanecarboxamide proceeded in 86, 80 and 84% yields. Reduction of III, IV and V with lithium aluminum hydride, using the excellent technique of Micovic and Mihailovic[13] as a model, gave VI, N-methylcyclohexylamine (VII) and VIII in 74, 89 and 26% yields, respectively. From the reaction mixture from the reduction of V, crude cyclohexanemethanol was isolated in 32% yield as a by-product. Other workers have reported alcohol by-products in the lithium aluminum hydride reduction of disubstituted amides.[13–16] The crude cyclohexanemethanol was converted into its acetate, and the latter was pyrolyzed in the usual manner to give XIII in 71% over-all yield.

The further methylation of VII by the Eschweiler–Clarke technique gave VIII in 81% yield. From these results it appears that the maximum yield of VIII (57% over-all) was obtained by the sequence I → IV → VII → VIII. Indeed, this sequence gave essentially the same yields as the shorter sequence II → VI → VIII (56% over-all yield). It is interesting to note that the yield of

VIII by the monomethylation of VII was appreciably higher than that by dimethylation of VI, due in large part to a smaller incidence of by-product formation in the former example.

The degradation of III to 1-methylcyclohexylamine (X) by the Schmidt reaction has been reported to proceed in only 42% yield,[17] and a rationale explaining in part this behavior has been offered. In our hands a similar yield (45%) of X was obtained. Treatment of X by the Eschweiler–Clarke procedure gave N,N-dimethyl-1-methylcyclohexylamine (XI) in 46% yield. Oxidation of the amine to the N-oxide XII and pyrolysis of XII gave a 76% yield of methylenecyclohexane (XIII). The identity of the latter was established by distillation through a precision distillation column and examination of the infrared spectra of the distillate and the column holdup and pot residue for evidence of the other most probable olefinic product, 1-methylcyclohexene. As far as we were able to determine by physical constants and infrared spectra, the pyrolysis product consisted solely of XIII.

Since general conclusions drawn from a single example are not especially compelling, the above result can only suggest that the direction of elimination in the Cope pyrolysis of tertiary amine oxides may follow the Hofmann rule much as in the controlled pyrolysis of acetates.[18] The validity of this generalization is under study. Very probably considerations[19] similar to those already suggested for acetate pyrolysis play a large part in determining the selectivity, even though the present elimination apparently takes place in the liquid phase and acetate pyrolysis in the vapor phase. Furthermore, in the pyrolysis of XII no special precautions as to technique (such as are required in acetate pyrolysis[18,19]) other than those normally observed appeared to be necessary to ensure this high degree of selectivity.

Studies of the further degradation of olefins such as XIII have not progressed to the point where an entirely satisfactory procedure can be offered; however, a procedure based on the conversion of methylenecyclobutane to cyclobutanone[20] has been very successful with XIII itself.[21] Oxidation of XIII with performic acid (formic acid and hydrogen peroxide) followed by alkaline hydrolysis of the resultant hydroxyformate gave up to 99% yields of crude 1-hydroxymethylcyclohexanol (XIV). Yields of this magnitude were made possible by the following deviation from the usual isolation procedure.[22] The alkaline reaction mixture from the hydrolysis was saturated with potassium carbonate and the glycol was extracted with ethanol.[23] Oxidation of XIV with lead tetraacetate in benzene solution gave cyclohexanone in 67% yield.[24] The oxidation of XIV with periodic acid under a variety of conditions gave only traces at best of ketone. This observation is consistent with that of Roberts and Sauer[20] relative to the oxidation of 1-hydroxymethylcyclobutanol.

Evaluations of the original degradation procedure of von Braun[4] by application of the process to the model acid II have been carried out by Lochte and co-workers[25] and in this Laboratory. Employing as nearly as possible the original techniques of von Braun (reagents over the arrows) in the sequence

$$\text{II} \longrightarrow \text{VI} \xrightarrow[\text{or MeI}]{Me_2SO_4} \underset{\text{XVI}}{RCH_2N(CH_3)_3X} \xrightarrow[\text{IRA-400-OH}]{\text{KOH or}} RCH_2N(CH_3)_3OH \xrightarrow[\text{heat}]{} \underset{\text{XIII}}{R'{=}CH_2} \xrightarrow{O_3} \underset{\text{XV}}{R'{=}O}$$

$$\text{XVII}$$

Lochte and co-workers obtained an 89% yield of VI, an undetermined yield of trimethylcyclohexylmethylammonium sulfate (XVI) and of the corresponding hydroxide XVII and a 19–25% yield (over-all from VI) of XIII. Ozonolysis of XIII gave a 39% yield of XV (as the semicarbazone). In our study (reagents under the arrow) the reaction of VI with methyl iodide gave trimethylcyclohexylmethylammonium iodide in 94–98% yield. The latter was converted into the quaternary ammonium hydroxide XVII and decomposed by the excellent modification of the Hofmann procedure described recently by Weinstock and Boekelheide,[26] giving XIII in 31–38% yield together with 34–21% of recovered VIII. The maximum over-all yield of XIII from the von Braun degradation as run by Lochte was about 7% (this would be about 11% if the modified Hofmann degradation were employed), compared with a maximum over-all yield of about 32% using the tertiary amine oxide pyrolysis and subsequent oxidation as described herein. Even in comparing only the over-all change VI → XIII by the Hofmann degradation and by the Cope amine oxide pyrolysis, the results favor the latter (56 to 37%).[27]

Details of the application of the degradation described here to the naphthenic acids will be reported elsewhere. However, the results may be summarized by noting that, in applying this procedure to some twenty fractions of acids in the C_8–C_{12}

(26) J. Weinstock and V. Boekelheide, THIS JOURNAL, **75**, 2546 (1953).

(27) Recyclization of the recovered VIII would be expected to raise the over-all yield of XIII in the modified Hofmann reaction, but in small runs this recyclization is often impractical.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

range, in the majority of the experiments yields of olefin equal to or greater than that reported here for the degradation of II were obtained.

In the Experimental section the results of some orienting experiments are described in which β-phenylethylamine was converted *via* the tertiary amine N-oxide into styrene in 56% over-all yield.

Experimental[28]

1-Methylcyclohexanecarboxylic Acid (III).—1-Methyl-3-cyclohexenecarboxylic acid, m.p. 77–78°, was prepared in 85% yield as described by Petrov and Sopov,[10] substituting an equivalent quantity of hydroquinone for pyrogallol and effecting a first isolation of the crude acid by steam distillation. In one run at the boiling point of toluene[29] none of the desired product was obtained. Hydrogenation of 61 g. of the unsaturated acid was carried out in usual manner in 150 ml. of ethanol at 45 p.s.i. over platinum oxide and required 2 hr. for completion. Distillation of the product gave 59 g. (96%) of 1-methylcyclohexanecarboxylic acid, b.p. 133–135° (17 mm.) (lit.[30] b.p. 137–138° (24 mm.)).

Amides of Cyclohexanecarboxylic Acid (III, IV and V).—Cyclohexanecarboxylic acid (90 g., 0.7 mole) was refluxed with 166 g. (1.4 moles) of thionyl chloride for 2 hr. Distillation of the reaction mixture gave 102 g. (99%) of cyclohexanecarbonyl chloride, b.p. 77° (21 mm.) (lit.[31] b.p. 76° (17 mm.)).

Dropwise addition of 130 g. (0.8 mole) of cyclohexanecarbonyl chloride to 400 ml. of chilled, concentrated ammonium hydroxide, filtration, washing with water and drying gave 98 g. (86%) of crude cyclohexanecarboxamide, m.p. 184–186° (lit.[32] m.p. 184°), which was used without further purification.

From the similar treatment of 80 g. (0.55 mole) of cyclohexanecarbonyl chloride and 200 g. of ice-cold 33% aqueous methylamine, 63.5 g. (80%) of crude N-methylcyclohexanecarboxamide, m.p. 109–111° (lit.[14] m.p. 110–111°), was obtained and was used without further purification.

Cyclohexanecarbonyl chloride (120 g., 0.83 mole) was added dropwise with stirring to 143 ml. of cooled 33% aqueous dimethylamine. After stirring the solution for 1 hr., the organic layer was separated and the aqueous layer was extracted with ether. The combined organic layer and ether extracts were dried over magnesium sulfate, filtered and distilled, giving 107.5 g. (84%) of N,N-dimethylcyclohexanecarboxamide, b.p. 158° (44 mm.) (lit.[14] b.p. 135–140° (20 mm.)).

Cyclohexylmethylamine (VI). (a) **From Cyclohexaneacetic Acid.**—Concentrated sulfuric acid (175 g., 1.80 moles) was added to a solution of 28.4 g. (0.20 mole) of cyclohexaneacetic acid in 200 ml. of chloroform. While maintaining the temperature between 52–55°, 14.3 g. (0.22 mole) of sodium azide was added in small portions over a 3-hr. period to the stirred solution (hood). Heating was continued overnight to complete the evolution of nitrogen. The reaction mixture was chilled to freeze the sulfuric acid–amine sulfate layer, and the chloroform was removed by decantation. The sulfuric acid solution, diluted with 400 ml. of ice-water, was added cautiously to 1 l. of 5 *N* sodium hydroxide solution in a flask arranged for steam distillation. The mixture was steam distilled and the distillate layers separated. The aqueous layer was extracted with ether. The combined organic layers were dried over potassium carbonate, filtered and distilled, giving 19.6 g. (86%) of cyclohexylmethylamine, b.p. 98–100° (98 mm.) (lit.[33] b.p. 56–58° (12 mm.)). In three runs, two of which were on twice the scale described, the yields were 83–86%.

(b) **From Cyclohexanecarboxamide.**—Cyclohexanecarboxamide (205 g., 1.63 moles) was powdered and suspended in 2 l. of dry ether. Lithium aluminum hydride (215 g., 5.67 moles) was added at such a rate as to maintain gentle reflux. The reaction mixture was allowed to stand overnight and then treated with water as described by Micovic and Mihailovic[13] to decompose the excess reducing agent. The inorganic solids were removed by filtration and the ethereal solution was dried and distilled giving 136 g. (74%) of cyclohexylmethylamine, b.p. 74° (35 mm.). An unidentified by-product (15 g., b.p. 180–190° (35 mm.)) was also obtained.

N-Methylcyclohexylmethylamine (VII).—N-Methylcyclohexanecarboxamide (63.5 g., 0.45 mole) was reduced with 34 g. (0.8 mole) of lithium aluminum hydride in the manner described above, giving 51 g. (89%) of N-methylcyclohexylmethylamine, b.p. 160–162° (lit.[34] b.p. 161–162° (748 mm.)).

N,N-Dimethylcyclohexylmethylamine (VIII). (a) **From Cyclohexylmethylamine.**—Technical grade 90% formic acid (89.5 g., 1.9 moles) was added with cooling to 39 g. (0.34 mole) of cyclohexylmethylamine. Formalin (10 g. of 40% solution) was added, and the mixture was warmed under reflux on the steam-bath until the evolution of carbon dioxide subsided. Additional small portions of formaldehyde were added until the total was 29.5 g. (0.7 mole). The mixture was heated for 10–15 hr. after which time the evolution of carbon dioxide had ceased. Concentrated hydrochloric acid (42.5 ml., 0.5 mole) was added and the excess formic acid and water were removed under reduced pressure. The viscous residue was made alkaline with 120 ml. of 10% sodium hydroxide solution, and the mixture was steam distilled. The organic layer was separated and the aqueous layer was extracted with ether. The combined organic layers were dried over potassium carbonate and distilled, giving 31.2 g. (65%) of N,N-dimethylcyclohexylmethylamine, b.p. 102–103° (100 mm.), micro b.p. 173° (lit.[14] b.p. 75–76° (15 mm.)). Yields in other experiments ranged from 62–64%.

(b) **From N-Methylcyclohexylmethylamine.**—Following the procedure described in (a) above, from 51 g. (0.40 mole) of N-methylcyclohexylmethylamine 46 g. (81%) of N,N-dimethylcyclohexylmethylamine was obtained.

(c) **From N,N-Dimethylcyclohexanecarboxamide.**—N,N-Dimethylcyclohexanecarboxamide (41 g., 0.27 mole) was reduced with 15.2 g. of lithium aluminum hydride in the manner described for the reduction of cyclohexanecarboxamide. Distillation of the product gave 10 g. (26%) of N,N-dimethylcyclohexylmethylamine, b.p. 102–105° (100 mm.), micro b.p. 172–173°, and a second fraction, 11.8 g., which boiled at 117° (83–89 mm.), micro b.p. 184°. The latter fraction was apparently a crude mixture consisting largely of cyclohexanemethanol (b.p. 182°). This fraction was converted into the acetate, b.p. 101–103° (30 mm.), and pyrolyzed in the usual manner, giving a 71% over-all yield of methylenecyclohexane, b.p. 101–103°.

N,N-Dimethylcyclohexylmethylamine Oxide (IX).—To 31 g. (0.22 mole) of N,N-dimethylcyclohexylmethylamine 125 g. (1.09 moles) of 30% hydrogen peroxide was added with shaking while maintaining the temperature between 35–40°. The completion of the reaction was gaged by the complete solution of the amine, requiring 48–72 hr. of shaking depending on the amount of tertiary amine being oxidized. The excess hydrogen peroxide was decomposed with a small amount of platinum oxide shaken in the solution overnight. The solution was filtered and the water was evaporated at 35–40° under reduced pressure, giving 28.3 g. (83%) of semi-solid N,N-dimethylcyclohexylmethylamine oxide. The yields in several other experiments ranged from 73–89%. The amine oxide was pyrolyzed without further purification.

Pyrolysis of N,N-Dimethylcyclohexylmethylamine Oxide.—The pyrolysis was conducted in a 100-ml., round-bottomed flask equipped with a side arm for introduction of nitrogen. The flask was connected in turn to a 6-in. Vigreux column, a Claisen head, two receivers connected in series and a vacuum pump. The receivers were immersed in a Dry Ice–acetone-bath.

The flask was charged with 5–20 g. of N,N-dimethylcyclohexylmethylamine oxide, evacuated to 10 mm. pressure and immersed in an oil-bath. The Vigreux column was heated to 120–130° and the oil-bath temperature was raised from 30–130° during 30 minutes. The amine oxide liquefied before pyrolysis, which took place at about 115–125°. The temperature was elevated to 160° for a few minutes to complete the pyrolysis. The contents of the receiver were separated and the hydrocarbon layer was washed with 2 *N* hydrochloric acid and water, dried over magnesium sulfate

and distilled, giving yields ranging from 71–86% of methylenecyclohexane, b.p. 102–103° (lit.[35] b.p. 102–103.5°).

1-Methylcyclohexylamine (X).—1-Methylcyclohexanecarboxylic acid (52 g., 0.37 mole) was converted to the amine by the Schmidt reaction as described above for the preparation of cyclohexylmethylamine. Distillation of the product gave 18.6 g. (45%) of 1-methylcyclohexylamine, b.p. 143–145° (lit.[17] b.p. 142–142.5° (750 mm.)).

N,N-Dimethyl-1-methylcyclohexylamine (XI).—1-Methylcyclohexylamine (14 g., 0.12 mole) was methylated using the procedure described for the preparation of N,N-dimethylcyclohexylmethylamine. Distillation of the product gave 8.1 g. (46%) of N,N-dimethyl-1-methylcyclohexylamine, b.p. 88.5–90° (31 mm.).

Anal. Calcd. for $C_9H_{19}N$: C, 76.52; H, 13.56; N, 9.92. Found: C, 76.81; H, 13.76; N, 9.70.

N,N-Dimethyl-1-methylcyclohexylamine Oxide (XII).—N,N-Dimethyl-1-methylcyclohexylamine (8.0 g., 0.06 mole) was oxidized as described above for the preparation of N,N-dimethylcyclohexylmethylamine oxide. The crude oxide was pyrolyzed without further purification; however, a small sample of the oxide was converted into the picrate, m.p. 163–164°, for analysis.

Anal. Calcd. for $C_{16}H_{22}N_4O_8$: C, 46.7; H, 5.75; N, 14.3. Found: C, 46.94; H, 5.63; N, 14.05.

Pyrolysis of N,N-Dimethyl-1-methylcyclohexylamine Oxide.—Utilizing the technique employed for the pyrolysis of N,N-dimethylcyclohexylmethylamine oxide, the oxide of N,N-dimethyl-1-methylcyclohexylamine was pyrolyzed and the olefinic product was distilled through a concentric-tube column rated at 45 theoretical plates or better, giving 4.1 g. (76%, based on tertiary amine) of methylenecyclohexane, b.p. 100.0–101.5° (730 mm.), $n^{25}D$ 1.4481 (lit.[18b] b.p. 100–101° (730 mm.), $n^{25}D$ 1.4484). The infrared spectrum of the product was identical with that of methylenecyclohexane prepared by the pyrolysis of cyclohexylmethyl acetate and of N,N-dimethylcyclohexylmethylamine oxide. In the event that the other isomer, 1-methylcyclohexene (lit.[36] b.p. 110° (760 mm.), $n^{20}D$ 1.4503; our values for authentic material distilled through an 85-plate concentric-tube column, b.p. 106–107° (730 mm.), $n^{20}D$ 1.4498, $n^{25}D$ 1.4475), might be present in small amount, the column hold-up and pot residue was collected, flash distilled from a small distilling flask and submitted to infrared analysis. The spectrum and refractive index of this material were identical with those from the main body of the distillate.

1-Hydroxymethylcyclohexanol (XIV).—Methylenecyclohexane (4.8 g., 0.05 mole) was added slowly with continuous shaking to a solution consisting of 60 g. (1.1 moles) of 90% formic acid and 10 g. (0.08 mole) of 30% hydrogen peroxide. The rate of addition was such as to maintain the temperature at 40–45°. After addition of the olefin was complete, the mixture was shaken overnight. The excess reactants were removed under reduced pressure. The residual ester was hydrolyzed with 50 ml. of 10% sodium hydroxide solution warmed to 50°. The solution was saturated with potassium carbonate and the organic layer separated. The aqueous layer was extracted with absolute ethanol. The combined organic layers were dried over potassium carbonate, and the ethanol was removed carefully under reduced pressure. The yield of the crude glycol was essentially quantitative (about 97–99% in most runs). Recrystallization of the crude product from benzene gave 4.8 g. (72%) of 1-hydroxymethylcyclohexanol, m.p. 73–75° (lit.[37] m.p. 74–75°).

Oxidation of 1-Hydroxymethylcyclohexanol.—A solution of 1-hydroxymethylcyclohexanol (4.8 g., 0.04 mole) in 100 ml. of dry benzene was refluxed in a Soxhlet extractor in which the siphon tube had been replaced by a direct return tube to the distillation pot. The thimble of the extractor contained 14 g. of 90% lead tetraacetate. The benzene was refluxed for 1 hr. after the lead tetraacetate dissolved. After standing overnight the solution was filtered from the lead diacetate and the filtrate was washed with 0.5 *N* potassium carbonate and water. After drying over magnesium sulfate, the benzene solution was fractionally distilled giving 2.5 g. (70%) of cyclohexanone, b.p. 50–51° (20 mm.). In other experiments, oxidation of the crude glycol gave yields of 53–67%.

Trimethylcyclohexylmethylammonium Iodide (XVI).—To an ice-cooled solution of N,N-dimethylcyclohexylmethylamine (28 g., 0.20 mole) in 100 ml. of ether was added in four portions 18.6 ml. (0.3 mole) of methyl iodide, and the mixture was allowed to stand overnight. Evaporation of the ether left 55.4 g. (98%) of trimethylcyclohexylmethylammonium iodide, m.p. 220° (lit.[38] m.p. 225°), which was used without further purification. In other experiments the yields varied from 94–98%.

Anal. Calcd. for $C_{10}H_{22}NI$: I, 44.82. Found: I, 45.05.

Decomposition of Trimethylcyclohexylmethylammonium Iodide.—A solution of 12.3 g. (0.044 mole) of trimethylcyclohexylmethylammonium iodide in 50 ml. of water was passed through a 2 × 22-cm. column packed with ion-exchange resin, Amberlite IRA-400(OH). The methiodide was washed down the column with water until the final volume of solution was 300 ml. The solution was concentrated under reduced pressure to 50 ml. The solution was refluxed for 1 hr. in an apparatus similar to that described by Fieser,[39] and the distillate collected from the side arm was washed with 5% hydrochloric acid and with water. The hydrocarbon layer was separated, dried over magnesium sulfate and distilled, giving 1.60 g. (38%) of methylenecyclohexane. From the acid wash, 1.3 g. (21%) of dimethylcyclohexylmethylamine was recovered. In other experiments the yields of methylenecyclohexane varied from 31–34% and the yields of recovered tertiary amine from 21–34%.

Degradation of β-Phenylethylamine.—β-Phenylethylamine was methylated as described above for the methylation of cyclohexylmethylamine, giving dimethyl-β-phenylethylamine, b.p. 200–208° (lit.[40] b.p. 198–202°), in 70% yield. Oxidation of the tertiary amine and pyrolysis of the resultant N-oxide were carried out as described above for the degradation of N,N-dimethylcyclohexylmethylamine except that a few crystals of hydroquinone were added to the receiver to inhibit polymerization of the styrene. Distillation of the crude product gave an 82% yield of styrene, b.p. 46° (17 mm.), identified by oxidation in 94% yield, by the procedure described above for the oxidation of methylenecyclohexane, to phenylethylene glycol, m.p. 66–68° (lit.[41] m.p. 67–68°).

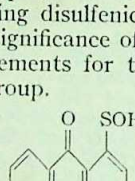
The Synthesis of a Disulfenic Acid. Anthraquinone-1,4-disulfenic Acid

BY THOMAS C. BRUICE AND R. T. MARKIW

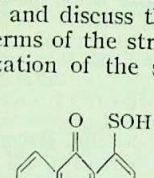
RECEIVED DECEMBER 13, 1956

The synthesis of anthraquinone-1,4-disulfenic acid (II) is described. This compound represents the first disulfenic acid and the second sulfenic acid to be isolated.

Sulfenic acids, generally designated as RSOH, may be considered as the parent compounds of the sulfenyl thiocyanates (RSSCN), sulfenyl halides (RSCl), sulfenic acid esters (RSOR′) and the sulfenamides ($RSNR_2'$). They have been suggested to be hydrolytic scission products of disulfides[1-5] and S-arylthiosulfuric acids,[6] while certain sulfenic acids have been proposed as intermediates in the chemical or metabolic oxidation of thiols,[7] participants in the photosynthetic processes of plants[1,8] and as possible intermediates in the oxidation of proteins.[9] However, with the single exception of the isolation of 1-anthraquinonesulfenic acid (I) in 1912,[10] all attempts to isolate other sulfenic acids in the anthraquinone, benzene or aliphatic series have been unsuccessful.[1,11-19] In this paper, we describe the synthesis of the corresponding disulfenic acid (II) and discuss the possible significance of this in terms of the structural requirements for the stabilization of the sulfenic acid group.



I



II

The synthetic sequence leading to II, as well as the conversions effected in the present study, are summarized in Fig. 1. The potassium salt of 1-anthraquinonesulfonic acid (III) was converted to 1-chloroanthraquinone by the procedures of Scott and Allen.[20] Nitration of 1-chloroanthraquinone according to the method of Eckert and Steiner[21] yielded IV. Treatment of IV at reflux with sodium disulfide, in aqueous dioxane, yielded a brick-red, high melting, nitrogen-free substance whose structure has been established as that of V. In the preparation of V, if solvent conditions other than those specified were used, various mixtures were obtained whose color and composition depended upon the time of reflux, solvent, stoichiometry, etc. The polymeric disulfide V is insoluble in all solvents investigated and, therefore, could not be freed of the usual impurities accompanying reactions of this nature. The structure of V was established by conversion to anthraquinone-1,4-disulfonic acid (IX), a previously reported compound.[22] The disulfonic acid was then converted to the also known 1,4-dichloroanthraquinone (X) which, in turn, was reconverted to V by the same procedures employed for the sequence IV → V. The polymeric disulfide, prepared in this manner, was of lighter color but otherwise identical in its reactions and high decomposition point (> 360°) to that prepared from IV. Conversion of IV to V involves replacement of a nitro group (situated *ortho* to a strong electron attracting substituent) by a nucleophilic agent. Reactions of this type are well known and the use of S^- as the nucleophile has been reported previously.[23]

Chlorinolysis of V, under anhydrous conditions, employing aluminum chloride (formed *in situ*) catalysis,[24] gave 1,4-anthraquinonedisulfenyl chloride (VI) as balls of red needles from benzene. Treatment of VI with anhydrous methanol in benzene (trace of pyridine)[25] yielded dimethylanthraquinone-1,4-disulfenate (VII), which crystallized as red, glistening needles from benzene and methanol. When either VII or VI were treated with boiling morpholine, the same dimorpholide (VIII) was obtained. Compounds VI and VIII are stable when pure. The dimethyl ester VII is particularly stable and no precautions are required for its storage. Compounds VI, VII, VIII and, as previously noted V, were all converted in high yield to IX by oxidation with moist chlorine.

Fries[10] accomplished the synthesis of 1-anthraquinonesulfenic acid (I) by hydrolyzing the corresponding methyl sulfenate with strong potassium hydroxide solution, followed by the liberation of the free sulfenic acid with acetic acid. The hydrolysis of VII to 1,4-anthraquinonedisulfenic acid (II) was carried out similarly and, for comparative purposes, the hydrolysis of methyl 1-anthra-

quinonesulfenate to I was repeated.[26] A comparison of the observations on the hydrolysis and products formed from methyl 1-anthraquinonesulfenate and VII are recorded in Table I.

TABLE I

COMPARATIVE OBSERVATIONS ON 1-ANTHRAQUINONESULFENIC ACID AND 1,4-ANTHRAQUINONEDISULFENIC ACID

	I	II
Methyl esters in ethanol	Yellow	Red
Dil. ethanolic soln. of free acids	Orange	Magenta
Aqueous soln. of potassium salts	Blue	Blue
Acetone soln. of potassium salts	Green	Green
Lead salts	Blk. ppt.	Blk. ppt.
Barium salts	Green	Green
Dil. aq. acetone soln. of barium salts	Blue	Blue
Crystalline form of acid from acetone–water	Red microscopic needles	Purple microscopic needles
Color change on heating above 100°	Red → Yellow	Purple → Brick-red

Though II was found to be stable to desiccation (see following discussion) attempts at recrystallization were always accompanied by the formation of small quantities of bright red alkali-insoluble material, which prevented the preparation of a suitable analytical sample. As expected, also, the product presumed to be the disulfenic acid (II) was readily oxidizable. Thus, in dilute methanolic solution, the characteristic purple color persisted for about a week, slowly changing to a pale yellow; and, in dilute base, the blue color of the potassium salt persisted for many weeks before fading, if the solution was kept in the dark and free of air. However, either the potassium salt or the free acid were immediately destroyed if their alcohol solutions were shaken with activated carbon (Norite). When treated with moist chlorine, II was converted to IX.

The strongest evidence for the proposed structure for II was obtained by converting the purple acid to the dimethyl sulfenate (VII). When II was treated with anhydrous hydrogen chloride in an inert solvent, followed by solution in absolute methanol, the methyl ester VII could be regenerated in 47–55% over-all yield from II. This conversion of the purple acid to the methyl sulfenate, *via* the sulfenyl chloride (VI), corresponds to the like reactions of I,[10] and we interpret this as unequivocal evidence that the oxidation state of the purple acid is at the sulfenic acid level. The stability of II, in the dry state and in the absence of air, was confirmed by the finding that weeks after its isolation it could be converted to the methyl sulfenate in yields corresponding to those obtained when freshly prepared acid was employed. Simply treating II with methanol did not yield VII.

The barium salt of II was obtained by treatment of either the free disulfenic acid or its dimethyl ester with barium hydroxide. When carbon dioxide was passed through a dilute aqueous ethanol solution of either the barium or potassium salt of II, the blue color faded to the red of the sulfenic acid. The sodium salt, but not the barium salt, could then be regenerated by removing excess carbon dioxide *in vacuo*. This would tend to place the first ionization constant of II at between 10^{-6} and 10^{-12}. The black amorphous lead salt of II was prepared easily by adding an acetone solution of II to an aqueous solution containing excess lead acetate. The lead salt was insoluble in water and all neutral organic solvents but dissolved readily if a suspension of the salt in aqueous ethanol was acidified with acetic acid, to yield the color of the free sulfenic acid, or when the solution is made alkaline with potassium hydroxide, to yield the blue color of the potassium salt.

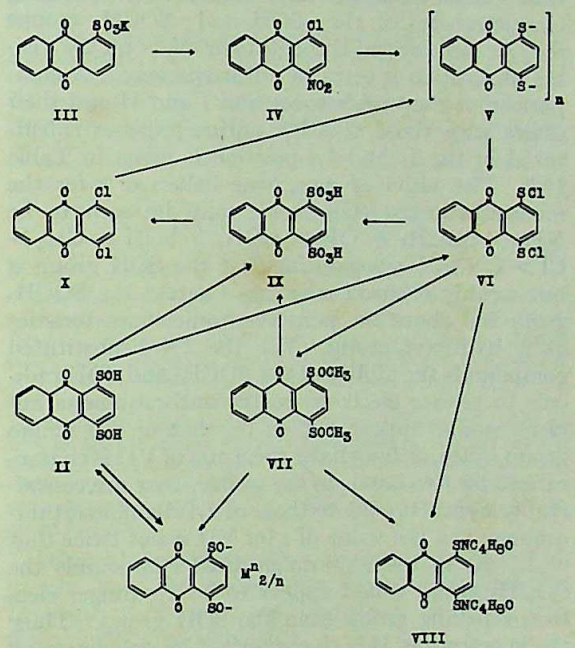

Fig. 1.

The reason for the stabilities of I and II, at least so far as to permit their isolation, as contrasted to the complete instability of 2-anthraquinonesulfenic acid[11] (XI) and 4-amino-1-anthraquinonesulfenic acid (XII)[12] as well as the apparent non-existence of 1-fluorenonesulfenic acid (XIII),[13] is not evident. Stabilization through hydrogen bonding of the acid hydrogen to the carbonyl group of anthraquinone,[27] or interaction of the sulfur with the carbonyl oxygen,[6] do not appear to offer a complete explanation, since XII and XIII are not so stabilized. It appears reasonable to suppose that, in addition to the interaction of the sulfenic acid group with the carbonyl oxygen of anthraquinone, there is required for the stabilization of the sulfenic acid grouping its attachment to a highly electronegative carbon atom.[28] Employing such a dual prerequisite for the stabilization of the SOH group, the instability of XI would be explained on the basis of the inability of SOH to interact with the carbonyl group, while for XII and

(26) The original work of Fries has been confirmed previously by A. T. Fowler (see footnote 12 of ref. 18) and C. W. Jefferys, *Helv. Chim. Acta*, **35**, 845 (1952).

(27) N. Kharasch, S. J. Potempa and H. L. Wehrmeister, *Chem. Revs.*, **39**, 276 (1946).

(28) Similar reasoning can be used in the case of the selenenic acids, where *o*-nitro or *o*-keto groups apparently are required for stability (see ref. 27). Sulfenic acids are not stabilized by *o*-nitro groups, in part due to the intermolecular oxidation of the sulfenic acid moiety and reduction of the nitro group to yield aminosulfonic acids (see ref. 19).

XIII instability could be ascribed to the decreased positive nature of the 1-position as compared to anthraquinone. This may be a logical argument, since it is certain that a *p*-amino group would lower the positive character or the 1-position of anthraquinone and the fluorenone nucleus is known to be not as electron deficient as that of anthraquinone.[29]

Since II is less stable than I but of greater stability than XII, the above reasoning suggests that the *p*-SOH group is electron releasing but not to such a degree as the *p*-amino group. From the known properties of the *p*-sulfhydryl and *p*-hydroxyl groups, this would appear to be a logical supposition. Semi-quantitatively, the electron releasing characteristics of the –SOH and $-SOCH_3$ groups may be determined through their effect on the visible absorption spectra of anthraquinone. A comparison of the visible spectra of I and II and their esters with those of other anthraquinones substituted in the 1- and 1,4-position is given in Table II.[30] The order of increasing values of *e* for the monosubstituted compounds may be seen to be $NH_2 > SOCH_3 = OH > OCH_3 > SOH > CH_3 > Cl > CN > NO_2$ suggesting that the SOH group is but weakly electron releasing whereas the $SOCH_3$ group has about the same electronic characteristics as a hydroxyl group. For the 1,4-disubstituted compounds the ability of the $SOCH_3$ and SOH radicals to release electrons to the anthraquinone nucleus would appear not to be that of the amino group, since, although the spectrum of VII is characterized by two bands in the visible, they are considerably hypsochromic to those of 1,4-diaminoanthraquinone and the value of *e* for VII is not twice that of I. As in the monosubstituted compounds the $SOCH_3$ group would appear to be a stronger electron repelling group than the SOH group. Thus, the spectrum of II is characterized by only one peak in the visible, and the value of *e* for II is smaller than that for VII.

On the basis of spectral evidence alone, it would appear that in accordance with the hypothesis presented above, the 1- and 4-positions of II are more positive than the 1-position of XII but less positive than the 1-position of I. As an extension of the present work, a study of the stabilities of a series of anthraquinone-1-sulfenic acids substituted with various groups in the 4-position is desirable as a further test of the hypothesis.

(29) H. Adkins, R. M. Elofson, A. G. Rossow and C. C. Robinson, THIS JOURNAL, **71**, 3622 (1949).

(30) R. H. Peters and H. H. Summers (*J. Chem. Soc.*, 2101 (1953)) consider the position of the visible band of anthraquinone to be predictably related to the electronic properties of the substituent in the 1-position. It appears to us that a better correlation is obtained by considering the molar extinction coefficients. Thus, for substituents in the 1-position the order of increasing bathochromic effect is: $-NH_2 > Cl = CN = CH_3 > OH > OCH_3 > NO_2$, while the increase in the molar extinction follows the more reasonable order $NH_2 > OH > OCH_3 > CH_3 > Cl > CN > NO_2$. The arguments presented herein on the electronic characteristics of the SOH and $SOCH_3$ groups remain the same regardless of whether the position of the bands or the molar extinctions are considered. Peters and Summers (ref. 30) point out that, in the case of the substitution of identical, strongly electron releasing groups in the 1- and 4-positions of anthraquinone, two peaks are noted in the visible region with a molar extinction coefficient twice that observed for the similarly monosubstituted compound.

[a] Data of Peters and Summers, see footnote 30; solvent methanol. [b] Solvent chloroform. [c] Solvent acetone.

Experimental

Poly-1,4-dithioanthraquinone (V).—1-Chloro-4-nitroanthraquinone (IV) was recrystallized several times from chlorobenzene and then from equal volumes of hot dioxane and ethyl acetate, m.p. 262° (lit.[20] 259°). The so purified IV (4.40 g., 0.0153 mole) was suspended in 400 ml. of a good grade of dioxane (Fisher Certified) to which was added 0.512 g. (0.0157 mole) of sulfur. The solution was brought to a boil when 3.84 g. (0.0238 mole) of sodium sulfide nonahydrate dissolved in 80 ml. of dioxane and 160 ml. of water was added. The reaction mixture was heated under reflux for 5 hr. when the amorphous, brick-red precipitate of V was immediately collected and washed with large quantities of hot dioxane, water and acetone and dried at 80° (3.2 g., 77%), m.p. > 350°.

Because V was completely insoluble in all solvents, it could not be freed from silicate and other contaminants, and analyses were not performed. The compound was identified, however, in the manner given under preparation of IX and X.

1,4-Anthraquinone Disulfenyl Chloride (VI).—V (2 g., 0.0074 mole) was suspended in 100 ml. of chloroform in a flask fitted with side arm, gas inlet tube and condenser for downward distillation. One-half of the solvent was removed by distillation and a small piece of clean aluminum foil added. Into the cooled solution there was passed a stream of dry chlorine. After 3 hr., the flask was tightly stoppered and set aside at room temperature for at least 12 hr. After refrigeration for an additional several hours, the product was collected, washed with dry ether and the small pieces of unreacted aluminum picked out. The product (2.2 g., 87.5%) was used without further purification in the preparation of VII, VIII and IX.

For analysis the sulfenyl halide was recrystallized to constant melting point from anhydrous benzene and dried at 130° over P_2O_5 at 1 mm., m.p. 270°.

Anal. Calcd. for $C_{14}H_6S_2Cl_2O_2$: C, 49.4; H, 1.77; S, 18.8. Found: C, 49.57; H, 2.01; S, 18.15.

Dimethyl 1,4-Anthraquinonedisulfenate (VII).—Two grams (0.0059 mole) of VI was suspended in 250 ml. of absolute methanol, and there was then added 150 ml. of anhydrous benzene and 1 ml. of dry pyridine. The mixture was then brought to a boil when all but a trace of the solid material dissolved. The flask containing the reaction mixture was tightly stoppered and set aside for two days.

The reaction mixture was brought to a boil for a few minutes, a small amount of activated carbon (Norite) added, boiling continued for 5 min. when the red solution was filtered and concentrated to one-half volume. After several hours, long red needles begin to form. At this time the reaction mixture was chilled for 12 hr. and the product collected. In this manner there was obtained 1.0 g. (51%) of VII, m.p. 170–170°. For analysis the product was recrystallized several times from a mixture of benzene and

methanol and dried at 100° for 2 hr. over P_2O_5 at 1.0 mm., m.p. 189–190°.

Anal. Calcd. for $C_{16}H_{12}O_4S_2$: C, 57.81; H, 3.64; S, 19.30. Found: C, 58.1; H, 3.81; S, 19.45.

1,4-Anthraquinonedisulfenyl Morpholide (VIII).—Either VI or VII when boiled for a short time in a small volume of morpholine dissolves, and on cooling, red-brown needles of the dimorpholide are deposited. After collecting and washing with hot ethanol and benzene the product was found to sinter at 271° and not to melt below 300°, though decomposition was complete. For analysis the compound was recrystallized from pyridine (charcoal) several times (melting characteristic unchanged) and dried at 100° for 12 hr. over P_2O_5 at 1.0 mm.

Anal. Calcd. for $C_{22}H_{22}O_4S_2N_2$: C, 59.9; H, 5.01; N, 6.34; S, 14.49. Found: C, 59.91; H, 5.21; N, 6.33; S, 14.14.

1,4-Anthraquinonedisulfenic Acid (II).—The disulfenate ester VII (0.5 g., 0.0015 mole) was suspended in 20 ml. of absolute ethanol which was brought to a boil and 1.0 ml. of 33% aqueous potassium hydroxide (0.006 mole) added. Boiling was continued for 4 min. when 100 ml. of hot distilled water was added. The resultant clear blue solution was then quickly chilled, filtered and the filtrate made weakly acid with acetic acid. The purple coagulant was collected and washed with a large quantity of cold water. The moist precipitate was then taken up in cold acetone, the deep magenta solution filtered, and to the filtrate there was added water until the solution became just slightly cloudy. The solution was then refrigerated and water added very gradually until precipitation was completed. In this manner the acid II was obtained as purple microscopic needles (0.1 to 0.12 g., 22–26%). When heated above 100° II turned from purple to yellow.

Additional recrystallizations from acetone always resulted in the formation of small amounts of alkali-insoluble material. No other solvent was found that was better for recrystallization than acetone and an analytical sample could not be prepared.

The Stability of II and the Conversion of II to VII.—Anhydrous chloroform (100 ml.) previously saturated with dry hydrogen chloride at 0° was added to 118 mg. (0.00039 mole) of dry II and the reaction mixture allowed to set at 0° for 12 hr. All the solvent was then aspirated off, and to the dry residue there was added 100 ml. of anhydrous methanol and 1 ml. of dry pyridine. The flask was then warmed to a boil and set aside for 12 hr. The methanolic supernatant solution was decanted and the residue taken up in 50 ml. of hot, anhydrous benzene. The benzene and methanolic solutions were then combined and allowed to cool. After a few hr. the precipitation of a high melting amorphous material (*ca.* 40 mg.) was complete. This substance was removed and the filtrate concentrated to 100 ml. and set aside. The characteristic crystals of the diester soon appeared. These were collected and the filtrate concentrated in turn to 50 and 25 ml., respectively, the crystalline ester being removed each time. In this fashion there was obtained a total of 60–70 mg. of VII, m.p. 176–179° (47–55% yield from II). The melting point was identical to that of VII as obtained from the reaction of VI and methanol, and on recrystallization several times from benzene and methanol the melting points were found to be between 185–188° which is very close to that of the analytical sample of VII (no mixed melting point depression with an authentic sample of VII).

This procedure was carried out on samples of the sulfenic acid prepared a month in advance with no appreciable difference in yield of VII if II were kept in a desiccator under refrigeration.

1,4-Anthraquinonedisulfonic Acid (IX) and 1,4-Dichloroanthraquinone (X).—The disulfonic acid IX was obtained in good yield when either V, VI, VII or II was suspended in 200 volumes of 90% aqueous acetic acid which was then saturated, in the cold, with chlorine gas. The reaction mixture was filtered and allowed to set for 10 hr. when the white to yellow needles were collected. The crude acid is best recrystallized from 90% acetic acid, m.p. 269–269.5° (lit.[21] 264–265°). The crude yield from 0.4 g. (0.0015 mole) of V was 0.41 g. or 75% of theory (m.p. 263–264°).

Anal. Calcd. for $C_{14}H_8O_8S_2 \cdot H_2O$: C, 43.52; H, 2.61; S, 16.60. Found: C, 43.61; H, 2.85; S, 17.47.

The disulfonic acid could be converted to 1,4-dichloroanthraquinone by the usual procedure,[20] m.p. 190° (lit.[21] 186.5°). When the dihalide, so obtained (0.531 g., 0.0019 mole), was treated in the same manner as in the preparation of V from IV, the polymeric disulfide was obtained (0.52 g., 100% yield), m.p. > 360°.

Absorption Spectra.—These were determined with a Model DU Beckman spectrophotometer. Extinction coefficients were calculated from spectral measurements made with $\sim 10^{-4}$ molar solutions; the maximum absorbances were all between 0.5 and 0.8. The solvents employed are as noted in Table II .

Observations on Some Alkyl Substituted Anthracenes and Anthraquinones

BY ROBERT J. CRAWFORD, SIDNEY LEVINE, RICHARD M. ELOFSON AND REUBEN B. SANDIN

RECEIVED JANUARY 9, 1957

1,2-Dimethylanthraquinone and some related alkyl substituted anthraquinones have been examined from the standpoint of polarographic and chemical reduction and controlled potential electrolysis. The effectiveness of alkyl substitution in lowering the negative potential is: $\alpha > \beta$, dimethyl > monomethyl, six-membered ring > five-membered ring and 1,2-dimethyl > six-membered ring. The α-substituted anthraquinones show evidence of oxanthrol isomerization. It is suggested that 1,2,9,10-tetramethylanthracene behaves as a crowded molecule from the standpoint of preparation and properties.

It is known that 9,10-dihydro derivatives of 1,2-dimethylanthracene are very resistant to aromatization. For example, compound II resists demethoxylation and does not yield 1,2,9,10-tetramethylanthracene (I) even after shaking for six days with sodium powder in ether.[1] On the other hand, 9,10-dimethylanthracene is obtained in good yield from the corresponding dimethoxy compound. Again, compound III does not undergo dehydrogenation to yield I, whereas 9,10-dihydroanthracene is smoothly transformed into 9,10-dimethylanthracene with sulfur at 230°.[2]

In contrast to this behavior it is known that compound I tends to lose aromaticity and to revert to the 9,10-dihydro state. For example, I has been

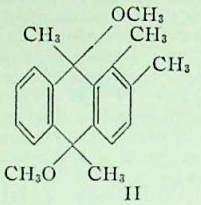
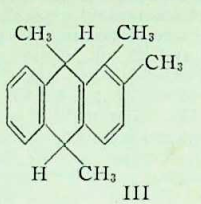
found to undergo peroxidation after brief periods of storage in the solid state.[3]



II



III

The marked stability of the 9,10-dihydro derivatives of 1,2-dimethylanthracene appeared to us to justify a polarographic study of 1,2-dimethylanthraquinone and some related compounds. Therefore in this paper are reported some observations which have been made on the polarographic reduction and also the chemical reduction and the controlled potential electrolysis of 1,2-dimethylanthraquinone and some related quinones. A difference has also been noted in the stability of some 1,2-disubstituted hydrocarbons.

Experimental

Anthraquinones.—The quinones were for the most part well known and all of them have been described previously. Anthraquinone (Eastman Kodak Co.) melted at 286–288°. 2-Methylanthraquinone (Eastman Kodak Co.) was crystallized from alcohol and melted at 175°. 1,2-Dimethylanthraquinone,[3] m.p. 156–157°, 1,4-dimethylanthraquinone,[4] m.p. 140.5–141.5°, 1-methylanthraquinone,[5] m.p. 172–173°, and 1′,2′,3′,4′-tetrahydro-1,2-benzanthraquinone,[6] m.p. 153–154°, were made by the ring closures of the substituted *o*-benzoylbenzoic acids. 1,2-Cyclopenteno-9,10-anthraquinone[7] melted at 126.5–127.5°.

9,10-Dimethyl-1′,2′,3′,4′-tetrahydrobenzanthracene (IV).—To a solution of the Grignard reagent from 0.5 g. of magnesium and methyl iodide (2.0 ml.) in anhydrous ether (15 ml.) was added 0.5 g. of 1′,2′,3′,4′-tetrahydro-1,2-benzanthraquinone. The flask was stoppered and after standing at 0° for four days, the fluorescent solution was poured dropwise and with constant stirring into a cold solution of 50% hydriodic acid (5.7 ml.), hydrobromic acid (d. 1.4, 4 ml.) and methanol (15 ml.). Glacial acetic acid (15 ml.) was added and the iodo compound (0.6 g.) separated as an orange solid. A solution of the iodo compound (1.2 g.) in dioxane (45 ml.) was added to a solution of stannous chloride (7.5 g.) in dioxane (40 ml.) and concentrated hydrochloric acid (12 ml.). The solution was brought to its boiling point, diluted with water (250 ml.) and extracted with benzene. The highly fluorescent benzene extract was washed with water and dried by filtering through ordinary filter paper. The benzene was evaporated under diminished pressure, which afforded a brown sirupy material which was extracted with alcohol. The alcohol extract was saturated with picric acid and yielded a black crystalline picrate. It was crystallized from alcohol; weight 0.6 g., m.p. 153–154°.

Anal. Calcd. for $C_{26}H_{23}N_3O_7$: C, 63.81; H, 4.74. Found: C, 64.09; H, 4.93.

The picrate was dissolved in benzene (30 ml.), and the solution was passed through a column consisting of an equal part mixture of activated alumina and Super-cel. The benzene was evaporated under reduced pressure and afforded 9,10-dimethyl-1′,2′,3′,4′-tetrahydrobenzanthracene as a yellow solid, m.p. 89–90°.

Anal. Calcd. for $C_{20}H_{20}$: C, 92.23; H, 7.73. Found: C, 91.98; H, 7.65.

Reduction at the Dropping Mercury Electrode.—A Leeds and Northrup Electro-chemograph, type E, was used to record the polarograms. A minimum of damping (position 1) was used to prevent distortion of the waves. Half-wave potentials were measured with both increasing and decreasing cathodic voltage and the average was computed. The capillary used was made from marine barometer tubing obtained from the Corning Glass Works. The value of the capillary constant $M^{2/3}\,t^{1/6}$ was 2.27 at h equal to 35.6 cm. The drop time was measured with the current flowing in the region of the half-wave potential. The electrolysis cells were of the usual type. A saturated calomel electrode was used as the anode and was connected by means of a flexible saturated potassium chloride agar bridge to the electrolysis cell. The quinones were dissolved in a 50:50 mixture of reagent grade isopropyl alcohol and 0.1 *M* acetate buffer, *p*H 5.6, or in 0.1 *M* hydrochloric acid in 50% isopropyl alcohol, *p*H 1.5, to give a final concentration of 5×10^{-4} *M*. The *p*H measurements were recorded with a Beckman model G *p*H meter. All of the solutions were kept out of direct sunlight and preferably in the dark to prevent any possible reaction between the alcohol and the quinone. Also determinations were carried out as soon as possible after the solutions had been made, and all determinations were carried out under the same conditions. The nitrogen used was purified grade supplied by Canadian Liquid Air. The temperature during the experiments was thermostated at 25°. A summary of observed half-wave potentials is given in Table I. In the acetate buffer the waves did not show semiquinone formation. Instead, perfectly smooth waves were obtained, corresponding to a reversible two-electron reduction. In strongly acid solutions the waves were not quite so well formed, but the potentials correspond quite closely with those measured in the acetate buffer and indicate quite clearly the reliability of the measurements to the nearest 0.01 V.

TABLE I

$E_{1/2}$ *vs.* THE SATURATED CALOMEL ELECTRODE FOR ANTHRAQUINONES IN VARIOUS BUFFERS AND 50% ISOPROPYL ALCOHOL. ALL $E_{1/2}$ VALUES ARE NEGATIVE

Quinone	0.1 *M* Acetate buffer, *p*H 5.6	0.1 *M* HCl, *p*H 1.5
Anthraquinone	0.43[a]	0.18
2-Methylanthraquinone	.44[a]	.19
1-Methylanthraquinone	.48	.23
1,2-Dimethylanthraquinone	.51	.25
1,3-Dimethylanthraquinone	.50	..
1,2-Cyclopenteno-9,10-anthraquinone	.47	..
1′,2′,3′,4′-Tetrahydro-1,2-benzanthraquinone	.49	..
1,4-Dimethylanthraquinone	.53	0 29

[a] These values correspond to E_0 values of +0.15 and +0.14 v. for anthraquinone and 2-methylanthraquinone, respectively. This is in good agreement with the values of +0.155 and +0.150 v. obtained by J. B. Conant and L. F. Fieser, *ibid.*, 46, 1858 (1924). See also (a) H. Adkins and F. W. Cox, *ibid.*, 60, 1151 (1938); (b) S. Wawzonek, H. A. Laitinen and S. J. Kwiatkowski, *ibid.*, 66, 827 (1944); (c) N. H. Furman and K. G. Stone, ref. 8.

Polarograms which were run in 0.1 *M* tetramethylammonium hydroxide, *p*H 13.7, and which are not reported in this paper, indicated semiquinone formation by the fact that two-step waves, each involving one electron, were noticed. The separation of the two waves varied considerably from one compound to another but was greatest with anthraquinone and a minimum with 1,4-dimethylanthraquinone. Furman and Stone[8] in their careful work have attributed this phenomenon to complex formation with the buffer. However, in the present work the waves were too indistinct to permit quantitative measurements of the differences.

In order to establish whether the systems studied were strictly reversible or not, the quinones were reduced to the hydroquinones and then the oxidation waves of the hydroquinones were determined. Reduction was carried out by chemical means and also by controlled potential electrolysis as described by Lingane.[9]

Chemical Reduction.—Titanous chloride in the acetate buffer reduced all compounds smoothly and produced anodic waves, the potentials of which were in exact agreement with the cathodic waves of the hydroquinones. In hydrochloric acid solution the expected anodic waves were likewise obtained for all compounds except 1,4-dimethylanthraquinone, which was not reduced under these conditions. When sodium hydrosulfite reduction of the quinone in 0.1 *M* tetramethylammonium hydroxide was carried out, anodic waves were obtained and the potential agreed within experimental error with the cathodic waves of the quinone. In the case of anthraquinone and 2-methylanthraquinone, the anodic waves were of the same height as the original cathodic waves. However, with the 1-substituted anthraquinones, the hydroquinone waves were greatly reduced in height. Apparently the hydroquinone primarily formed was changing rapidly to some other form such as the oxanthrol. No reduction wave could be found for the postulated oxanthrol.

Electrochemical Reduction.—In order to check the results of chemical reduction, 1,2-dimethylanthraquinone was reduced by controlled potential electrolysis. In these experiments 0.5×10^{-4} *M* solutions in 50% isopropyl alcohol were electrolyzed under purified nitrogen using a large mercury pool stirred magnetically as cathode and a saturated calomel electrode as anode. The cathode potential was controlled manually.

In 0.1 *M* tetramethylammonium hydroxide the reduction of 1,2-dimethylanthraquinone proceeded smoothly, but the height of the anodic wave decreased rapidly to a small fraction of the original height of the cathodic wave. The half-wave potential of this wave was the same as that of the quinone. Bubbling oxygen through the solution followed by nitrogen produced the original cathodic wave corresponding to the original concentration. This indicated that the isomerization that was taking place was completely reversible. Anthraquinone under these conditions showed no decrease in height of the anodic wave over a 12-hr. period.

Electrolysis of 1,2-dimethylanthraquinone in the acetate buffer produced an anodic wave, with unchanged half-wave potential. The height of this wave decreased to about 60% of its original value after 4 hr. and 30% of its former value after 8 hr. In addition, a reduction wave developed at −1.1 v. which probably corresponds to the oxanthrol. The over-all height of the two waves equalled that of the original quinone. When the solution was oxidized with oxygen, the cathodic wave of the quinone was produced, but its height was only slightly higher than that of the hydroquinone. This indicated that the isomerization between the hydroquinone and oxanthrol was much slower at the lower *p*H.

In 0.1 *M* HCl, 1,2-dimethylanthraquinone was reduced smoothly to the hydroquinone which did not indicate any appreciable isomerization to the oxanthrol. In 0.1 *M* HCl, 1,4-dimethylanthraquinone, which was not reduced by titanous chloride, was reduced smoothly to the hydroquinone with no evidence of isomerization. In both cases the potentials of the hydroquinone were the same as that of the original quinones.

Air Oxidation of 1,2,9,10-Tetramethylanthracene (I) and 9,10-Dimethyl-1′,2′,3′,4′-tetrahydrobenzanthracene (IV) in the Solid State.—Freshly prepared hydrocarbon I, m.p. 52–54°,[3] and hydrocarbon IV, m.p. 89–90°, were exposed to air in the solid state. Compound I, after 7 days exposure, had a m.p. 50–73° and gave off bubbles of gas at 109°. Freshly prepared I gave no reaction with starch–potassium iodide solution, whereas the exposed material gave a definite test. In contrast to this behavior, IV after 7 days exposure had a m.p. 89.5–91° and gave no evidence of having undergone oxidation. Moreover, IV after one month of exposure showed no appreciable change in chemical composition as indicated by analysis.

Discussion

The influence of alkyl substitution upon the ease of polarographic reduction is indicated in Table I. α-Substitution yields a more negative potential than β-substitution. Potentials become more negative with disubstitution and a six-membered ring is more effective in lowering the potential than the five-membered ring.[10] Our observed value for 2-methylanthraquinone probably gives a rough estimate of the conjugative and inductive effects of the methyl group.[11] However, our recorded potential difference between anthraquinone and the 2-methylanthraquinone may not be too significant.

The lower negative value for α-methylanthraquinone brings in an added steric effect.[12,13]

Leonard, Laitinen and Mottus[14] have given a very clear picture of the type of polarization which is believed to occur at the electrode in the case of the polarography of certain 1,2-diketones. They have also suggested that the lowering of the potential is due in part to a steric hindrance to coplanarity of the dicarbonyl system. In the present work it is quite possible that the steric requirements of the carbonyl group and the α-substituent are involved. Gill and Stonehill[12a] suggest a steric hindrance which pushes both the =O and large α-substituent out of the ring plane. This would inhibit any resonance of the carbonyl group and also of the α-substituent with the ring. The enhanced effect of 1,2-dimethyl substitution over an additive effect may be due to a buttressing action where the α-methyl group is buttressed by the adjacent methyl group.[15] That the six-membered ring is more effective in lowering the potential than the five-membered ring may be due to the greater amount of crowding associated with the conformation of the six-membered ring. However, a six-membered ring is not as important from the standpoint of crowding as 1,2-dimethyl substitution. This is particularly noticeable when the stabilities of the two hydrocarbons I and IV are compared. The chemical and electrochemical reduction of α-substituted anthraquinones indicates isomerization to an oxanthrol. Gill and Stonehill[16] have shown that certain anthrahydroquinones give polarographic oxidation waves which decrease in height with time. This decrease is attributed to a reversible change to oxanthrols. The latter are polarographically reducible only at highly negative potentials. There are two possible structures for

(10) This is consistent with the interesting work of Arnold and co-workers who have shown that the relative steric influence of methylene groups decreases in the order CH_2 (in CH_3) > CH_2 (in a six-membered ring) > CH_2 (in a five-membered ring). the oxanthrol from 1,2-dimethylanthraquinone, *viz.*, V and VI.

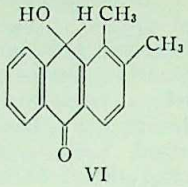
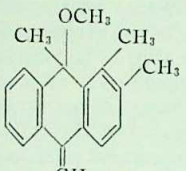
V

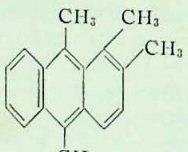


VI

The preferred structure is believed to be VI, *i.e.*, the carbon atom which is the more crowded is believed to be the one which becomes tetrahedral. Moreover there is a precedent for this type of structure in the 1,2-benzanthracene series.[17] It is also interesting that a mixture of the compounds VII and VIII has been isolated.[3] It is quite possible that the isomerization may be due to the resistance



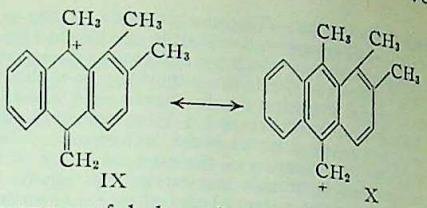
VII



VIII

offered to the formation of a planar crowded molecule, which in this case is the hydroquinone.

From our study we conclude that compounds such as 1,2,9,10-tetramethylanthracene and the corresponding hydroquinones behave as crowded molecules. Superficially, from the standpoint of structure, I resembles the crowded molecule of octamethylnaphthalene.[18] The successful preparation of hydrocarbon I evidently requires, besides the driving force of aromatization, the added effect of a carbonium ion stabilized by the resonance forms IX and X.[3]



IX X

The unsuccessful demethoxylation[1] and dehydrogenation[2] attempts to prepare I, compared with the successful reactions where there is no 1,2-disubstitution, may involve an unfavorable reaction mechanism. Again it is possible that a hindered or unfavorable conformation of the starting material is involved, where a preferrred conformation for 9,10-elimination is necessary. Some recent interesting work has been carried out[19] which indicates that 9,10-dihydroanthracenes may be considered as cyclo-1,4-hexadienes and therefore may have bond orientations at the 9- and 10-positions which are not equivalent. For example, *cis*-9,10-dihydro-9,10-dimethylanthracene[19c] is stable to aluminum chloride in benzene, whereas the *trans* isomer[19c] is dehydrogenated under the same conditions.[20] Evidently in the former compound both hydrogen atoms are in equatorial positions, and in the latter compound one hydrogen is in an axial position. It should be mentioned, however, that the first compound, in spite of its stability to aluminum chloride in benzene, is dehydrogenated with sulfur without any difficulty.

Acknowledgment.—We take pleasure in expressing our appreciation to Dr. Richard T. Arnold of the Sloan Foundation for very stimulating discussions and suggestions, to Dr. Walter Harris for his help in connection with polarographic technique, and to Dr. Robert Christiansen for his help in the preparation and analysis of some of the compounds.

The *para* Claisen Rearrangement: Rearrangement of 6-Allyl-2,6-dimethyl-2,4-cyclohexadienone[1]

BY DAVID Y. CURTIN AND ROBERT J. CRAWFORD

RECEIVED JANUARY 10, 1957

The synthesis of 6-allyl-2,6-dimethyl-2,4-cyclohexadienone from sodium 2,6-dimethylphenoxide and allyl bromide is here reported. The dienone rearranges to a mixture of 4-allyl-2,6-dimethylphenol and allyl 2,6-dimethylphenyl ether in a ratio of 2.7/1 when heated to 70°. On standing at room temperature it yields a dimer. The rates of the rearrangements have been measured at three temperatures. The results are compared with data of previous workers. The steady state concentration of dienone in the *para* Claisen rearrangement is shown by examination of the reaction mixture to be of the order of 0.1%.

Studies[2] of the mechanism of the *para* Claisen rearrangement have indicated that allyl-cyclohexadienones are intermediates in this reaction. It was the purpose of the present investigation to prepare such a compound and examine its behavior under the conditions of the Claisen rearrangement. The

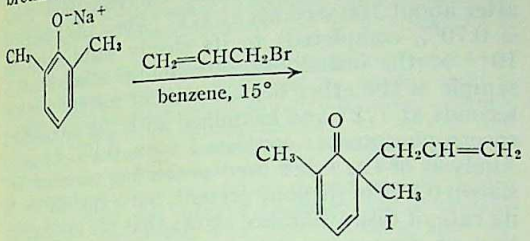
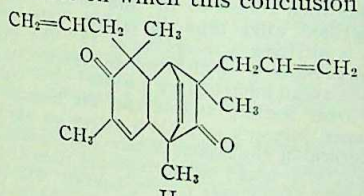
methyl-2,4-cyclohexadienone (I) which was prepared in 60% yield based on unreacted starting material by treatment of a suspension of the sodium salt of 2,6-dimethylphenol in benzene with allyl bromide.[3,4]

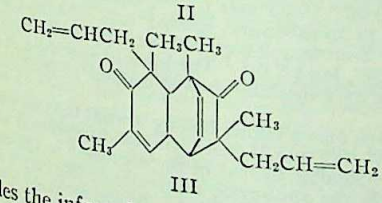


I

The allyldienone I rearranges readily when heated, but could be purified by distillation at reduced pressure. It was characterized by comparison of its infrared and ultraviolet spectra with those of other 2,4-cyclohexadienones. It reacted with maleic anhydride in benzene at 100° to form an adduct which is apparently identical with that which had been obtained by Conroy and Firestone[5] when they carried out the Claisen rearrangement of allyl 2,6-dimethylphenyl ether (IV) in the presence of maleic anhydride. When the dienone I was allowed to stand for several weeks, it was found to have undergone extensive reaction and eventually a crystalline compound, m.p. 92°, having twice the molecular weight of the dienone was formed. This substance is undoubtedly one of the diastereoisomers of the two Diels–Alder products II or III formed by condensation of the dienone I with itself. Evidence on which this conclusion is based

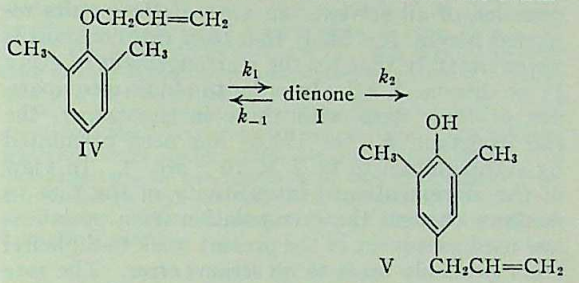


II



III

includes the infrared and ultraviolet spectra, a molecular weight determination in camphor and the observation that hydrogenation over platinum resulted in the rapid uptake of three moles of hydrogen followed by a slower uptake of a fourth. The three unconjugated carbon–carbon double bonds in the structures II or III account for the rapid hydrogenation. The dimer when heated at 120° underwent what is apparently the reversal of its formation followed by a Claisen rearrangement of the dienone I to yield 4-allyl-2,6-dimethylphenol in 64% yield. A similar dimerization reaction was observed by Conroy and Firestone when they prepared 2,6-dimethyl-6-*n*-propyl-2,4-cyclohexadienone.[5b] The allyldienone I rearranges at temperatures above 70° to give a mixture of allyl 2,6-dimethylphenyl ether (IV) and 4-allyl-2,6-dimethylphenol (V). The reaction was conveniently carried out in cyclohexane solution. Under the conditions employed, the ratio of *p*-allylphenol V to allyl ether IV was 2.7.



Kinetics.—The rearrangement of the dienone I in cyclohexane at temperatures of 75–100° was conveniently followed with an ultraviolet spectrophotometer. At these temperatures the rearrangement of the allyl ether IV is negligible. Concentrations employed were low enough so that the Diels–Alder dimerization of I (which is presumably second order) was negligible. The disappearance of the dienone I followed a first-order rate law. If the reasonable assumption is made that dienone I is disappearing by two simultaneous first-order paths with constants k_{-1} and k_2 (each irreversible under the reaction conditions), then the measured rate constant is $k_{-1} + k_2$. Values of the experimental constants calculated from the data by the method of least squares are shown in Table I. The ratios k_2/k_{-1} in the table were obtained by an analysis of the products of the completed rearrangement with the ultraviolet spectrophotometer. It will be seen that this ratio is independent of temperature over the range studied.

TABLE I

RATE CONSTANTS FOR THE REARRANGEMENT OF THE DIENONE I

Run	Temp., °C.	Init. concn., *M*	$10^5(k_{-1} + k_2)$, sec.$^{-1}$	k_2/k_{-1}	$10^6 k_{-1}$	$10^5 k_2$
1	75.00 ± 0.01	0.617	2.20			
2	75.00 ± .01	0.0305	1.44 ± 0.01	2.8	3.89	1.05
3	83.96 ± .01	.0249	3.56 ± .17	2.7	9.62	2.60
4	101.68 ± .01	.0305	20.7 ± .2	2.7	56.0	15.1

This conclusion was confirmed by the fact that infrared spectra of the products of rearrangement of 10% solutions at each of the temperatures studied were identical. The separate rate constants, calculated by partitioning the total rate constant, are shown in Table I. Quantities of activation calculated from these data are given in Table II.

The rate of rearrangement of the allyl ether IV to the 4-allylphenol V in diphenyl ether solution at 171.6° was measured by Tarbell and Kincaid.[6]

(3) D. Y. Curtin and R. J. Crawford, *Chemistry and Industry*, 313 (1956). This reaction was suggested by the report of L. Claisen, F. Kremers, F. Roth and E. Tietze [*Ann.*, **442**, 210 (1925)] that the sodium salt of phenol underwent alkylation in an *o*-position when suspended in benzene and treated with allyl halides.

(4) The factors which determine whether the phenoxide ion undergoes alkylation on carbon to give dienone or on oxygen to give ether have been made the object of a more extended investigation and will be reported in a separate communication.

TABLE II

QUANTITIES OF ACTIVATION FOR THE REARRANGEMENT AT 83.96° OF THE DIENONE I

Rate constant	E_a, kcal./mole	$\Delta H\ddagger$, kcal./mole	$\Delta S\ddagger$, cal./mole deg.	$\Delta F\ddagger$, kcal./mole
k_{-1}	26.8	26.1	−8.8	29.3
k_2	26.8	26.1	−7.1	

They found the reaction to be first order and quite insensitive to such changes in the reaction medium as added acetic acid or dimethylaniline or even omission of all solvent. In view of the results reported herein, it is likely that their rate constant is approximately that for the rearrangement of ether IV to dienone I, k_1.[7] In order to obtain a comparison of their data with those in this paper, the rate constant, k_{-1}, at 171.6° has been calculated by extrapolation to be 2×10^{-2} sec.$^{-1}$. In view of the aforementioned insensitivity of the rate to medium changes the extrapolation from cyclohexane used as solvent in the present work to diphenyl ether probably leads to no serious error. The rate constants together with the quantities of activation obtained by extrapolation of the present data may be compared with those of Tarbell and Kincaid. Their value for the entropy of activation was −10.1 e.u. at 171.6°. It was calculated from the Eyring equation with the assumption that $\Delta H^{\ddagger} = E_a$. A recalculation using the relationship[8] $\Delta H^{\ddagger} = E_a - RT$ gives a value of −12.1 e.u. A further correction must be applied before their value may be compared with that reported here for the reverse reaction. Their rate was the rate of rearrangement to two *o*-positions and must be corrected with a statistical factor of 2. Such a correction gives $\Delta S^{\ddagger}$ for rearrangment of the allyl ether IV to one *o*-position equal to −13.5 e.u. This is to be compared with the value of −8.5 e.u. for the reverse reaction obtained from the extrapolated values of $\Delta H^{\ddagger}$ and $\Delta F^{\ddagger}$ in the present work. If interpreted literally, this difference requires that the entropy of the dienone I be lower than that of the ether IV by some 4 e.u.[9] However, in view of the possible errors in these values, it is not clear how valid such a comparison may be. It is of interest that ΔH for the process IV $\rightleftarrows$ I when calculated as $\Delta H_1^{\ddagger} - \Delta H_{-1}^{\ddagger}$ amounts to +3.5 kcal./mole as compared with the value of +7 calculated by Conroy and Firestone[5] from bond energies.

A further point of interest is the steady-state concentration of the dienone I in the rearrangement of the ether IV. From the integrated rate expression of Lowry and John[10] for two successive reversible reactions and the data discussed above, it has been calculated that the dienone concentration rises after about 100 seconds at 171° (when the reaction is 0.70% completed) to its steady state value of $10^{-3} \times$ the initial concentration of ether IV. A sample of the ether heated without solvent for 100 seconds at 172° and examined with the ultraviolet spectrophotometer contained some 0.1% dienone. Analysis of the ether used as starting material had shown 0.2% of dienone present, but a calculation of its rate of disappearance shows that the concentration of dienone remaining from that present initially would be less than 10^{-5}% at that time. It was reported by Conroy and Firestone[5a] that when the allyl ether IV was heated to 200° and treated with maleic anhydride at 100° (at which temperature it no longer rearranged), that the maleic anhydride adduct of the dienone I was obtained in small yield. Calculation of the yield from data given in the Experimental section of their paper[5b] indicates that it was 0.6% of incompletely purified product. This is in fair agreement with our value of 0.1% estimated from ultraviolet spectral data.

Experimental[11]

6-Allyl-2,6-dimethyl-2,4-cyclohexadienone (I).—A solution of 2,6-dimethylphenol (12.2 g., 0.10 mole) was treated with 5.6 g. (0.10 mole) of sodium methoxide in 300 ml. of dry benzene under a nitrogen atmosphere and the mixture distilled until the refractive index of the distillate corresponded to that of benzene (*ca.* 100 ml. of distillate). The mixture was then cooled to 15° and 30 ml. (0.38 mole) of freshly distilled allyl bromide added. After 44 hr. of stirring in a nitrogen atmosphere at 15°, the solid sodium bromide was removed by filtration and the filtrate extracted with Claisen alkali and then with water. The organic layer was dried over sodium sulfate and the benzene removed under reduced pressure to yield a yellow oil which, on distillation through a Holzmann column at 0.05 mm. pressure, gave 3.8 g. (60% based on unrecovered phenol) of dienone I, b.p. 36–37° (0.05 mm.), n^{25}D 1.5050. The ultraviolet spectrum in cyclohexane showed λ_{max} 303 mμ, ε 4,400. [Compare 2-acetoxy-2-methyl-3,5-cyclohexadienone[12] which has λ_{max} 292, log ε 3.6.] The infrared spectrum of a 10% solution in cyclohexane[13] showed maxima at 1663 and 1645 cm.$^{-1}$.

There was also a higher boiling neutral fraction (*ca.* 1 g., b.p. 72–73° (0.2 mm.)) which showed absorption at 1640 and 1670 cm.$^{-1}$ similar to that of the dienone I in the carbonyl region while the absorption maximum at 920 cm.$^{-1}$ was approximately double that of I. It seems likely that this material is a dienone–ether mixture formed from the reac-

(7) ADDED IN PROOF.—It will be noted that application of the steady state approximation shows that the observed rate constant of Tarbell and Kincaid is equal to the constant $k_1 \times f$ where f is the fraction of dienone molecules which go on to 4-allylphenol rather than back to ether I. Their constant should therefore be multiplied by $1/f$ to give k_1 for their rearrangement. Unfortunately $1/f$ is unknown for their rearrangement conditions. In the present work it is 3.7/2.7 or 1.4 but previous results have suggested that it may be sensitive to changes in medium.[2] Since the correction is probably not large in any case no attempt has been made to apply one in the following comparisons of our data with those of Tarbell and Kincaid. While this paper was in press a report on the kinetics of the rearrangement of carbon-four-teen-labeled allyl 4-allyl-2,6-dimethylphenyl ether has appeared [F. Kalberer and H. Schmid, *Helv. Chim. Acta*, **40**, 13 (1957)].

(8) A. A. Frost and R. G. Pearson, "Kinetics and Mechanism," John Wiley and Sons, Inc., New York, N. Y., p. 97.

(9) For the calculation of the entropy change for the reaction IV $\rightleftarrows$ I the rate constant for the total rate of conversion of IV to I (*i.e.*, without the statistical correction for the two *o*-positions) has been used.

(10) T. M. Lowry and W. T. John, *J. Chem. Soc.*, **97**, 2673 (1910).

(11) Microanalyses were carried out by Mr. J. Nemeth, Mrs. K. Pih, Mrs. L. Chang, Mrs. E. Pett, Mr. R. N. Benassi and Miss C. Higham. Certain of the ultraviolet spectra were determined by Miss Gerardine Meerman. Infrared spectra were recorded by Mr. James Brader and Mrs. Louise Griffing. All melting points are corrected. The ultraviolet and infrared spectra and also detailed kinetic data are available in the Ph.D. Thesis, of Robert J. Crawford and reproduced by University Microfilms, Ann Arbor, Mich.

(12) F. Wessely and F. Sinwel, *Monatsh.*, **71**, 1055 (1950).

(13) Because of the small difference between the b.p. of the allyl ether IV, b.p. 50° (0.5 mm.), and the dienone I and because of the ease of rearrangement of I to IV, it was not possible to prepare dienone I demonstrably free from the ether IV. However, the ether IV has absorption at 837, 1097 and 1267 cm.$^{-1}$ in the infrared which is apparently absent in the dienone spectrum. Using these bands, it was possible to set an upper limit of approximately 5% on the amount of ether present in the best sample of dienone. This means that the [illegible] is lower by that amount.

tion with allyl bromide with 4-allyl-2,6-dimethylphenol which was produced by a small amount of rearrangement of the dienone I under the reaction conditions.

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.3; H, 9.0. Found: C, 83.1; H, 9.0.

Acidification of the alkaline extracts gave 7.0 g. of a phenol fraction which was estimated by infrared analysis to contain about 55% of 2,6-dimethylphenol and 44% of 4-allyl-2,6-dimethylphenol.

The maleic anhydride adduct (m.p. 139–140° uncor.) of dienone I was formed in 40% yield by heating 0.50 g. (0.0030 mole) of dienone with 0.35 g. (0.0035 mole) of maleic anhydride in a nitrogen atmosphere for 3 hr. at 100° and washing the product with ether after it solidified.

Dimerization of Dienone I.—A sample of the dienone I after 3 weeks at room temperature showed an entirely different ultraviolet and infrared spectrum and eventually crystallized. The product after recrystallization from petroleum ether melted at 92–93°. The infrared spectrum of a 10% solution in carbon tetrachloride shows weak absorption at 1638 cm.$^{-1}$ and strong bands at 1680 and 1715 cm.$^{-1}$. The ultraviolet spectrum (in cyclohexane) had a shoulder at 237 mμ, ε 5700.

Anal. Calcd. for $C_{22}H_{28}O_2$: C, 81.5; H, 8.7; mol. wt., 324. Found: C, 81.9; H, 8.8; mol. wt., 320.

Hydrogenation of the dimer in ethyl acetate at room temperature with hydrogen at one atmosphere pressure and Adams platinum catalyst led to the rapid absorption of 2.95 moles of hydrogen and an additional mole over a period of 4 hr., after which no further hydrogen reacted. No attempt was made to isolate the reduced product.

When the dimer of I (0.5 g.) was heated at 150° for 3 hr. and the product distilled (only a portion was distillable), 4-allyl-2,6-dimethylphenol was formed as shown by its solubility in alkali and the identity of its infrared spectrum with that of a known sample. The dimer when heated at 120° for 8 hr. gave 64% of the phenol.

Rearrangement of Dienone I.—After 12 hr. at 135°, the product from 2 g. of dienone was added to 15 ml. of cyclohexane, extracted with Claisen alkali washed with water, dried over sodium sulfate and the solvent evaporated at room temperature. Distillation of the remaining oil gave 0.55 g. of the allyl ether IV, b.p. 63° (1.2 mm.), $n^{25}D$ 1.5045. The ultraviolet spectrum showed no absorption at 303 mμ (where the dienone has strong absorption) but instead λ_{max} 270, ε 500, in agreement with that characteristic of the allyl ether IV.

Acidification of the Claisen alkali-soluble fraction above followed by extraction with 15 ml. of cyclohexane, drying over magnesium sulfate, evaporation of the solvent and distillation of the residual oil under vacuum gave 1.0 g. of 4-allyl-2,6-dimethylphenol (V), b.p. 87° (1.8 mm.), $n^{25}D$ 1.5365 (lit.[6] b.p. 90.5° (2 mm.), $n^{25}D$ 1.5370).

Determination of the Rates of Rearrangement of the Dienone I.—Since the dienone rearranges slowly at room temperature, only freshly prepared samples could be employed. Its infrared spectrum was determined as a check on its purity. There was always a trace of the ether IV present which could be determined by its absorption at 1698 cm.$^{-1}$. The sample was diluted to the appropriate concentration and stored at −10° until used. The cyclohexane was purified by washing with cold concentrated sulfuric acid and fractionation from calcium oxide through a 30-cm. Widmer column. The first and last 10% fractions were discarded.

Pyrex tubing (6 mm. o.d.) was cut into 10-cm. lengths and soaked in a solution of chromium trioxide in sulfuric acid. The tubes were thoroughly rinsed in deionized water and dried. They were then sealed at one end, constricted at a distance of 3 cm. from the unsealed end, flushed with dry nitrogen and filled with the dienone in cyclohexane (concentrations indicated in Table I). The contents were frozen in a brine–ice mixture and the tubes sealed. The tubes were then inserted into an oil-bath thermostatically regulated to within ±0.05°. The temperature of the bath was measured with a totally immersed thermometer graduated in tenths of a degree and calibrated by the Bureau of Standards.

At the proper time intervals the samples were removed from the bath and immersed in an isopropyl alcohol–Dry Ice mixture. After completion of the reaction the tubes were brought to 20°, opened and the solutions diluted to the appropriate concentrations (*ca.* 3×10^{-4} *M*) with cyclohexane. The absorbancies at 303 mμ were determined by the use of a Cary model 11 ultraviolet recording spectrophotometer using 1.00-cm. matched cells. At this wave length ε for the dienone I is 4,400 while the ether IV has ε < 5 and the *p*-allylphenol V has ε 30. The infinity absorbance is thus negligible compared to the measured absorbance over the range studied.

The complete spectrum was recorded for a control tube and for the infinity tube at each temperature. The infrared spectrum of the product (10% solution in cyclohexane) of a rearrangement for ten half-lives at each temperature confirmed the product analysis with the ultraviolet spectrophotometer. The rate constants ($k_{-1} + k_2$) were evaluated from the equation

$$\ln A_0 - \ln (A) = kt$$

where A_0 = initial absorbancy and A = absorbancy at time t, using the method of least squares.[14] At each temperature the reaction was followed to greater than 60% completion, and the least squares calculation is based on measurements of twelve points.[10]

Use of the ultraviolet spectrum to calculate the composition of the product mixture is illustrated by the data for the run at 75 ± 0.01°. The absorbancy at 303 mμ was used to calculate the concentration (1.0×10^{-5} *M*) of dienone I remaining in the sample assuming that the absorbancies of ether IV and *p*-allylphenol V are negligible. The concentration of total starting material was 3.57×10^{-4} *M*. These data together with the absorbancy at 280 mμ where the dienone has ε 2200, the phenol has ε 1630 and the ether has ε 38 were used to calculate the concentrations of *p*-allylphenol (2.31×10^{-4}) and ether (1.16×10^{-4}). However, the starting material was shown to contain 0.33×10^{-4} *M* ether (from comparison of its infrared spectrum with those of authentic samples) and the ether concentration of 1.16×10^{-4} was corrected by the subtraction of this amount to yield the amount of ether formed in the reaction (0.83×10^{-4}). The ratio ether/*p*-allyl ether formed in the reaction is therefore 2.78. Values of 2.7 were obtained for reactions at each of the other temperatures employed. The individual rate constants were calculated using the assumption that the measured $k = k_{-1} + k_2$ and that $k_2/k_{-1} = 2.7$.

Detection of Dienone I in the Rearrangement of the Ether IV.—A sample of allyl 2,6-dimethyl ether sealed in a Pyrex tube was heated in refluxing phenetole (b.p. 172°) for 100 seconds. Samples of the product and the unheated starting solution were diluted to concentrations of 1.00×10^{-2} *M* in cyclohexane and their ultraviolet spectra determined. The absorbancy at 303 mμ showed that the unheated sample contained 0.20% of dienone I, whereas the heated sample contained 0.13%. Calculation from the rate constants ($k_{-1} + k_2$) for the rearrangement of the dienone I shows that only 1×10^{-5} % of the dienone present in the heated sample can be left from the dienone originally present.

1,3-Shifts. V. The Intermolecular Nature of Some 1,3-Shifts

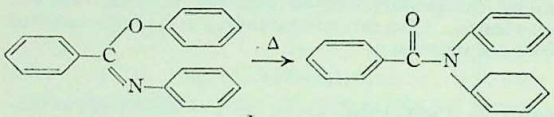
BY KENNETH B. WIBERG, THOMAS M. SHRYNE AND R. ROY KINTNER

RECEIVED JANUARY 16, 1957

It has been found that the rearrangements of α-methoxystyrene to propiophenone, of methyl benzoate with oxygen-to-oxygen migration of the methyl group, of methyl N-phenylformimidate to N-methylformanilide and of 2-methoxypyridine to N-methylpyridone are all intermolecular. The reactions were studied using a C^{13}-labeled methyl group as the tracer, and analyzing for the mixed reaction product with a mass spectrometer. The mechanisms of the reactions are discussed.

Introduction

We have shown previously that the thermal rearrangement of phenyl N-phenylbenzimidate (I) to N-phenylbenzanilide is intramolecular,[1] whereas the corresponding rearrangement of an alkyl N-phenylbenzimidate or an alkyl styryl ether is probably a free radical chain reaction.[2] In order to



I

obtain further evidence on this matter, we have examined four reactions in order to determine whether they are inter- or intramolecular. The examples chosen were the rearrangements of α-methoxystyrene (II), methyl benzoate (III), methyl N-phenylformimidate (IV) and α-methoxypyridine (V). The reactions were studied in a manner which permitted the use of a mass spectrometer's unique ability to sort molecular species on a mass basis.

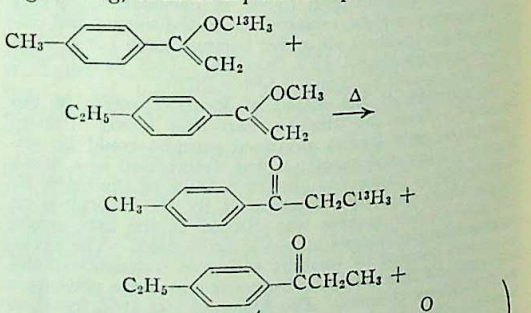
Results

The most common method of determining whether a reaction is inter- or intramolecular involves carrying out the reaction using a mixture of two similar compounds which undergo the reaction, and analyzing the product for a mixed compound which would arise from an intermolecular reaction. For a satisfactory determination of this type, three factors must be considered. First, the two compounds must react at very similar rates. Second, the migrating groups must have essentially equal reactivity toward either of the two reactants. Third, it should be possible to quantitatively isolate any mixed products which might be formed.

In the rearrangement of α-alkoxystyrenes, the rates of reaction will be essentially the same if the two compounds are substituted in the *p*-position with methyl and ethyl groups, respectively, since the σ-values for these groups are very close.[3] Ordinarily, it would be difficult to separate the mixed product if two such similar groups were used, since all of the products would have very similar properties. However, the use of a mass spectrometer obviates this difficulty if the reactants can be separated from the products, or if the reaction is carried to completion, since it can quantitatively separate the products on a mass basis. One may use essentially the same migrating group in both compounds if one contains an ordinary methyl group and the other contains a C^{13}-labeled methyl group. The only difference would be due to the C^{13} isotope effect which would be negligible in this case. If the lower molecular weight reactant is labeled, one may analyze for a mixed compound in the product by examining the mass spectrum of the product and determining if a new peak appears at a mass number one higher than that of the higher molecular weight reactant. In this way, one can quantitatively determine the amount of mixed product without resorting to long, tedious separation procedures.



The alkyl styryl ethers were prepared by treating the appropriately substituted styrene with methanol or methanol-C^{13}, mercuric oxide and iodine, followed by dehydrohalogenation of the intermediate iodoether. The rate of rearrangement of each of the two alkoxystyrenes was determined using the infrared spectrum, and in each case somewhat more than half-reaction was noted after heating for four hours at 220°. The C^{13} content of the α-methoxy-*p*-methylstyrene was determined by com-

paring its mass spectrum with that of an unlabeled sample,[4] both spectra being obtained at a low ionizing potential in order to minimize cracking (Table I).

TABLE I

MASS SPECTRA FOR VINYL ETHER REARRANGEMENT

	Reactant α-Methoxy-p-methylstyrene, ionizing potential 7.0 v.		Product p-Ethylpropiophenone, ionizing potential 14 v.		
Mass	Labeled	Unlabeled[a]	Mass	Labeled	Unlabeled[a]
147	0.0	0.0	161	18.4	12.3
148	100.0	100.0	162	100.0	100.0
149	40.4	12.5	163	23.9	13.8
% C^{13}	28.8	11.1		20.0	12.3
Excess C^{13}	17.7	0.0		7.9	0.0

[a] Containing the natural abundance of C^{13}.

A mixture of equal amounts of labeled α-methoxy-p-methylstyrene and ordinary α-methoxy-p-ethylstyrene was heated to 250° for a time corresponding to several half-lives. The mass spectrum of the product, and of unlabeled p-ethylpropiophenone was determined, allowing a calculation of the amount of C^{13} in the p-ethylpropiophenone from the reaction. Starting with α-methoxy-C^{13}-p-methylstyrene containing 17.7% excess C^{13} over normal abundance, the p-ethylpropiophenone was found to contain 7.9% excess C^{13}. For an intermolecular reaction, if the rates were equal, this product should contain 8.9% excess C^{13} since it can be equally distributed between the two mixed products. The good agreement between the observed and calculated values indicates the reaction to be intermolecular.

In the rearrangement of methyl benzoate, the requirement for equal rates of rearrangement for the two reactants is of little consequence so long as the rates are comparable, since the products and reactants are identical, and the rearrangement can be observed only by using O^{18} labeling.[5] Methyl-C^{13} benzoate was mixed with methyl p-toluate and the mixture was heated to 410° for a time corresponding to about three half-lives for the methyl benzoate rearrangement.

The mass spectra of the methyl-C^{13} benzoate and the product were compared with that of methyl benzoate and methyl toluate giving the data in Table II. Starting with methyl-C^{13} benzoate having 17.9% excess C^{13}, the product methyl toluate had 8.7% excess C^{13} indicating the rearrangement to be intermolecular.

(4) In this and subsequent compounds, the unlabeled material was found to have a C^{13} content very close (±0.2%) to the expected amount (1.1% times the number of carbons). The precision of the results determined from duplicate spectra was also about ±0.2% in the observed values.

The C^{13} content was determined by dividing the $(p + 1)$ peak by the sum of the parent and $(p + 1)$ peaks. In the cases in which cracking was found, this was corrected for by subtracting the product of the intensities of the $(p + 1)$ and $(p - 1)$ peaks divided by 100 from the parent peak before calculating the C^{13} content. Since the observed C^{13} content of the unlabeled compounds was very close to the expected amount, the excess C^{13} in the labeled compounds was taken as the observed C^{13} content less that expected in the unlabeled compound.

In the case of methyl benzoate and methyl toluate, it was shown that the C^{13} found in the product did not arise from an exchange process occurring in the mass spectrometer since the observed C^{13} content of methyl toluate mixed with an equal amount of methyl benzoate having 17.9% excess C^{13} was identical with that of pure methyl toluate.

TABLE II

MASS SPECTRA FOR METHYL BENZOATE REARRANGEMENT

	Reactant Methyl benzoate, ionizing potential 10 v.		Product Methyl p-toluate, ionizing potential 10 v.		
Mass	Labeled	Unlabeled[a]	Mass	Labeled	Unlabeled[a]
135	1.5	1.5	149	0.0	0.5
136	100.0	100.0	150	100.0	100.0
137	36.3	9.4	151	22.8	10.7
% C^{13}	26.7	8.6		18.6	9.7
Excess C^{13}	17.9	0.0		8.7	0.0

[a] Containing the natural abundance of C^{13}.

The product of the rearrangement of methyl N-phenylbenzimidate is of too high molecular weight for a mass spectrometric analysis. Its hydrolysis product is also not desirable since it contains a readily exchangeable hydrogen, and the mass spectrometer had previously been used for the analysis of methanol-d and contained some exchangeable deuteriums adsorbed on its walls. Consequently, the corresponding methyl N-phenylformimidates[6] were used.

Methyl-C^{13} N-(p-tolyl)-formimidate was prepared by treating the silver salt of p-methylformanilide[7] with methyl-C^{13} iodide. Methyl N-(p-ethylphenyl)-formimidate was prepared by the same method, and a mixture of the two esters was rearranged at 300° for four hours. It had been found that either of the esters was about three-quarters decomposed (as indicated by the infrared spectrum) under these conditions. The products were separated from the reactants, and then reduced with lithium aluminum hydride to the N,N-dimethylanilines. This was necessary since the formanilides had too low a vapor pressure to be analyzed directly with the mass spectrometer. The data are given in Table III.

TABLE III

MASS SPECTRA FOR N-PHENYLFORMIMIDATE ESTER REARRANGEMENT

Ionizing potential = 10 v.

Mass	Labeled	Unlabeled[a]
148	1.7	0.8
149	100.0	100.0
150	22.8	12.4
% C^{13}	18.6	11.0
Excess C^{13}	7.5	0.0

[a] Containing the normal abundance of C^{13}.

The methyl-C^{13} N-(p-tolyl)-formimidate was assumed to have the C^{13} content of the alcohol from which it was prepared, 17.8% excess C^{13}. The product N,N-dimethyl-p-ethylaniline was found to contain 7.5% excess C^{13} indicating the rearrangement to be intermolecular.

The rearrangement of α-methoxypyridine to N-methylpyridone was found to proceed in essentially quantitative yield in contrast to previous reports.[8] α-Methoxy-C^{13}-4-methylpyridine was prepared by the reaction of 2-bromo-4-methylpyridine with methoxide-C^{13} ion. The α-methoxy-4-ethylpyridine was prepared in a corresponding manner, and a mixture of the methoxypyridines was heated

to 200° for 14 hours. It had been found that the two methoxypyridines rearranged at essentially the same rate (as indicated by the infrared spectra) and that this length of time gave almost complete reaction. The N-methylpyridones obtained as the product were reduced to the N-methylpiperidones before being analyzed since the latter gave more satisfactory mass spectra. The spectra of the products and the reduced reactants are given in Table IV.

TABLE IV

MASS SPECTRA FOR METHOXYPYRIDINE REARRANGEMENT

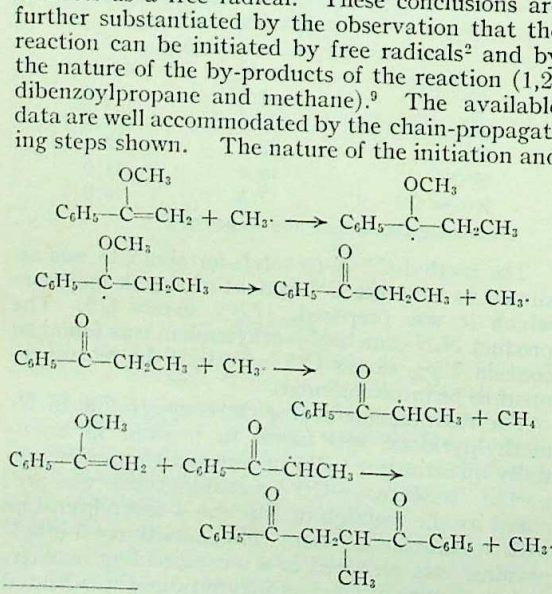
	Reactant α-Methoxy-4-methylpyridine, ionizing potential 7.5 v.		Product N-Methyl-4-ethyl-2-piperidone, ionizing potential 35 v.		
Mass	Labeled	Unlabeled[a]	Mass	Labeled	Unlabeled[a]
126	25.2	26.4	144	20.5	22.8
127	100.0	100.0	145	100.0	100.0
128	30.9	8.4	146	20.4	9.6
% C^{13}	24.8	7.8		17.6	8.9
Excess C^{13}	17.1	0.0		8.8	0.0

[a] Containing the normal abundance of C^{13}.

Starting with α-methoxy-4-methylpyridine containing 17.1% excess C^{13}, the product N-methyl-4-ethyl-2-piperidone was found to contain 8.8% excess C^{13} indicating the reaction to be intermolecular.

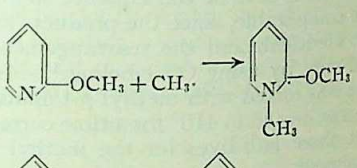
Discussion

The relationship of the above results to the mechanisms of the reactions may now be considered. In the vinyl ether rearrangement, it is known that the migrating group, if optically active, is racemized during the reaction.[2] The rearrangement of α-neopentoxystyrene led to the formation of a ketone without skeletal rearrangement of the migrating group.[2] These data, coupled with the observation of an intermolecular path for the reaction, demonstrate that the migrating group is free at some time during the rearrangement and strongly suggest that it exists as a free radical. These conclusions are further substantiated by the observation that the reaction can be initiated by free radicals[2] and by the nature of the by-products of the reaction (1,2-dibenzoylpropane and methane).[9] The available data are well accommodated by the chain-propagating steps shown. The nature of the initiation and termination steps are not known, although the former possibly involves the decomposition of a hydroperoxide formed by the autoöxidation of the vinyl ether. The kinetics of the rearrangement of α-benzyloxystyrene, a case which gives essentially no by-products, is now being studied.



In contrast to the rearrangement of phenyl N-phenylbenzimidate,[1] the rearrangement of methyl N-phenylformimidate was found to be intermolecular. The yield of rearranged product is quite low (about 40% from the unsubstituted compound and about 20% from the *p*-ethyl or *p*-methyl substituted compounds) and a principal by-product is N,N′-diphenylformamidine.[10] There are no available data on which to base a mechanistic hypothesis for this reaction, although it is possible that it may be similar in nature to the vinyl ether rearrangement. The reason for the difference between the phenyl migration and the alkyl migration has been discussed already.[1]

The rearrangement of 2-methoxypyridine to 2-pyridone also has been found to be intermolecular. This fact, coupled with the observations that the reaction may be catalyzed by benzoyl peroxide and that old samples of 2-methoxypyridine rearrange at a much faster rate than fresh samples (probably due to hydroperoxide formation), suggest that this is also a free radical chain reaction. In contrast to the previously mentioned reactions, this one leads to a nearly quantitative yield of rearranged product with a negligible amount of side reaction. If the radical chain mechanism is correct, it would appear that the attack of a methyl radical on a hydrogen is much less favorable than the attack on nitrogen, in contrast to the vinyl ether rearrangement.



The rearrangement of methyl benzoate, although found to be intermolecular, may be different from the previously discussed rearrangements. A rather high temperature (400°) is required for this reaction, whereas the others proceed at 250° or below. This may indicate a change in mechanism, or may be a consequence of the fact that only the ester cannot form hydroperoxides which may be chain initiators. In the case of methyl toluate, no gas formation was noted, whereas if methyl radicals were formed as an intermediate one might expect that a certain proportion of them would react with the methyl group attached to the ring to give methane and *p*-carbomethoxybenzyl radicals. It is somewhat unlikely that a methylcarbanion or carbonium ion was formed in the reaction.

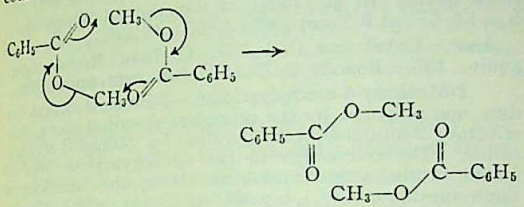
This suggests that the mechanism could involve the formation of an eight-membered cyclic activating complex. This is of course speculation, and a knowledge of the rate law for the reaction would be required before any mechanism for the reaction could be accepted.



Acknowledgment.—We wish to acknowledge the invaluable assistance of Mr. B. J. Nist in obtaining the mass spectra. The work was supported by the Office of Ordnance Research, U. S. Army, and assistance in purchasing certain equipment for the mass spectrometer was given by the Atomic Energy Commission.

Experimental[11]

Methanol-C^{13}.—Methanol-C^{13} was prepared by the lithium aluminum hydride reduction of carbon-C^{13} dioxide using essentially the same procedure as described by Nystrom, Hanko and Brown for the reduction of carbon-C^{14} dioxide.[12] On a tenth-mole scale, 85% of the theoretical amount of methanol was obtained.

Methyl-C^{13} Iodide.—Methanol-C^{13} was converted to the iodide by the procedure previously described for the conversion of methanol-C^{14} to the iodide.[12] On a 0.03-mole scale, 90% of the theoretical amount of methyl-C^{13} iodide was obtained.

α-Methoxy-*p*-ethylstyrene.—To a mixture of 16.3 g. (0.075 mole) of mercuric oxide, 25.0 g. of methanol and 36.5 g. (0.15 mole) of iodine in a glass stoppered bottle cooled in an ice-bath was added, with shaking, 20.0 g. (0.15 mole) of *p*-ethylstyrene (b.p. 74–76° at 15 mm., n^{25}D 1.5364)[13] in 50 ml. of pentane. The bottle was sealed, placed in an ice-bath and shaken for four hours. The reaction mixture was filtered and the precipitated mercuric iodide was washed twice with 10-ml. portions of pentane. The combined pentane solutions were washed with sodium bisulfite solution to remove excess iodine, and then washed with water and dried over anhydrous potassium carbonate.

The pentane was removed under reduced pressure and the residue was treated with a solution of 16.8 g. (0.30 mole) of potassium hydroxide in 78 ml. of 95% ethanol. The reaction mixture was heated to reflux for three hours, and then cooled and filtered; 30 ml. of water was added and the solution was extracted three times with 30-ml. portions of pentane. The combined pentane extracts were dried over potassium carbonate. Distillation gave 13.3 g. (51%) of α-methoxy-*p*-ethylstyrene, b.p. 110° at 12 mm., n^{25}D 1.5334, d^{25} 0.965.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.4; H, 8.7. Found: C, 81.2; H, 8.6.

α-Methoxy-C^{13}-*p*-methylstyrene.—The unlabeled material was prepared by the above procedure substituting *p*-methylstyrene (b.p. 65° at 20 mm., n^{25}D 1.5364) for *p*-ethylstyrene. The methoxy-*p*-methylstyrene had b.p. 94° at 10 mm., n^{25}D 1.5397, d^{25} 0.977, and was obtained in 60% of the theoretical amount.

Anal. Caled. for $C_{10}H_{12}O$: C, 81.0; H, 8.2. Found: C, 80.8; H, 8.4.

To a mixture of 3.5 g. (0.016 mole) of mercuric oxide, 1.0 g. (0.031 mole) of methanol-C^{13} and 7.9 g. (0.062 g. atom) of iodine in a glass stoppered bottle cooled in an ice-bath was added with shaking, 3.7 g. (0.031 mole) of *p*-methylstyrene in 6 ml. of freshly distilled ether. The bottle was sealed with paraffin, and placed in an ice-bath and shaken for four hours. The solution was filtered and the precipitated mercuric iodide was washed with a few ml. of ether. The ether solution was washed with sodium bisulfite solution, water and then dried over anhydrous potassium carbonate.

The ether was removed under reduced pressure and the residue was treated with a solution of 3.5 g. (0.063 mole) of potassium hydroxide dissolved in 16 ml. of 95% ethanol. The mixture was warmed briefly on a steam-bath, and then allowed to stand overnight. The solution was filtered and diluted with 20 ml. of water followed by extraction with three 10-ml. portions of pentane. The pentane extracts were dried over potassium carbonate and distilled giving 2.13 g. (46%) of α-methoxy-C^{13}-*p*-methylstyrene, b.p. 93–94° at 10 mm., n^{25}D 1.5370.

Rearrangement of α-Methoxystyrene.—α-Methoxy-*p*-methylstyrene was found to be slightly less than one-half decomposed (as indicated by the infrared spectrum) after heating for four hours at 220°.

α-Methoxy-*p*-ethylstyrene was found to be slightly less than one-half decomposed after heating for four hours at 220°. In one case the product, *p*-ethylpropiophenone, was isolated (60%), b.p. 112–114° at 10 mm. The oxime had m.p. 57–58° and the 2,4-dinitrophenylhydrazone had m.p. 167° and showed no depression on admixture with an authentic sample.[14]

A mixture of 1.0 g. of α-methoxy-C^{13}-*p*-ethylstyrene and 1.0 g. of α-methoxy-*p*-ethylstyrene was heated in a sealed tube for 2 hours and 45 minutes at 250°. The reaction mixture was distilled, collecting the fraction having b.p. 112–114° at 10 mm. (largely *p*-ethylpropiophenone). This material was analyzed for its C^{13} content giving the data shown in Table I.

***p*-Ethylformanilide.**—To 50 ml. of 90% formic acid was added 25 g. (0.21 mole) of *p*-ethylaniline (b.p. 94–95° at 11 mm., n^{25}D 1.5524)[15] which had been purified *via* the *p*-toluenesulfonamide. The mixture was heated for one hour on a steam-bath. The liquid was poured onto cracked ice and separated and distilled giving 28 g. (96%) of *p*-ethylformanilide, b.p. 132–134° at 0.8 mm., m.p. 42.5–44.2°.

Anal. Calcd. for $C_9H_{11}NO$: C, 72.4; H, 7.4; N, 9.4. Found: C, 72.1; H, 7.4; N, 9.1.

Silver Salt of *p*-Ethylformanilide.—To a filtered solution of 28 g. of *p*-ethylformanilide and 29 g. of silver nitrate in 250 ml. of 50% ethanol was added slowly with stirring at 0°, a solution of 4.9 g. of sodium dissolved in 25 ml. of ethanol. The precipitate was washed by decantation, filtered and dried in a vacuum oven at 85–90°. The dark brown material was ground to a powder and dried over phosphorus pentoxide in an evacuated desiccator. The yield was quantitative.

Methyl N-(*p*-Ethylphenyl)-formimidate.—To 30 g. (0.12 mole) of the silver salt of *p*-ethylformanilide was added 10 ml. (0.16 mole) of methyl iodide and sufficient anhydrous ether to make a paste. The reaction mixture was allowed to stand for one week. The silver iodide was filtered and washed twice with 20-ml. portions of pentane. The combined extracts were concentrated and the residue was distilled giving 10.9 g. (56%) of methyl N-(*p*-ethylphenyl)-formimidate, b.p. 106° at 13 mm., n^{25}D 1.5288.

Anal. Calcd. for $C_{10}H_{13}ON$: C, 73.5; H, 8.0. Found: C, 73.6; H, 8.2.

Methyl-C^{13} N-(*p*-Tolyl)-formimidate.—This compound was prepared by the procedure previously described for the unlabeled compound[16] except that methyl-C^{13} iodide was used instead of methyl iodide. The compound had b.p. 92–93° at 10 mm., n^{25}D 1.5335, and was obtained in 56% of the theoretical amount.

Rearrangement of Methyl N-Phenylformimidates.—Both methyl N-(*p*-tolyl)-formimidate and methyl N-(*p*-ethylphenyl)-formimidate were found to be about three-quarters decomposed (as indicated by the infrared spectrum)

(11) All melting points are corrected; boiling points are not corrected. The mass spectra were obtained using a Consolidated Engineering Corp. model 21-103 mass spectrometer. The analyses were obtained by B. J. Nist.

after heating to 300° for four hours. In each case, the amide was obtained in about 20% yield, whereas the unsubstituted compound gave the amide in approximately 40% yield.

A mixture of 1.25 g. of methyl-C^{13} N-(*p*-tolyl)-formimidate and 1.25 g. of methyl N-(*p*-ethylphenyl)-formimidate was heated in a sealed evacuated tube for four hours at 300°. The reaction mixture was distilled and the fraction having b.p. 132–140° at 10 mm. (largely N-methyl-*p*-ethylformanilide) was collected (0.24 g.). This material was not sufficiently volatile for mass spectrometric analysis, and thus it was treated with 50 mg. of lithium aluminum hydride dissolved in 8 ml. of anhydrous ether and the solution was heated to reflux for three hours. Water was added, and the ether solution was separated and concentrated to a small volume. The solution was distilled in a micro still at 10 mm. with a bath temperature of 135–140° giving 0.05 ml. of N,N-dimethyl-*p*-ethylaniline. The infrared spectrum of this material was identical with that of an authentic sample of N,N-dimethyl-*p*-ethylaniline.[15] The C^{13} content was determined giving the data in Table II.

Methyl-C^{13} Benzoate.—To 0.75 ml. (0.0185 mole) of methanol-C^{13} dissolved in 3.1 g. (0.039 mole) of pyridine was added 2.5 ml. (0.02 mole) of benzoyl chloride, and the resulting mixture was shaken for one-half hour. The reaction mixture was poured into 10 ml. of water and extracted three times with 5-ml. portions of ether. The ether extracts were washed with dilute hydrochloric acid and with water. After drying over potassium carbonate, distillation gave 1.32 g. (53%) of methyl-C^{13} benzoate, b.p. 198–199°, $n^{25}D$ 1.5131.

Rearrangement of Methyl Benzoate.—A mixture of 1.0 g. of methyl-C^{13} benzoate and 1.0 g. of methyl *p*-toluate was heated in an evacuated sealed tube at 410–412° for six hours. The reaction mixture was distilled, and the fraction having b.p. 215–217° (mainly methyl toluate) was collected and analyzed for its C^{13} content. The data are given in Table II.

2-Methoxy-4-ethylpyridine.—A mixture of 99 g. (0.93 mole) of 4-ethylpyridine, 42.5 g. (1.09 moles) of sodium amide and 210 ml. of xylene was heated to reflux for 11 hours. The solution was cooled in an ice-bath and cautiously treated with water, followed by concentrated hydrochloric acid. The aqueous layer was separated and made basic by the addition of potassium hydroxide. The amine was extracted with ether, and isolated by distillation giving 42 g. (37%) 2-amino-4-ethylpyridine, b.p. 140–148° at 20 mm., m.p. 64–66°.[17]

To 210 ml. (1.86 moles) of 48% hydrobromic acid was added 40 g. (0.33 mole) of 2-amino-4-ethylpyridine. The solution was cooled to 0° and 64 ml. (1.25 moles) of bromine was added with stirring. A solution of 73 g. (1.16 moles) of sodium nitrite in 100 ml. of water was then added over a period of 90 minutes, maintaining the temperature between 5–10°. After an additional 30 minutes, a solution of 160 g. (4.0 moles) of sodium hydroxide in 150 ml. of water was added with cooling. The amine was extracted with ether, and the ether solution was dried over potassium hydroxide and distilled giving 41.7 g. (62%) of 2-bromo-4-ethylpyridine, b.p. 124–125° at 28 mm., $n^{25}D$ 1.5511, d^{25} 1.425.

(17) German Patent 398,204 (*Chem. Zent.*, **95**, **II**, 1409 (1924)) reported b.p. 134–139° at 14 mm., m.p. 68–69°.

Anal. Calcd. for C_7H_8NBr: C, 45.2; H, 4.3. Found: C, 45.1; H, 4.5.

A solution of 20 g. (0.097 mole) of 2-bromo-4-ethylpyridine and 8.1 g. (0.150 mole) of sodium methoxide in 120 ml. of *t*-butyl alcohol was heated to reflux for 6 hours. Most of the *t*-butyl alcohol was then removed by distillation. The solution was filtered and the precipitate of sodium bromide was washed with ether. The combined filtrates were distilled giving 10 g. (75%) of 2-methoxy-4-ethylpyridine, b.p. 66–67° at 9.5 mm., $n^{25}D$ 1.4970, d^{25} 1.001.

Anal. Calcd. for $C_8H_{11}NO$: C, 70.0; H, 8.1; neut. equiv., 137. Found: C, 70.1; H, 8.3; neut. equiv., 139.

2-Methoxy-4-methylpyridine.—2-Bromo-4-methylpyridine was prepared by the procedure described above, substituting 2-amino-4-methylpyridine for 2-amino-4-ethylpyridine. The conversion to the methoxypyridine was effected in the same manner as above, and 2-methoxy-4-methylpyridine (65%), b.p. 67° at 21 mm., $n^{25}D$ 1.5021 was obtained. The 2-methoxy-C^{13}-4-methylpyridine was obtained in the same manner.

Anal. Calcd. for C_7H_9NO: C, 68.3; H, 7.4. Found: C, 68.1; H, 7.5.

Rearrangement of Methoxypyridines.—Both 2-methoxy-4-methylpyridine and 2-methoxy-4-ethylpyridine were found to be one-third rearranged (as indicated by the infrared spectrum) after heating at 210° for 4.5 hours in a sealed tube. The rearrangement of 1.0 g. 2-methoxy-4-methylpyridine at 210° for 20 hours gave 0.9 g. of N-methyl-4-methylpyridone, m.p. 56–59°; hydrochloride, m.p. 169–171°; picrate, m.p. 167–168°.[18]

The rearrangement of 1.2 g. of 2-methoxy-4-ethylpyridine at 210° for 20 hours gave 0.98 g. of N-methyl-4-ethyl-2-pyridone, b.p. 152° at 14 mm., $n^{25}D$ 1.5462; hydrochloride, m.p. 129–130°; neut. equiv. calcd. 174; found 175; picrate, m.p. 132.5–133.0°.

Anal. Calcd. for $C_{14}H_{14}N_4O_8$: C, 45.9; H, 3.9. Found: C, 46.2; H, 4.2.

The rearrangement of a mixture of 0.6 g. of 2-methoxy-C^{13}-4-methylpyridine and 0.6 g. of 2-methoxy-4-ethylpyridine was effected at 200° for 14 hours. Since the pyridones did not give good mass spectra, the crude product was reduced with platinum and hydrogen in dilute aqueous hydrochloric acid solution giving the corresponding piperidones.[19] The fraction (0.3 g.) having b.p. 115–118° at 13 mm. (largely N-methyl-4-ethyl-2-piperidone, b.p. 117–121° at 12 mm., $n^{25}D$ 1.4755) was collected and analyzed for its C^{13} content, giving the data in Table IV.

Peroxide Catalysis of 2-Methoxy-4-methylpyridine Rearrangement.—A mixture of 0.5 g. (4.06 mmoles) of 2-methoxy-4-methylpyridine and 22.6 mg. (0.1 mmole) of benzoyl peroxide was heated to 165° for 22.5 hours giving an essentially quantitative yield of N-methyl-4-methylpyridone, m.p. 54.5–57.5°, and which did not depress the m.p. of an authentic sample on admixture. In the absence of benzoyl peroxide, less than one-quarter of complete rearrangement was observed.

SEATTLE 5, WASH.

(18) R. Adams and A. W. Schrecker, THIS JOURNAL, **71**, 1186 (1949), reported m.p. 59°; hydrochloride, m.p. 173–174°; picrate, m.p. 168–169°.

(19) The procedure was essentially that described by T. B. Grave, *ibid.*, **46**, 1470 (1924).

The Ozonolysis of Indene in Ethanol

BY JOSEPH L. WARNELL[1] AND R. L. SHRINER

RECEIVED AUGUST 9, 1956

The use of ethanol as a solvent for selective ozonolysis has been explored using indene. No true ozonide was isolated: the product has been shown to be 3-hydroxy-4,5-benzo-7-ethoxy-1,2-dioxacycloheptane. Its structure was established by conversion to 3,7-diethoxy-4,5-benzo-1,2-dioxacycloheptane, homophthalic acid, homophthaldehyde, homophthalyl alcohol, *o*-carboxyphenylacetaldehyde and 1-isochromanone.

The cleavage of olefins by ozone is usually carried out in two steps: reaction with ozone in an inert solvent to form ozonides and subsequent oxidation or reduction in the presence of water or acetic acid. Since ozonides are somewhat unstable,[2] have variable composition,[3] form polymeric ozonides,[4,6] disproportionate,[5] and because occasionally other oxidations occur during the reaction of olefins with ozone–oxygen mixtures,[2–4] ozonolyses have been carried out in glacial acetic acid which presumably reacts with the ozonide as soon as it is formed; however, the primary reaction product has not been characterized.

Until recently, alcohols have seldom been employed as solvents for ozonizations because of their ease of oxidation.[6,7] However, methanol has been used by a number of investigators[8–10] and also a *t*-butyl alcohol–sulfuric acid medium has been employed in studies on the mechanism of ozonolysis.[11]

In the present work, the use of absolute ethanol as a solvent for ozonolysis was found to be possible because passage of a stream of 3% ozone in oxygen through 500 ml. of absolute ethanol for one hour at 0–5° produced less than 0.1 mole of acetic acid, 0.03 mole of peroxide and 0.01 mole of acetaldehyde. This slight attack made it possible to explore the use of ethanol as a solvent, using an olefin, indene, which reacted rapidly and selectively with 3% ozone.

Ozonolysis of 0.1 mole of indene in absolute ethanol at 0–5° was complete in one hour; removal of the alcohol left a 99% yield of a white, non-explosive compound melting at 105–108°. Analytical data gave the formula $C_{11}H_{14}O_4$ and showed one ethoxyl group and one peroxide grouping. Infrared analysis indicated the presence of a hydroxyl group and an acetal linkage but the complete absence of any carbonyl. No oxygen was liberated when this product was treated with lead tetraacetate which indicates that the peroxide grouping is not –OOH but must be of the ROOR type.[12] The most probable structure is shown by formula I which is analogous to the structure assigned by Bailey[9] to the product obtained by ozonolysis of phenanthrene in methanol. This structure also provides a reasonable explanation of the degradation products shown in Chart I.

The acid-catalyzed reaction of I with ethanol yielded the diethoxy compound II. Alkali converted both compounds I and II to *o*-carboxyphenylacetaldehyde (VIII). The structure of the latter was shown by: (a) solubility in dilute alkali, (b) positive Benedict test, (c) formation of a monosemicarbazone, and (d) reduction of the aldehyde group to the alcohol by means of either sodium borohydride or aluminum isopropoxide and loss of water to yield the lactone, 1-isochromanone (IX). The properties of the latter agreed with those given by Wegler and Frank[13] but differed from the properties of 3-isochromanone prepared by Murahashi.[14] The formation of IX shows that the carboxyl group of VIII is attached to the ring and not to the side chain.

The oxidation of both peroxy compounds I and II with hydrogen peroxide produced homophthalic acid (III) in good yield. The homophthalic acid was identified by converting it into 1,3(2,4)-isoquinolinedione[15] by heating its ammonium salt.

Reduction of the peroxide I with zinc dust and a trace of acetic acid at room temperature produced homophthalaldehyde[16] (IV), an oil, which was characterized by the formation of its bis-*p*-nitrophenylhydrazone. This dialdehyde IV when treated with zinc dust and acetic acid at 80° was further reduced to *o*-hydroxymethylphenylacetaldehyde (V). Reduction of the hydroperoxide I with lithium aluminum hydride in ether produced a nearly quantitative yield of homophthalyl alcohol[17] (VI). This compound on refluxing with a trace of sulfuric acid was converted completely into isochroman[17] VII.

This use of ethanol as a solvent for ozonolysis not only avoids the handling of explosive ozonides but also furnishes a stable intermediate I valuable for the synthesis of compounds IV through IX which are otherwise difficult to obtain.

Experimental

3-Hydroxy-4,5-benzo-7-ethoxy-1,2-dioxacycloheptane (I).—The indene was purified by fractionally distilling it twice

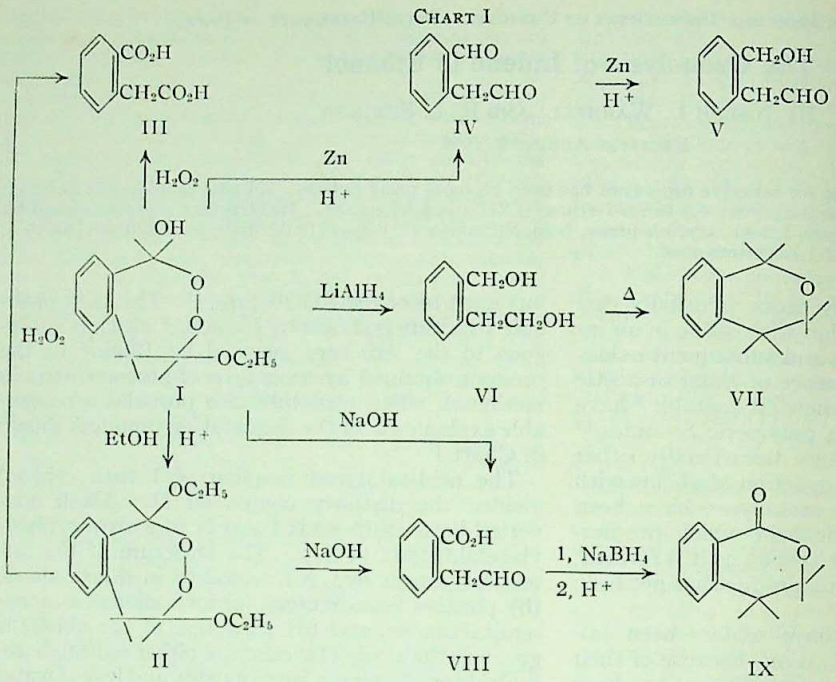
CHART I



at 10 mm. pressure, and storing it at −3° until used. A solution of 11.6 g. (0.1 mole) of indene in 500 ml. of anhydrous ethanol was cooled in an ice-bath and a 3% stream of ozone in oxygen was passed through the solution for 55 minutes. When the ozonization was carried out under the above conditions, only a trace of unreacted ozone passed through the ethanol into the potassium iodide trap during the reaction. The potassium iodide trap was changed once or twice during the experiment and thus the end-point of the reaction was easily detectable by the sudden liberation of iodine in the trap. The flow rate of ozonized oxygen was 80 l./hr.

The peroxide I was isolated by concentrating the ethanol solution to dryness under vacuum at room temperature. The weight of white, solid, amorphous product was 21 g. (99%), m.p. 105–108° (softens 95–105°). The product was not crystalline but was similar to paraffin wax in appearance. It did not decompose explosively when subjected to a variety of thermal and physical shocks.

Analysis of the peroxide I for active oxygen was carried out by the following method. The peroxide, approximately 0.001 mole, was dissolved in 25 ml. of glacial acetic acid, and 2 g. of potassium iodide and 1 ml. of concentrated hydrochloric acid were added. The solution was warmed to 50–70° for 10 minutes, poured into 400 ml. of water and the liberated iodine titrated with standard sodium thiosulfate solution. Infrared absorption curves obtained in Nujol paste showed a peak at 3.05 μ and broad peaks at 9.30 and 9.65 μ.

Anal. Calcd. for $C_{11}H_{14}O_4$: C, 62.84; H, 6.71; active oxygen, 7.61; ethoxyl, 21.4; mol. wt. 210.2. Found: C, 63.17; H, 6.56; active oxygen, 7.53; ethoxyl, 21.0; mol. wt. (cryoscopic), 214.

The Criegee[12] lead tetraacetate test for the hydroperoxy grouping was carried out by treating 1 g. of the compound I in 25 ml. of glacial acetic acid with 3 g. of lead tetraacetate in 50 ml. of glacial acetic acid. No evolution of oxygen occurred. Control tests with peracetic acid and ethyl hydroperoxide were positive.

CAUTION: Absolute ethanol has been used satisfactorily as a solvent in over 25 ozonolyses without the formation of explosive products. However, only a dilute (3%) stream of ozone in oxygen, and temperatures of 0–5° have been employed for selective ozonolyses of olefins. Use of 9–10% ozone leads to attack of aromatic nuclei and more concentrated ozone–oxygen mixtures should be investigated with great caution.[18]

(18) M. L. Kilpatrick, C. C. Herrick and M. Kilpatrick, THIS JOURNAL, 78, 1784 (1956).

During the ozonolysis the exit gases from the reaction flask appeared as a dense white smoke. The amount of smoke produced can serve as a method for following the progress of the reaction; as the concentration of unreacted olefin in the solvent decreases so does the volume of smoke produced. When vapors of indene at 182° were mixed with a stream of 3% ozone in oxygen, again copious amounts of dense white colloidal particles were produced. These may possibly arise from the polymerization of intermediates in the vapor phase. These colloidal particles could not be removed from the gas stream by either a Dry Ice trap or by passing the vapors through various solvents. The colloidal particles were removed from the gas stream by a small copper grid charged to approximately 25,000 volts with a Tesla coil. The actual weight of material in the smog was too small to permit purification and identification.

3,7-Diethoxy-4,5-benzo-1,2-dioxacycloheptane (II).—To a solution of 21 g. (0.1 mole) of the peroxide I in 500 ml. of anhydrous ethanol was added 3 drops of concentrated sulfuric acid. The anhydrous solution was kept at room temperature for 24 hours and the solution was evaporated to dryness under vacuum. The precipitate was filtered, washed with water and after recrystallization from either acetone or glacial acetic acid, there resulted 15.5 g. (65%) of white needles, m.p. 80–81°.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61; active oxygen, 6.72; ethoxyl, 37.8. Found: C, 65.42; H, 7.41; active oxygen, 6.72; ethoxyl, 37.3.

Homophthalic Acid (III).—To a solution of 3.0 g. of the peroxide I in 20 ml. of acetic acid was added 30 ml. of 15% hydrogen peroxide. After warming to 60° for 10 hours the mixture was concentrated to 20 ml. by boiling and upon cooling, crystals of homophthalic acid separated. Recrystallization from acetic acid gave 1.6 g. of material, m.p. 180°. Homophthalic acid also was obtained from the diethoxy compound II under similar conditions.

For the large-scale preparation of homophthalic acid it was preferable to carry out the ozonization reaction in glacial acetic acid. The acetic acid was removed under vacuum leaving a non-explosive viscous colorless sirup.

This sirup could not be obtained analytically pure. However, the gain in weight corresponded to the combination of one mole of indene with one mole of ozone plus one mole of acetic acid. It contained approximately one peroxy group and one acetoxy group indicating that this product of ozonolysis in acetic acid may be an acetoxy derivative analogous to compound I. Treatment of the sirup with hot aqueous sodium carbonate and hydrogen peroxide followed by acidification gave an 82% yield of homophthalic acid, m.p. 180°. The latter was identified by conversion to 1,3-(2,4)-isoquinolinedione, m.p. 233°, by heating the ammonium salt as described by Buu-Hoi.[15] Both compounds I and II were also converted to homophthalic acid by refluxing with dilute nitric acid for one hour.

Homophthalaldehyde (IV).—A solution of 21 g. (0.1 mole) of compound I in 500 ml. of ethanol, 50 ml. of water and 15 ml. of acetic acid was vigorously stirred while 10 g. of zinc dust was added in 1-g. amounts approximately every six minutes. After one hour the reaction mixture was filtered to remove the zinc dust and evaporated to dryness under vacuum. The residue, a yellow gum, was mixed with 50 ml. of water and ether extracted. The ether layer was washed with dilute sodium carbonate solution and dried over sodium carbonate. Evaporation of the ether gave homophthalaldehyde, 14.5 g. (98%), as a yellow oil. This aldehyde is very unstable since it undergoes self-condensation.

Digitized by Arya Samaj Foundation Chennai and eGangotri

It was identified as homophthalaldehyde by treating 1 g. of the oil with excess *p*-nitrophenylhydrazine and isolating the bis-*p*-nitrophenylhydrazone derivative in quantitative yield. Recrystallization from 80% ethanol gave orange crystals, m.p. 220–221°. The literature[16] listed the m.p. as 185–190°; hence an elemental analysis was obtained.

Anal. Calcd. for $C_{21}H_{18}N_6O_4$: C, 60.28; H, 4.34; N, 20.09. Found: C, 60.29; H, 4.39; N, 19.83.

o-**Hydroxymethylphenylacetaldehyde** (V).—A solution of 14.8 g. (0.1 mole) of homophthaldehyde in 100 ml. of ethanol was stirred vigorously with 200 ml. of 50% acetic acid and an excess of zinc dust for 2 hours at 80°. The zinc dust was added in 1-g. quantities to maintain a constant suspension in the solution. The mixture was filtered and evaporated to dryness under vacuum leaving a yellow gum. This was mixed with 100 ml. of water and ether extracted. The ether solution was washed with dilute sodium carbonate solution and dried over sodium carbonate. Upon evaporation of the ether, *o*-hydroxymethylphenylacetaldehyde was obtained as a yellow oil, b.p. 116–120° (5 mm.), $n^{25}D$ 1.5240.

Anal. Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71. Found: C, 72.03; H, 7.22.

Homophthalyl Alcohol (VI).—To a solution of 20 g. of lithium aluminum hydride in 200 ml. of ether was slowly added 21 g. (0.1 mole) of the peroxide I over a 30-min. period. The solution was vigorously stirred under reflux for an additional 20 minutes and water was added slowly to decompose the excess lithium aluminum hydride. The solution was acidified with 25% sulfuric acid, and the water and ether layers were separated. The water solution was ether extracted with an additional 200 ml. of ether and the ether extracts were combined, washed with dil. sodium carbonate solution, and dried over sodium carbonate. Removal of the ether under vacuum gave 14.5 g. (95%) of colorless oil of homophthalyl alcohol.[17] Identification of the oil was carried out by treating 1 g. of the oil with excess *p*-nitrobenzoyl chloride in pyridine to form the di-*p*-nitrobenzoate derivative, m.p. 134–135°.

Anal. Calcd. for $C_{23}H_{18}O_8N_2$: C, 61.33; H, 4.03; N, 6.22. Found: C, 61.36; H, 4.32; N, 6.24.

Isochroman VII.—The distillation of homophthalyl alcohol at 70° (3 mm.) with a drop of sulfuric acid gave a nearly quantitative yield of isochroman and water. Redistillation yielded a fraction boiling 69–70° at 3 mm. The isochroman[17] was a colorless liquid; m.p. 3–4°, $n^{20}D$ 1.5422, d^{25}_4 1.0707.

Anal. Calcd. for $C_9H_{10}O$: C, 80.56; H, 7.51. Found: C, 80.42; H, 7.26.

o-**Carboxyphenylacetaldehyde** (VIII).—A solution of 21 g. (0.1 mole) of the peroxide (I) in 200 ml. of ethanol was warmed with 200 ml. of 5% sodium hydroxide solution. The mixture turned a dark red as an exothermic reaction occurred and the temperature rose to 50°. The alkaline solution was kept at this temperature for 20 minutes, acidified with acetic acid, and concentrated to a viscous oil under vacuum. The oil was dissolved in ether and extracted with cold 1 *N* sodium hydroxide. Careful neutralization of the alkaline solution with dilute acetic acid precipitated yellow crystals of *o*-carboxyphenylacetaldehyde, 14.7 g. (90%), m.p. 130–140°. This substituted phenylacetaldehyde is unstable and the melting point decreased with standing and the compound finally became an oil. This probably accounts for the range of melting and for the fact that the m.p. observed in this work is higher than that previously reported by Schopf and Kuhne.[19] The semicarbazone derivative melted sharply at 209–210° and analyzed correctly.

Anal. Calcd. for $C_{10}H_{11}N_3O_3$: C, 54.29; H, 5.01; N, 19.00. Found: C, 54.28; H, 5.06; N, 19.34.

The compound VIII differed from the known isomeric *o*-formylphenylacetic acid[20] whose semicarbazone melts at 220°.

1-Isochromanone (IX).—A solution of 16.4 g. (0.1 mole) of *o*-carboxyphenylacetaldehyde in 200 ml. of isopropyl alcohol was refluxed with 400 ml. of isopropyl alcohol and 82 g. (0.4 mole) of aluminum isopropoxide for 9 hours. The apparatus was arranged with a fractionating column which permitted the slow distillation of acetone and isopropyl alcohol (200 ml.) during the reaction. The solution was evaporated to dryness under vacuum, mixed with 200 ml. of 6 *M* sulfuric acid, and ether extracted. The ether extract was washed with water, dried over sodium sulfate, and evaporated under vacuum. The residue, a yellow oil, was vacuum distilled to yield 12 g. (79%) of 1-isochromanone, b.p. 148–150° (5 mm.), $n^{25}D$ 1.5622, d^{25}_4 1.1996; Wegler and Frank[13] report a b.p. of 165° (16 mm.).

Reduction of *o*-carboxyphenylacetaldehyde with excess sodium borohydride in water at 30–40° also gave 1-isochromanone in 40% yield.

Anal. Calcd. for $C_9H_8O_2$: C, 72.96; H, 5.44. Found: C, 72.44; H, 5.21.

Acknowledgment.—The authors wish to thank Dr. Philip S. Bailey for valuable suggestions in interpreting these results.

Tetrachloroisoindolines and Related Systems. Alkylation Reactions and Inductive Effects[1]

BY WILLIAM E. ROSEN, VIRGINIA P. TOOHEY AND ANTHONY C. SHABICA

RECEIVED DECEMBER 13, 1956

The basicity of an isoindoline nitrogen atom is profoundly affected by inductive factors. Four chlorine atoms on the four available positions of the benzene ring or a positively charged nitrogen atom β to the isoindoline nitrogen decrease the reactivity of the isoindoline nitrogen toward alkylation. These effects cannot be results of resonance interaction and are, therefore, either steric (unlikely) or inductive (most probable). These conclusions, based on observations of alkylation behavior under certain conditions, are supported by pK_a determinations which are consistent with relative basicities of model amines. Stabilities of quaternized nitrogens, especially those with bromoethyl substituents, are also discussed.

The interesting physiological action of the ganglionic blocking agent 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-isoindoline dimethochloride (VIIb)[2] has focused attention on the tetrachloroisoindoline system itself. Although isoindolines have been considered[3] typical amines, the alkylabe extended to related isoindolines, is 4,5,6,7-tetrachloro-2-methyl-2-(2-trimethylammonioethyl)-isoindolinium dichloride. The term "ammonio" was originally proposed by J. F. Bunnett and co-workers [*Chem. Revs.*, **49**, 291 (1951); THIS JOURNAL, **75**, 642 (1953)]. It has also been mentioned in A. M. Patterson's column on Nomenclature in *Chem. Eng. News*, **32**, 2320 (1954); **33**, 5262 (1955). It is used in this paper for the tetrasubstituted terminal nitrogen.

tion behavior of the 2-substituted isoindolines proved to be of considerable interest. Rice and coworkers have prepared[4,5] 2-dialkylaminoalkylisoindolines and 2-methylisoindolines, characterizing these compounds as hydrochlorides, picrates and methiodides. The work described in this paper contrasts the alkylation behavior of 2-substituted isoindolines and 2-substituted *tetrachloro*isoindolines.

Methyl iodide is, of course, a better alkylating agent than methyl chloride. 2-Methylisoindoline[5,6] (Ia) and 4,5,6,7-tetrachloro-2-methylisoindoline (Ib) were both alkylated readily by methyl iodide under mild conditions. With methyl chloride, however, a difference in the reactivity of the isoindoline and the tetrachloroisoindoline was evident. Gaseous methyl chloride quaternized 2-methylisoindoline (Ia) completely in chloroform or in hot dimethylformamide solution giving the methochloride salt IIa. Tetrachloro-2-methylisoindoline (Ib), on the other hand, was little affected by methyl chloride in chloroform, although in hot dimethylformamide it was converted to the methochloride IIb in 79% yield.

2-Methylisoindoline (Ia) and ethylene dibromide, in refluxing acetone, gave a bromoethyl salt IIIa in which only one end of the molecule had reacted; it has been reported[5] that no bis-salt IVa forms even when a large excess of base is used. The tetrachloro compound Ib, on the other hand, was completely unaffected under these conditions. It was possible to get 50–60% yields of the tetrachloroisoindolinium bromide IIIb but only at considerably higher temperatures. Under such conditions, a small amount (8%) of the symmetrical dibromide IVb was also isolated.

Although the tetrachloroisoindoline Ib was completely unreactive toward refluxing ethylene dichloride, 2-methylisoindoline (Ia) did form a small amount of 2-(2-chloroethyl)-2-methylisoindolinium chloride; this is consistent with the greater activity of the unchlorinated isoindoline nitrogen toward ethylene dibromide.

When the 2-substituent was dimethylaminoethyl, the contrast between isoindoline and tetrachloroisoindoline was even more striking. With the unchlorinated 2-dimethylaminoethylisoindoline (Va) practically no dimethochloride VIIa formed under the mild conditions of chloroform reflux. This was in contrast to the ready quaternization of 2-methylisoindoline (Ia). In hot dimethylformamide, the unchlorinated dimethylaminoethylisoindoline (Va) formed an approximately 1:1 mixture of monomethochloride VIa and dimethochloride VIIa. Under the same conditions, the tetrachloroisoindoline nitrogen was little affected; the monomethochloride VIb[7] was isolated in over 90% yield. In order to get a satisfactory conversion to the dimethochloride VIIb with the tetrachloroisoindoline compound Vb, it was necessary to go to higher pressures.

These alkylation experiments indicate that four chlorine atoms on the benzene ring decrease the basicity of the isoindoline nitrogen. The effect cannot be one of resonance interaction and is not likely to be steric. It therefore appears to be an *inductive* effect. A positively charged nitrogen atom β to the isoindoline nitrogen likewise decreases the reactivity of the isoindoline nitrogen. This decrease is also attributable to inductive factors. These conclusions are supported by pK_a determinations.

As may be seen from Table I, the inductive effect of the aromatic chlorines decreases the basicity of the isoindoline nitrogen almost a thousand-fold (pK_a from 7.7 to 4.8). Replacing the methyl substituent with a group having a β-ammonio cation decreases the basicity about four thousand-fold (pK_a from 7.7 to 4.1). When both influences are present, the basicity is decreased by a factor of about 50,000 to 65,000 (pK_a from 7.7 to 2.9–3.0). A β-ammonio cation decreases basicity one thousand-fold compared with a β-amino group (terminal nitrogen pK_a from 8.2–8.4 to 5.3). Similar inductive effects[8] are known for simple amines. The base strength of the amine nitrogen of ethylenediamine is one thousand times greater than that of ethylenediamine monoacid salt,[11] but it is only about one-fourth as strong as alkylamines[10-12]; benzylamine is a weaker base than either ethylamine (35-fold) or isobutylamine (13-fold).[12] It is interesting that the effect of the β-ammonio cation

(8) The term "inductive effect" in this paper is meant to include any contribution made by the so-called "direct field effect."[9,10] Although the "direct field effect" has been shown to be considerable with cyclic amines, accounting for one-half[9] or more[10] of the total effect, proportions cannot be assigned in the examples discussed here. The inductive effect of the aromatic system on the isoindoline nitrogen probably has a large "direct field" component, whereas the "direct field effect" of the linear β-ammonio cation is probably small.

is about the same whether the cation be a quaternary salt or an acid salt.

A series of reactions starting with 4,5,6,7-tetrachloro-2-methylisoindoline (VIII) showed some additional aspects of the chemistry of the isoindoline nitrogen. Bromoethyltrimethylammonium bromide, prepared from ethylene dibromide and trimethylamine, reacted with 4,5,6,7-tetrachloro-2-methylisoindoline (VIII) in refluxing dimethylformamide to give two products. The major product, isolated in 57% yield, was the transquaternized methobromide salt X. The other product, isolated in 7% yield, was 4,5,6,7-tetrachloro-2-(2-trimethylammonioethyl)-isoindoline bromide (IX). This monomethobromide IX was identical with that prepared from monomethochloride VIb by halide exchange. The monomethochloride VIb was formed, as mentioned above, from 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-isoindoline (Vb) and methyl chloride gas. The monomethobromide IX was further quaternized by methyl chloride to only a small extent but gave in good yield the diquaternary salt XI with methyl bromide.[13] Evidently the first-formed dimethobromide from VIII and bromoethyltrimethylammonium bromide dequaternized under the reaction conditions. When dimethobromide XI was subjected to these conditions, about 80% monomethobromide IX was isolated.[14] Attempts to isolate the first-formed dimethobromide under these or milder conditions were unsuccessful.

An alkylation which went through the other monomethobromide XIV led to the same dibromide. 4,5,6,7 - Tetrachloro - 2 - methylisoindoline (VIII) and bromoethyldimethylammonium bro-

TABLE I

pK_a VALUES OF ISOINDOLINE BASES (IN 80% METHYL CELLOSOLVE)

Isoindoline base			
X		R	pKa
			9.0
	H	CH_3	7.7
	Cl	CH_3	4.8
	H	$CH_2CH_2\overset{+}{N}H(CH_3)_2Cl^-$	4.1 (8.4)[a]
	Cl	$CH_2CH_2\overset{+}{N}H(CH_3)_2Cl^-$	2.9 (8.2)[a]
	Cl	$CH_2CH_2\overset{+}{N}(CH_3)_3Cl^-$	3.0
	Cl	$CH_2CH_2—N(CH_3)_2$	(5.3)[a]

[a] Figure in parentheses is pK_a of the second nitrogen.

(13) The dimethobromide XI can be prepared directly by the diquaternization of tetrachloro-2-(2-dimethylaminoethyl)-isoindoline (Vb) with methyl bromide in hot dimethylformamide (G. A. Nussberger, unpublished work).

(14) The same treatment of dimethochloride VIIb and dimethiodide gave 95% and 75% monomethobromide, respectively.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

mide[15] in warm dimethylformamide gave 65% of the 2-methyl hydrobromide salt XIII. A 10% yield of the expected monomethobromide monohydrobromide salt XII also was obtained. The monomethobromide-free base XIV corresponding to XII was different from the monomethobromide IX, which was the more stable monomethobromide. Since the monomethobromide XIV is the less stable of the two possible isomers, it must be, in fact, the expected product, *i.e.*, quaternized at the isoindoline nitrogen. As expected for the monomethobromide quaternized at the less reactive nitrogen, methyl chloride, in the presence of sodium acetate, *was* capable of converting XII to a dimethohalide. Methyl bromide, with sodium acetate, gave the dimethobromide XI.

In both of these alkylation reactions of VIII, the major product resulted from abstraction of a group from the bromoethylammonium salt. This was surprising at first, because the isoindoline nitrogen is a much weaker base than a tertiary amine. On the other hand, 4,5,6,7-tetrachloro-2-(2-bromoethyl)-2-methyl isoindolinium bromide (IIIb) was dequaternized in 83% yield by trimethylamine. Evidently the basicity of the nitrogens is not the important factor. In all three cases the nitrogen which was readily dequaternized had a bromoethyl substituent. Bromoethylamine formation may be favored because of its ability to react further as a nitrogen mustard, to give an ethyleneimmonium salt (XV)[17] (or possibly to give a piperazinium salt[15]).

Hydration.—The quaternized terminal nitrogen of XI, rather than the quaternized isoindoline nitrogen, seems to be responsible for hydration. The analytical sample of the monomethobromide IX was monohydrated, but that of XIV was anhydrous. For XVI, the analytical data indicate no hydration when R = CH_3, CH_2CH_2Br, or $CH_2CH_2N(CH_3)_2$, hemihydration when R = H, monohydration when R = $CH_2CH_2\overset{+}{N}(CH_3)_2Br^-$ (and also for IVb) and dihydration when R = $CH_2CH_2\overset{+}{N}H(CH_3)_2Br^-$. The tendency of salts for hydrate formation was found to be chloride salt > bromide salt > iodide salt. Chloride salts were either deliquescent or hygroscopic, bromide salts were sometimes hygroscopic and iodide salts, once dried, remained anhydrous.

Acknowledgment.—The authors are pleased to acknowledge the helpful discussions and coöperation of their many co-workers in the CIBA Research Department. We are also indebted to Mr. Louis Dorfman, head of our Microanalytical Group, and his staff for various determinations and for discussions of technical matters. Microanalyses were carried out by Mr. George Robertson, Mrs. Barbara Pita and Miss June Swantko, infrared absorption spectra by Mrs. Violet Loire and Miss Margaret Jones; and ultraviolet absorption spectra by Miss Natalie Cahoon. We thank Dr. M. J. Allen and Miss Verda Powell for the electrometric titrations.

Experimental[18]

N-(2-Dimethylaminoethyl)-phthalimide.—To a stirred suspension of 35.0 g. (0.236 mole) of phthalic anhydride in 350 ml. of acetic acid was added 27.0 g. (0.242 mole) of 77% dimethylaminoethylamine[19] dropwise over 30 minutes. The colorless solution was refluxed for 4 hr. (yellow color developed), the bulk of the solvent was removed *in vacuo* and the concentrated solution was made basic by slow addition of 15% ammonium hydroxide solution with stirring and cooling. The white solid which separated was collected, washed once with water and dried *in vacuo* at 70°, giving 31.0 g. (60%) of N-(2-dimethylaminoethyl)-phthalimide, m.p. 103–105°. Recrystallization from hexane (charcoal) gave 27.2 g. (53%) of white crystals, m.p. 104–106.5°, R_f 0.52.[20] The imide carbonyl groups absorbed at 1770 cm.$^{-1}$

(15) An attempt was made to alkylate 4,5,6,7-tetrachloro-2-methylisoindoline (VIII) with the tosylate of dimethylaminoethanol. When tosyl chloride and 2-dimethylaminoethanol were combined in pyridine in an attempt to form the tosylate, and VIII was added, the isoindoline was recovered and some 1,1,4,4-tetramethylpiperazinium dichloride was isolated. When tosyl chloride was added to a dioxane solution of VIII and 2-dimethylaminoethanol, the acid generated resulted in formation of salts (hydrochloric or *p*-toluenesulfonic acid salts) of VIII. In a run using excess VIII in the presence of excess sodium bicarbonate, 1,1,4,4-tetramethylpiperazinium ditosylate was isolated. Evidently dimerization of 2-dimethylaminoethyl tosylate (or chloride) occurred more rapidly than did alkylation of VIII, thereby permitting isolation of starting VIII (or its chloride or tosylate salt) and piperazinium dichloride or ditosylate, depending on the reaction conditions. Dimethylaminoethyl chloride itself is known to dimerize rapidly to 1,1,4,4-tetramethylpiperazinium dichloride.[16]

(18) Melting points were taken on an electrically heated aluminum block in open capillaries and are uncorrected. Infrared absorption spectra were determined on a double-beam Perkin-Elmer model 21 infrared spectrophotometer using a sodium chloride prism. Ultraviolet absorption spectra were determined on a Beckman DK-1 spectrophotometer. Analytical samples were dried at water-pump vacuum over Drierite at 75° for 3–5 hr. and then permitted to equilibrate in air of 40–45% relative humidity at 23°, unless otherwise specified. All *pKa* values were determined in 80% methyl Cellosolve solutions. Melting points of methohalide salts were not reliable indices of purity or identity. Samples varied in decomposition range depending on the method of preparation, the age of the sample, solvation, etc. Mixtures of different salts frequently did not show a depression of melting point.

(m) and 1709 cm.$^{-1}$ (s) in the infrared. Moore and Rapala[22] reported m.p. 104–105° for imide prepared in 2.5% yield from equimolar amounts of phthalic anhydride and dimethylaminoethylamine (oil-bath 160–180°, 1 hr.).

N-(2-Dimethylaminoethyl)-3,4,5,6-tetrachlorophthalimide.—The tetrachlorophthalimide, m.p. 183–185°, was prepared in 85% yield by the method described above (refluxed 4 hr. in acetic acid). Two crystallizations from chloroform gave yellow prisms, m.p. 183–186°, R_f 0.70; λ_{max}^{EtOH} 288 mμ (ε 570), 298 (shoulder, 540), 322–328 (190), 333–335 (200). The infrared absorption spectrum showed a medium band at 1774 cm.$^{-1}$ and a strong band at 1707 cm.$^{-1}$.

Anal. Calcd. for $C_{12}H_{10}O_2N_2Cl_4$ (356.06): C, 40.48; H, 2.83; N, 7.87. Found: C, 40.73; H, 3.05; N, 7.55.

The monomethiodide, **N-(2-trimethylammonioethyl)-3,4,5,6-tetrachlorophthalimide iodide**, decomposed at 303–304°, R_f 0.42 (weak), after one crystallization from methanol. The infrared spectrum showed medium absorption at 1776 cm.$^{-1}$ and strong absorption at 1704 cm.$^{-1}$.

Anal. Calcd. for $C_{13}H_{13}O_2N_2Cl_4I$ (498.00): C, 31.35; H, 2.63; N, 5.63. Found: C, 31.35; H, 2.88; N, 5.63.

N-Methyl-3,4,5,6-tetrachlorophthalimide.—To 500 g. of tetrachlorophthalic anhydride, m.p. 256–259° (Niagara Alkali Co., Niagara Falls, N. Y.), in a 2-liter round-bottomed flask, was added with intermittent shaking and cooling 275 g. (25% excess) of 25% aqueous methylamine over 20 minutes. Water was removed slowly by heating at 100°, after which the yellow material was heated to 250°. The hot liquid was poured into a mortar, allowed to cool and the hard cake was then crushed to a fine, granular, yellow powder. The 516 g. (98%) of crude product, m.p. (s. 159) 203–205° (particles of solid to 230°), could be reduced directly (see below), but one crystallization from 10 to 20 volumes of chloroform (or ethylene dichloride or ethyl acetate, in decreasing order of solubility) gave a 75% yield of N-methyl-3,4,5,6-tetrachlorophthalimide, m.p. 210–212°. The infrared absorption spectrum had bands at 1775 (m) and 1714 (s) cm.$^{-1}$. Allen and Nicholls[23] reported m.p. 210–211° for their pure material, prepared by a sealed tube alkylation of the potassium salt of 3,4,5,6-tetrachlorophthalimide (no yield was given).

3,4,5,6-Tetrachlorophthalimide.—A mixture of 193.0 g. (0.676 mole) of tetrachlorophthalic anhydride and 80.0 g. (1.3 moles) of 29% ammonium hydroxide was heated to 340° and then allowed to cool. An additional 80.0 g. of 29% ammonium hydroxide was added and the mixture was heated again until completely liquid (over 350°). The brown liquid was poured into a mortar and pulverized when cool, m.p. (335) 342–347°. Crystallization from 6–7 volumes of dimethylformamide afforded yellow needles in 85% yield, m.p. (340) 345–347°, soluble in aqueous sodium carbonate; λ_{max}^{EtOH} 234 mμ (ε 8,230), 253 (sh., 8,120), 318 (sh., 2,080), 330 (2,350). The infrared spectrum showed typical imide absorption at 1775 (m) and 1708 (s) cm.$^{-1}$; phthalimide itself absorbs at 1777 (m) and 1752 (s) cm.$^{-1}$.

This procedure is essentially that described in "Organic Syntheses" (Coll. Vol. I, p. 457) for phthalimide. Previous workers have reported: (a) 91% yield, m.p. 336–337°, by fusion of tetrachlorophthalic anhydride and ammonium carbonate[23] and (b) 90% yield, m.p. 338–339°, by heating tetrachlorophthalic anhydride with formamide.[24]

Lithium Aluminum Hydride Reduction of N-(2-Dimethylaminoethyl)-phthalimide to 2-(2-Dimethylaminoethyl)-isoindoline (Va).—After 17.3 g. (0.456 mole) of lithium aluminum hydride had been refluxed in one liter of anhydrous ether for 30 minutes, 24.8 g. (0.114 mole) of N-(2-dimethylaminoethyl)-phthalimide was added portionwise over 10 minutes. The suspension was refluxed for 6 hr. with stirring, and then further stirred at room temperature overnight (16 hr.). The solution was cooled in an ice-bath, decomposed with 70 ml. of 10% aqueous sodium sulfate added dropwise (stirring and cooling) and filtered. The lithium aluminate cake was washed 3 times with 200-ml. portions of ether, and the combined ether solutions were dried over anhydrous magnesium sulfate, filtered and evaporated to dryness. The 21.1 g. (97.5%) of green oil, R_f 0.89, was suitable for quaternization (see below); it was stored under nitrogen in the refrigerator.

An analytical sample was obtained by fractional distillation. The pure 2-(2-dimethylaminoethyl)-isoindoline (Va) had b.p. 72–75° (0.06 mm.), m.p. (s. 18) 19.5–21.7°, $n^{23}D$ 1.5276; λ_{max}^{EtOH} 258 mμ (ε 660), 265 (860), 272 (850).

Anal. Calcd. for $C_{12}H_{18}N_2$ (190.29): C, 75.74; H, 9.53; N, 14.72. Found: C, 75.74; H, 9.32; N, 14.58.

2-Methyl-2-(2-trimethylammonioethyl)-isoindolinium Diiodide (Dimethiodide of Va).—A 2.00-g. sample of crude Va was refluxed for 1 hr. with 5 ml. of methyl iodide in 10 ml. of 95% ethanol. The solid was collected, washed with a little ethanol and dried, giving 4.21 g. (84.4% yield from isoindoline oil, 82.3% from phthalimide) of light green solid, m.p. 238–240° dec., R_f 0.13. Three crystallizations from 95% ethanol afforded long white prisms, m.p. 243–245° dec.; λ_{max}^{EtOH} 216–219 mμ (ε 29,440), 266 (490), 272 (490).

Anal. Calcd. for $C_{14}H_{24}N_2I_2$ (474.18): C, 35.46; H, 5.10; N, 5.91. Found: C, 35.41; H, 5.34; N, 5.72.

Lithium Aluminum Hydride Reduction of N-(2-Dimethylaminoethyl)-3,4,5,6-tetrachlorophthalimide to 4,5,6,7-Tetrachloro-2-(2-dimethylaminoethyl)-isoindoline (Vb).[7]—A suspension of 3.56 g. (0.01 mole) of N-(2-dimethylaminoethyl)-3,4,5,6-tetrachlorophthalimide and 1.5 g. (0.04 mole) of lithium aluminum hydride in 200 ml. of anhydrous ether was refluxed for 3 hr. and then stirred at room temperature overnight. The cooled solution was decomposed with 8 ml. of 10% aqueous sodium sulfate and further stirred for 1 hr. The pale yellow ether solution was filtered and the granular white cake was washed 5 times with 25-ml. portions of ether; further extraction with ether or chloroform gave no additional product. The combined ether solution was dried over magnesium sulfate and evaporated to dryness. When the residual oil was triturated with dimethylformamide, white crystals of 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-isoindoline (Vb) separated, m.p. 67.5–69.5°. Chromatography on alumina and crystallization from acetone gave pure Vb, m.p. 71.5–73°, R_f 0.98; λ_{max}^{EtOH} 236 mμ (sh., ε 18,550), 282 (530), 289–292 (450).

Anal. Calcd. for $C_{12}H_{14}N_2Cl_4$ (328.09): C, 43.93; H, 4.30; N, 8.54. Found: C, 43.98; H, 4.58; N, 8.75.

4,5,6,7-Tetrachloro-2-methyl-2-(2-trimethylammonioethyl)-isoindolinium Diiodide.[7]—The crude Vb oil from lithium aluminum hydride reduction of 3.56 g. (0.01 mole) of imide was stirred and refluxed for 4 hr. with 7 ml. of dimethylformamide and 3 ml. of methyl iodide. After the suspension had been diluted with 20 ml. of acetone and further stirred for 2 hr., the gray crystals were collected, washed with acetone and dried, giving 3.34 g. of crude product, m.p. 232–235° dec. Recrystallization from 500 ml. of methanol plus 25 ml. of water gave 2.34 g. (38% yield from starting phthalimide) of fine off-white needles, m.p. 239–241° dec.; a second crop of 0.45 g. (7.3%) was obtained after concentration of the mother liquors.

An analytical sample was obtained after three recrystallizations, m.p. 241–243° dec., R_f 0.25; λ_{max}^{EtOH} 237 mμ (sh., ε 17,740), 275 (340), 284–286 (350), 295 (260).

Anal. Calcd. for $C_{14}H_{20}N_2Cl_4I_2$ (611.98): C, 27.48; H, 3.29; N, 4.58. Found: C, 27.61; H, 3.41; N, 4.69.

Methyl iodide quaternization of pure Vb under the same conditions gave 93% pure dimethiodide (see below).

4,5,6,7-Tetrachloro-2-methylisoindoline (VII, Ib).—To a cooled and stirred suspension of 20.4 g. (0.54 mole) of lithium aluminum hydride in 400 ml. of ether was added 40.0 g. (0.13 mole) of N-methyl-3,4,5,6-tetrachlorophthalimide portionwise over 20 minutes (exothermic reaction). After the green suspension had been refluxed for 5 hr. and stirred at room temperature overnight, it was decomposed with 80 ml. of 10% aqueous sodium sulfate (stirred 1 hr. at room temperature) and filtered. Five ether and five chloroform washings (each of 100 ml.) of the lithium aluminate cake were combined with the original ether solution, solvent was removed *in vacuo* and the residue was crystallized from 500 ml. of acetone. The 4,5,6,7-tetrachloro-2-methylisoindoline separated as long, white prisms, 15.6 g. (43%), m.p. 156–158°. A reduction using only 2 moles of lithium aluminum hydride per

---

ammonium salts and tertiary amines, will be published in a separate communication.

mole of imide yielded only 10% pure plus 24% crude isoindoline.

Using the crude N-methyl-3,4,5,6-tetrachlorophthalimide described above (obtained in 98% yield from anhydride and methylamine) with 3 moles of lithium aluminum hydride afforded 24% pure product, m.p. 159–162° plus 17% crude product. Recrystallization of the pure product from acetone gave white prisms of the same melting point, R_f 0.96.

Anal. Calcd. for $C_9H_7NCl_4$ (270.99): C, 39.89; H, 2.60; N, 5.17. Found: C, 40.24; H, 2.80; N, 5.40.

2,2-Dimethylisoindolinium Halides.—A chloroform solution of 2-methylisoindoline (Ia)[5,6,25] (purified by sublimation and containing 0.5 mole of water, m.p. 45–47°, pK_a 7.7, volatile and unstable. *Anal.* Found: C, 76.02; H, 8.51) was refluxed on the steam-bath for 15 minutes with excess methyl iodide. The methiodide derivative was collected and dried in air, m.p. 253–255° dec., R_f 0.34. Rice and co-workers[5] reported m.p. 253–255°.

The methochloride derivative IIa, m.p. 206–209°, R 0.25, was a deliquescent white solid, prepared by bubbling methyl chloride gas for 0.5 hr. into a chloroform solution of 2-methylisoindoline either at reflux temperature or at 25–30° (or into a hot dimethylformamide solution). Paper chromatographic analysis showed that practically no starting isoindoline remained.

4,5,6,7-Tetrachloro-2,2-dimethylisoindolinium Halides. Chloride Salt IIb.—Gaseous methyl chloride was bubbled for 30 minutes through a heated (steam-bath) solution of 2.71 g. (0.01 mole) of 4,5,6,7-tetrachloro-2-methylisoindoline (Ib), m.p. 159–162°, in 10 ml. of dimethylformamide. The 2.80 g. of solid which separated after the solution had cooled to room temperature was collected, washed once with cold acetone and extracted once with boiling acetone. The hot acetone extracted 0.28 g. (11.4%) of starting Ib, m.p. 157–159°, and dilution of the dimethylformamide mother liquor (plus cold acetone wash) with water gave 0.08 g. (3%) more Ib. The 2.52 g. (78.5%) of acetone-insoluble 4,5,6,7-tetrachloro-2,2-dimethylisoindolinium chloride (IIb) melted 304–306°, R_f 0.34. Two crystallizations from methanol–ethyl acetate gave hexagonal white prisms, m.p. (s. 313) 315–317°.

Anal. Calcd. for $C_{10}H_{10}NCl_5$ (321.48): C, 37.36; H, 3.14. Found: C, 37.74; H, 3.27.

A 90.4% yield of IIb, m.p. 307–309°, was obtained when the reaction was run in refluxing dimethylformamide. In refluxing chloroform, on the other hand, 75% of the starting material Ib, m.p. 159–160°, was recovered and paper chromatographic examination of the mother liquors showed only traces of IIb.

Bromide Salt X.—Addition of gaseous methyl bromide to a refluxing chloroform solution of Ib gave the methobromide salt X, m.p. 309–310° sl. dec. (melting point decreased on standing or on grinding to a powder), R_f 0.55, molecular weight determination by isothermal distillation 378 (calcd. 366). The infrared spectrum was very similar to that of the chloride salt IIb.

Anal. Calcd. for $C_{10}H_{10}NCl_4Br$ (365.94): C, 32.82; H, 2.75; N, 3.83. Found: C, 32.91; H, 2.82; N, 3.94.

Iodide Salt.—The corresponding iodide salt, prepared in refluxing chloroform, melted 242–250° dec., R_f 0.61.

2-(2-Bromoethyl)-2-methylisoindolinium Bromide (IIIa)—One gram of 2-methylisoindoline was warmed on the steam-bath with 10 ml. of ethylene dibromide. After 15 minutes, the gray solid was collected and washed with ethylene dibromide and ether, giving 1.54 g. (64%) of light gray solid, m.p. 210.5–211° dec., R_f 0.43. Further heating of the mother liquors for a total of 1 hr. afforded 0.12 g. (5%) of more gray solid, m.p. 219–220° dec. Rice and co-workers[5] reported 223–224°. For yields under other conditions, see following table.

2-(2-Bromoethyl)-4,5,6,7-tetrachloro-2-methylisoindolinium Bromide (IIIb). (1).—Ten grams (0.037 mole) of 4,5,6,7-tetrachloro-2-methylisoindoline (Ib) and 30.0 ml. (65.4 g., 0.35 mole) of redistilled ethylene dibromide, b.p. 129–134° (atm.), were refluxed (temperature of the wet cake 135°) for 30 minutes using a heating mantle. After the slurry had cooled, 40 ml. of ether was added with swirling, and the suspension was filtered. The red ether solution on evaporating to dryness left 1.7 g. of red-brown tar. The ether-insoluble tan solid was extracted three times with hot water, (a) 40 ml., (b) 80 ml., (c) 80 ml. First crops from portions a and b and all of portion c darkened over 220° but did not melt to 300°; this combined white solid (6.32 g., 37.3%) was recrystallized from methanol to give 4.34 g. (25.5%) of white platelets of IIIb, shrinking 225°, black > 280°, not melted to 300°; R_f 0.61.

Anal. Calcd. for $C_{11}H_{11}NCl_4Br_2 \cdot CH_3OH$ (490.92): C, 29.35; H, 3.08; N, 2.85. Found: C, 29.27; H, 2.92; N, 3.07.

The aqueous mother liquors from portion a above were stripped to dryness, leaving 1.30 g. (7.7%) of off-white solid, m.p. 278–284° dec. One crystallization from 95% ethanol afforded white crystals of IVb, m.p. 274–289° dec., R_f 0.53.

Anal. Calcd. for $C_{20}H_{18}N_2Cl_8Br_2 \cdot H_2O$ (747.88): C, 32.12; H, 2.70; N, 3.75. Found: C, 32.33; H, 2.86; N, 4.03.

Neither the analysis nor the infrared spectrum nor the R_f value distinguished this compound from the hemihydrate of 4,5,6,7-tetrachloro-2,2-dimethylisoindolinium bromide (X). A molecular weight determination by isothermal distillation, however, gave 837, whereas X gave 378. The data is consistent with assignment of a 1,2-bis-(4,5,6,7-tetrachloro-2-methylisoindolinium)-ethane dibromide structure (IVb) formed by displacement reaction at *both* ends of the ethylene dibromide.

(2).—A suspension of 20.0 g. of 4,5,6,7-tetrachloro-2-methylisoindoline (Ib) in 20 ml. of ethylene dibromide was stirred and heated in an oil-bath to 170° over a period of 1 hr. and was then maintained at 165–175° for 15 minutes (moderate to vigorous boiling). After cooling to room temperature, it was diluted with 40 ml. of ether and filtered. The pink cake was washed twice with 40-ml. portions of ether, and crystallized from methanol. A first crop of 17.4 g. (51.5%) darkened but did not melt to 300°, R_f 0.65, was obtained, followed by 3.5 g. (10%) of a second crop which contained some isoindoline starting material.

(3).—When Ib and excess ethylene dibromide were refluxed in toluene for 6 hr., a 15% yield of white solid separated on cooling; this material darkened but did not melt to 320°, R_f 0.64; λ_{max}^{EtOH} 237 (ϵ 13,055), 284 (402), plateau 294 (347). Increasing the reflux time to 22 hr. raised the yield to 22%.

Anal. Calcd. for $C_{11}H_{11}NCl_4Br_2$ (458.88): C, 28.79; H, 2.42; N, 3.05. Found: C, 28.83; H, 2.51; N, 3.03.

(4).—Survey of reaction conditions for preparation of IIIb and IIIa:

Conditions for reaction of I and ethylene dibromide		Yield, %	
Solvent, reflux	Time, hr.	Of IIIb	Of IIIa
Acetone	0.25[b]	0	17
Acetone	5	0	
Methyl ethyl ketone	1	0	69
No solvent[a]	1	*ca.* 4	
Toluene	6	15	60
Toluene	22	22	
Xylene	0.5	3	
Ethylene dibromide	[b]	Up to 60	

[a] Steam-bath. [b] Various times.

(5) Dequaternization.—Gaseous trimethylamine was bubbled for 1 hr. into a refluxing solution of 2.00 g. of IIIb in 20 ml. of dimethylformamide. From the cooled solution, 0.56 g. (83%) of tetramethylammonium bromide was collected, not melting to 320°, R_f 0.11.

Anal. Calcd. for $C_4H_{12}NBr \cdot H_2O$ (172.08): N, 8.15. Found: N, 7.99.

2-Methyl-2-(2-trimethylammonioethyl)-isoindolinium Dichloride (VIIa).—Gaseous methyl chloride was bubbled for 45 minutes into a heated (steam-bath) solution of 5.00 g. of 2-(2-dimethylaminoethyl)-isoindoline in 25 ml. of dimethylformamide. The cooled solution was diluted with 25 ml. of acetone, and the dark solid was collected, washed with acetone and dried *in vacuo* at 60° for 16 hr. The 4.04 g. (53% yield) of deliquescent green-brown dimethochloride VIIa melted 209–215° dec., R_f 0.05; it was soluble in water, methanol and isopropyl alcohol and insoluble in acetone, ethyl acetate and chloroform. A paper chromatogram of the mother liquors showed the presence of both mono- (VIa)

(25) E. W. Cook and W. G. France, *J. Phys. Chem.*, **36**, 2383 (1932).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and dimethochloride (VIIa). Two crystallizations of the solid from 1-butanol–acetone gave deliquescent green prisms of VIIa. A sample was dried *in vacuo* at 75° over Drierite for 24 hr., and precautions were taken to obtain data on the anhydrous material: m.p. 223–225° dec.; λ_{max}^{EtOH} 254 mμ (ε 300), 256–258 (310), 263 (390), 269 (370).

Anal. Calcd. for $C_{14}H_{24}N_2Cl_2$ (291.28): C, 57.73; H, 8.31; N, 9.62. Found: C, 57.32; H, 8.51; N, 9.38.

4,5,6,7-Tetrachloro-2-methyl-2-(2-trimethylammonioethyl)-isoindolinium Dihalide.—A solution of 1.00 g. of 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-isoindoline (Vb) m.p. 71.5–72.5°, in 4.2 ml. of dimethylformamide and 1.3 ml. of methyl iodide was refluxed for 2 hr. with stirring. The dimethiodide product was collected by filtration from the cooled solution and washed twice with acetone. The dried product, m.p. 241–243° dec., R_f 0.25, weighed 1.73 g. (93.5%) and was identical with that described above.

Methyl bromide in dimethylformamide converted Vb into the dimethobromide, m.p. 246–247° dec., R_f 0.23.

A mixture of 32.8 g. (0.10 mole) of 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-isoindoline Vb, 32.8 ml. of formamide and 35.3 g. (0.70 mole, 250% excess) of methyl chloride in a pressure bomb was heated to 90–100° with shaking for 5 hr.; the pressure rose to 172 p.s.i.g. After the bomb had been cooled and vented, the tan-colored formamide cake was diluted with 328 ml. of acetone and chilled. The white crystalline product melted 246–254° dec., and one recrystallization from absolute ethanol afforded 41.2 g. (86.7%) of dichloride VIIb, m.p. 264–266° dec., R_f 0.16. It was identical with material prepared from the dimethiodide by halide exchange.

Anal. Calcd. for $C_{14}H_{20}N_2Cl_6 \cdot {}^1/_2H_2O$ (438.08): C, 38.38; H, 4.83; N, 6.40. Found: C, 38.32; H, 4.96; N, 6.22.

4,5,6,7-Tetrachloro-2-(2-trimethylammonioethyl)-isoindoline Chloride (VIb).—Methyl chloride gas was bubbled into a hot (steam-bath) solution of 5.00 g. of Vb in 50 ml. of dimethylformamide for 0.5 hr. The white crystalline product was collected, washed with acetone and dried *in vacuo*, giving 5.36 g. (93.3%) of monomethochloride VIb, m.p. 256–260° dec. The mother liquors, which contained traces of dimethochloride (R_f 0.16), afforded an additional 0.27 g. (4.7%) of monomethochloride on dilution with acetone. Recrystallization from isopropyl alcohol gave 4.95 g. of product, m.p. 265–267° dec., R_f 0.55, which was dried *in vacuo* over Drierite at 100° for 5 hr.

Anal. Calcd. for $C_{13}H_{17}N_2Cl_5 \cdot {}^1/_2H_2O$ (387.59): C, 40.29; H, 4.68; N, 7.23. Found: C, 40.12; H, 4.70; N, 7.12.

Crystallization from water gave a monohydrate, m.p. 280–281° dec.

Bromoethyltrimethylammonium Bromide.[26]—A clear, colorless solution of 10 ml. (21.8 g., 0.115 mole) of ethylene dibromide and 15 ml. (11.3 g., 0.47 mole) of 25% methanolic trimethylamine was refluxed for 1 hr. When the yellow solution cooled to room temperature, white crystals separated. After being chilled overnight, the solution was filtered and the collected crystals washed once with methanol and dried, giving 3.6 g. (13%) of white prisms, m.p. (s. 238) 251–253° dec. (red, foaming), R_f 0.22. Its water solution gave an immediate precipitate of silver bromide on addition of silver nitrate solution.

Anal. Calcd. for $C_5H_{13}NBr_2$ (247.00): N, 5.67. Found: N, 5.68.

Concentration of the methanol mother liquors gave 1.60 g. (6%) of a second crop, m.p. 239–243° dec. (orange foam); one crystallization raised the melting point to 248–250° dec. When the reflux period was increased to 2 hr., a 22% yield of salt, m.p. 237–240° dec., was obtained.

A mixture of 25 ml. (0.29 mole) of ethylene dibromide, 10 ml. (0.32 mole) of 25% methanolic trimethylamine and 25 ml. of benzene, after standing at room temperature for three days and then being chilled to 5°, gave 7.7 g. (11%) of product, m.p. 245–247° dec. (orange foam).

4,5,6,7-Tetrachloro-2-(2-trimethylammonioethyl)-isoindoline Bromide (IX) from VIII and Bromoethyltrimethylammonium Bromide.—A mixture of 2.00 g. (7.4 millimoles) of 4,5,6,7-tetrachloro-2-methylisoindoline (VIII) and 2.00 g. (8.1 millimoles) of bromoethyltrimethylammonium bromide was refluxed (153°) for 3 hr. in 10 ml. of dry dimethylformamide. The liquid darkened on heating, the bromide salt gradually dissolved and the solution became cloudy. After the cloudy solution had been cooled to room temperature and diluted with 10 ml. of acetone, it was filtered, removing 0.20 g. of light yellow solid, which decomposed but did not melt to 320°. The filtrate gave 2.40 g. of pale tan solid, m.p. (s. 226) 238–243° dec., after standing in the refrigerator (*ca.* 5°) for two weeks. Crystallization of this material from methanol afforded a first crop of 0.75 g. of off-white solid, m.p. (s. 255) 262–271° dec., R_f 0.56; the infrared spectrum was identical with authentic 4,5,6,7-tetrachloro-2,2-dimethylisoindolinium bromide (X). A second crop of 0.80 g. from methanol was similar to the first crop, but when slurried with 40 ml. of water at room temperature, it left 0.23 g. of insoluble off-white solid, m.p. (s. 245) 247–250° dec. Recrystallization of this water-insoluble material from methanol afforded 0.05 g. of IX, m.p. (s. 250) 252–255° dec. (reddish melt); R_f 0.55; the melting point was depressed 5° when mixed with X.

Anal. Calcd. for $C_{13}H_{17}N_2Cl_4Br \cdot H_2O$ (441.06): C, 35.40; H, 4.34; N, 6.35. Found: C, 35.74; H, 4.46; N, 6.64.

The infrared spectrum was identical with and the melting point was not depressed by authentic 4,5,6,7-tetrachloro-2-(2-trimethylammonioethyl)-isoindoline bromide (IX) (see below).

Treatment of the monomethobromide IX with methyl chloride (DMF, steam-bath, 1 hr.) gave recovered IX containing trace quantities of the dimethohalide (detectable by paper chromatography R_f 0.16). Treatment of IX with excess methyl bromide (DMF, steam-bath, 1 hr.) afforded 4,5,6,7-tetrachloro-2-methyl-2-(2-trimethylammonioethyl)-isoindolinium bromide (XI), m.p. 246–247.5° dec., R_f 0.23.

Anal. Calcd. for $C_{14}H_{20}N_2Cl_4Br_2 \cdot H_2O$ (536.01): C, 31.37; H, 4.14; N, 5.23. Found: C, 31.31; H, 4.41; N, 5.39.

A mixture melting point with authentic dibromide XI, m.p. 246–247° dec., prepared by methyl bromide quaternization of the diamine Vb, showed no depression. Furthermore, the infrared spectra of the two were identical.

Formation of IX by Demethobromination of XI.—When 2.08 g. of dimethobromide XI, m.p. 246–248° dec., was refluxed in 10 ml. of dimethylformamide for 3 hr., it gradually dissolved. The 1.11 g. (65%) of white needles of monomethobromide IX which separated on cooling melted 252–253° dec., R_f 0.54. An additional 0.40 g. of material was obtained by dilution of the dimethylformamide mother liquors with acetone. This material was separated into 0.23 g. (14%) more IX, plus 0.16 g. (8%) of recovered XI by extraction of IX with 5 ml. of hot dimethylformamide.

Dimethiodide analogous to the dimethobromide XI did not dissolve completely in refluxing dimethylformamide even after 10 hr. The filtered hot solution was evaporated *in vacuo* and the residue was diluted with acetone. The brown solid was washed well with ether, leaving 75% crude monomethiodide. Crystallization from methanol (charcoal) gave yellow crystals, m.p. 230–231° dec., R_f 0.62. The infrared spectrum was very similar to that of the monomethobromide IX.

Anal. Calcd. for $C_{13}H_{17}N_2Cl_4I$ (470.03): C, 32.22; H, 3.65; N, 5.96. Found: C, 32.77; H, 3.93; N, 6.20.

Three hours refluxing of VIIb in dimethylformamide gave a 95% yield of VIb.

4,5,6,7-Tetrachloro-2-(2-trimethylammonioethyl)-isoindoline Bromide (IX) from the Chloride VIb.—A 1.00-g. sample of VIb, m.p. 261–263° dec., was dissolved in 25 ml. of water and 25 ml. of 48% hydrobromic acid and boiled gently on a hot-plate for 20 minutes. The cloudy, yellow-brown solution was filtered and allowed to cool. The sticky, off-white semi-solid which separated was taken up in methanol, charcoaled, filtered and diluted with two volumes of ether. An off-white solid (0.39 g.), m.p. 237–264° dec., R_f 0.55, was collected, which was the hydrobromide salt of the desired product. Recrystallization of this material from

(26) Bromoethyltrimethylammonium bromide was first prepared by A. W. Hofmann, *Jahresb. Chem.*, **11**, 338 (1858). M. Kruger and P. Bergell, *Ber.*, **36**, 2901 (1903), obtained a 71% yield of the salt, m.p. 239–231°, from the reaction of ethylene dibromide and trimethylamine (no solvent), whereas R. R. Renshaw, THIS JOURNAL, **34**, 1615 (1912), got a 90% yield, m.p. 235.5° (corr.), in a bomb tube reaction. A. P. Gray, D. C. Schlieper, E. E. Spinner and C. J. Cavallito, *ibid.*, **77**, 3948 (1955), in a study of the reactions of tertiary amines and dibromoalkanes in benzene solution (giving ω-bromoalkyl quaternary ammonium salts), reported m.p. 229° for bromoethyltrimethylammonium bromide but did not give the yield.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

methanol containing some sodium acetate (solution color changed from yellow to colorless as the *p*H was raised to about six) gave 0.24 g. (21.4%) of white crystals of 4,5,6,7-tetrachloro-2-(2-trimethylammonioethyl)-isoindoline bromide (IX), m.p. 254–256° dec., R_f 0.55.

Anal. Calcd. for $C_{13}H_{17}N_2Cl_4Br \cdot H_2O$ (441.06): C, 35.40; H, 4.34; N, 6.35. Found: C, 35.58; H, 4.42; N, 6.39.

4,5,6,7-Tetrachloro-2-(2-dimethylaminoethyl)-2-methylisoindolinium Bromide (XIV).—A suspension of 2.71 g. (0.01 mole) of 4,5,6,7-tetrachloro-2-methylisoindoline (VIII) and 4.66 g. (0.02 mole) of bromoethyldimethylammonium bromide in 25 ml. of dimethylformamide was heated until completely dissolved, 0.90 g. (0.011 mole) of sodium acetate was added and the solution was swirled and allowed to cool to room temperature. After removal by filtration of 2.60 g. (96%) of starting VIII, m.p. 159–161°, R_f 0.94, the mother liquors were chilled to −15° for several days. The 0.15 g. of off-white solid which precipitated, m.p. (s. 215) 257–275° dec., was recrystallized from methanol. A tiny amount of VIII, m.p. 158–160°, was removed first, and spontaneous evaporation slowly deposited white prisms of 4,5,6,7-tetrachloro-2-(2-dimethylaminoethyl)-2-methylisoindolinium bromide (XIV), m.p. (s. 215) 255–265° dec., R_f 0.73.

Anal. Calcd. for $C_{13}H_{17}N_2Cl_4Br$ (423.04): C, 36.91; H, 4.05; N, 6.62. Found: C, 37.05; H, 4.19; N, 6.56.

4,5,6,7-Tetrachloro-2-(2-dimethylaminoethyl)-2-methylisoindolinium Bromide Hydrobromide (XII).—A solution of 2.71 g. (0.01 mole) of 4,5,6,7-tetrachloro-2-methylisoindoline (VIII) and 4.66 g. (0.02 mole) of bromoethyldimethylammonium bromide[27] in 25 ml. of dimethylformamide was heated on the steam-bath for 3 hr. After the solution had cooled to room temperature, 1.88 g. (53.5%) of 4,5,6,7-tetrachloro-2-methylisoindoline hydrobromide (XIII) was collected and washed with 25 ml. of acetone; m.p. (s. 267) 277–280° dec., R_f 0.94. Chilling the combined mother liquors and acetone washings at −15° for 18 hr. gave 0.40 g. (11.4%) more XIII, m.p. (s. 259) 262–275° dec., R_f 0.94. The first crop of XIII was washed twice with hot acetone and crystallized from methanol, giving white solid decomposing 305–309°.

Anal. Calcd. for $C_9H_8NCl_4Br \cdot {}^1/_2H_2O$ (360.92): C, 29.95; H, 2.51; N, 3.88. Found: C, 30.03; H, 2.46; N, 4.09.

Crystallization from 95% ethanol containing excess sodium acetate gave 4,5,6,7-tetrachloro-2-methylisoindoline (VIII), m.p. 158–160°.

The dimethylformamide–acetone mother liquors deposited 0.50 g. (10%) of white crystals, m.p. 250–265° dec. after standing for several days at room temperature. One crystallization from methanol gave white needles of XII, m.p. (s. 250) 256–264° dec., R_f 0.73, pK_a 5.3.

Anal. Calcd. for $C_{13}H_{18}N_2Cl_4Br_2 \cdot 2H_2O$ (540.09): C, 28.92; H, 4.11; N, 5.19. Found: C, 29.46; H, 4.43; N, 5.32.

Infrared Spectra.—The two products XII and XIII showed absorption in the infrared between 2300–2700 cm.$^{-1}$ typical of hydrohalide salts.[28] 4,5,6,7-Tetrachloro-2-methylisoindoline hydrobromide (XIII) absorbed strongly at 2625, 2548, 2490 and 2384 cm.$^{-1}$, whereas the free base VIII and its methobromide X did not. The hydrobromide XII absorbed at 2636 (ms), 2510 (w) and 2464 (m) cm.$^{-1}$; this region of the infrared spectrum was clear with the corresponding base XIV and the dimethobromide XI.

A solution of 0.10 g. (0.2 millimole) of the hydrobromide XII, 0.05 g. (0.6 millimole) of sodium acetate and excess methyl bromide in 5 ml. of dimethylformamide was warmed on the steam-bath for 1 hr. Solvent was removed *in vacuo* and the residue was taken up in methanol. When the solution was chilled to −15° 0.06 g. (58%) of white crystals separated, m.p. 239–243° dec., R_f 0.23. A mixture melting point with authentic dimethobromide XI, m.p. 246–247° dec., showed no depression. The infrared spectrum was identical with that of the dimethobromide, confirming the paper chromatographic and melting point data.

Treatment of XII with methyl chloride in hot dimethylformamide in the presence of sodium acetate gave the dimethohalide (R_f 0.17).

1,1,4,4-Tetramethylpiperazinium Salts. Dichloride.—A mixture of 1.8 g. (0.02 mole) of 2-dimethylaminoethanol, 1.9 g. (0.01 mole) of *p*-toluenesulfonyl chloride and 10 ml. of dry pyridine (exothermic reaction) was allowed to stand 18 hr. at room temperature. After addition of 2.71 g. (0.01 mole) of 4,5,6,7-tetrachloro-2-methylisoindoline (VIII), the solution was refluxed for 3 hr. The cooled solution deposited 2.9 g. of solid, of which 2.60 g. (96%) was recovered VIII, m.p. 158–160°, isolated by ether extraction. The 0.30 g. of ether-insoluble material was crystallized from methanol, giving material darkening 218–320° without melting, R_f 0.00, positive Beilstein test.

Anal. Calcd. for $C_8H_{20}N_2Cl_2$ (215.18): C, 44.66; H, 9.37. Found: C, 44.26; H, 9.18.

1,1,4,4-Tetramethylpiperazinium dichloride readily is formed from dimethylaminoethyl chloride and is reported to decompose over 300°.[16]

Di-*p*-toluenesulfonate.—To a solution of 2.71 g. (10 millimoles) of VIII in 150 ml. of dioxane was added 1.85 g. (22 millimoles) of sodium bicarbonate, 3.80 g. (20 millimoles) of *p*-toluenesulfonyl chloride and 1.80 g. (20 millimoles) of 2-dimethylaminoethanol. After the suspension had been stirred for 16 hr., the white solid was collected and dried giving 3.18 g. of mixed salts, darkening over 250° but not melting to 310°, positive Beilstein and silver nitrate tests (presence of chloride), no bubbling of an aqueous solution on addition of acid (no bicarbonate). This solid was extracted with hot 95% ethanol, and the filtered ethanol solution deposited 1,1,4,4-tetramethylpiperazinium di-*p*-toluenesulfonate on cooling, not melted to 310°, R_f 0.00, negative silver nitrate test. The infrared spectrum showed strong bands at 1012, 1035, 1124 and 1182 cm.$^{-1}$ typical of *p*-toluenesulfonate anion.

Anal. Calcd. for $C_{22}H_{34}O_6N_2S_2 \cdot {}^1/_2H_2O$ (495.67): C, 53.31; H, 7.12. Found: C, 53.33; H, 7.51.

Oxidative Cleavage of the Pyrazole Ring and the Structure of Azipyrazole

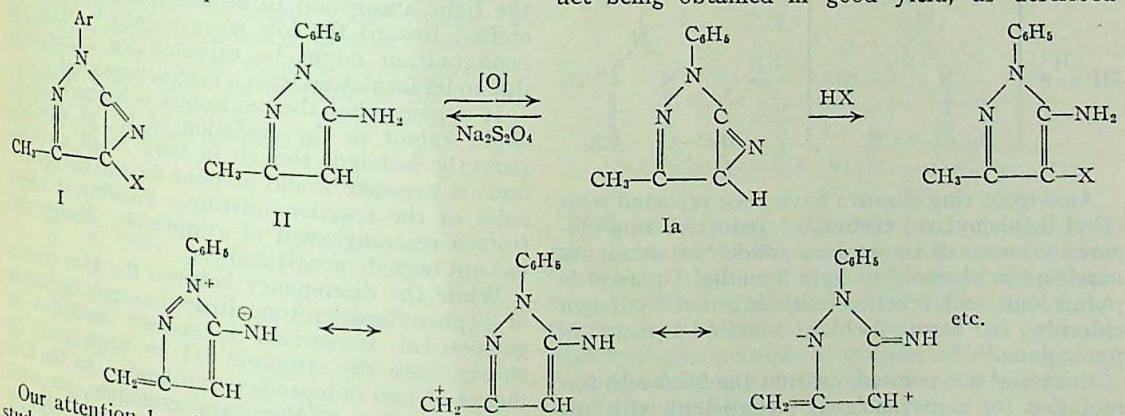
BY SCOTT SEARLES, JR., AND WILLIAM ROBERT HINE, JR.

RECEIVED JULY 19, 1956

Azipyrazole, a compound formed by the action of hydrogen peroxide on 5-amino-3-methyl-1-phenylpyrazole (II), was previously assigned a structure possessing the 2,3,6-triazabicyclo[3,1,0]-3,6-hexadiene ring system, in common with several other closely related compounds. Reinterpretation of the old chemical evidence for this structure, as well as new data, leads to reformulation of the structure of azipyrazole as 3-(phenylazo)-crotononitrile. Confirmation of this structure was obtained by two independent syntheses. Evidence was obtained for two geometrical isomers. A mechanism is proposed for the oxidative cleavage of the pyrazole ring, which is apparently a new reaction. Other products of the oxidation of II are 3-(phenyl-NON-azoxy)-crotonamide and di-(3-methyl-1-phenyl-5-pyrazolyl)-amine 2,2′(?)-dioxide.

An unusual new class of compounds, called "azipyrazoles," was reported by Michaelis and associates during the period 1905–1915.[1] These compounds seem of particular interest because of the 2,3,6-triazobicyclo[3,1,0]-3,6-hexadiene ring system[2] assigned to them. The assigned structures of the compounds known in this series can be generalized as I, with X and A_2 varying but all alike with regard to the methyl group.

Such a fusion of 3- and 5-membered unsaturated rings not only is unique but would be expected to lead to extremely high internal strain. The reported properties of the compounds, however, indicate ordinary stability. Nevertheless, the assigned structures cannot be immediately dismissed, for they are supported by several lines of experimental evidence. The paradox has been recognized recently by Erickson, who has reviewed the chemistry of these compounds.[3]



Our attention has been directed in the present study to the first and simplest azipyrazole reported, which has the specific name, "azipyrazole," and which seems typical of the general class. It had been assigned the structure Ia on the following bases: (1) its synthesis from 5-amino-3-methyl-1-phenylpyrazole (II) by mild oxidation with nitrous acid or with hydrogen peroxide in aqueous acetic acid, reportedly a general method of synthesis of azipyrazoles; (2) the elemental analyses and molecular weight determinations, which were in excellent agreement with the assigned structure and showed that the synthesis had caused loss of two hydrogens; (3) the general stability of the pyrazole ring toward oxidizing agents[4]; (4) easy formation of known pyrazoles as derivatives—compound II by sodium hydrosulfite reduction and the 4-halogeno derivatives of II by treatment with aqueous hydrochloric, hydrobromic and hydriodic acids.

Erickson[3] made the interesting suggestion that the structure of azipyrazole could be more plausibly interpreted by the mesoionic formulation

A third isomeric structure for azipyrazole is also possible, as will be shown below. It was the purpose of this work to determine which formulation might be correct.

The procedure described by the previous workers[1c] for the preparation of azipyrazole gave different results in our hands, a quite different product being obtained in good yield, as described later. By carrying out the oxidation with 90% hydrogen peroxide in glacial acetic acid and using high vacuum sublimation for purification, however, a compound was isolated, which fitted the description of azipyrazole exactly, except for its having an ivory rather than light brown color. This is understandable since the previous isolation was by crystallization of the dark brown crude product. The melting point (109°) checked with the literature, as well as the facile formation of 5-amino-3-methyl-1-phenylpyrazole (II) on reduction and the corresponding 4-bromo- and 4-iodo compounds on treating with hydrobromic and hydriodic acids.

The infrared spectrum of this compound differed from that of its precursor, II, in having new bands

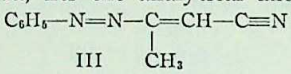
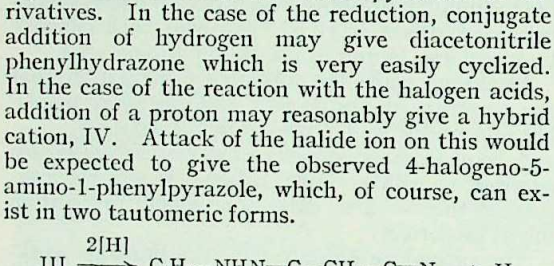
at 4.45 μ, indicative of a nitrile structure,[5] and at 6.20 and 6.25 μ, which might be assigned to a conjugated double bond and to an azo linkage. Furthermore, it lacked a band for N–H (found at 2.9 μ in II) and the bands characteristic of the pyrazole ring[6] (6.8 and 10.9 μ in II).[7] The spectrum contained bands at 7.18 and 6.76 μ which may be assigned to symmetrical and asymmetrical CH_3 deformation[5]; these would not be expected for the mesoionic formation.

It will be observed that the structure of 3-(phenylazo)-crotononitrile (III) closely fits the spectral features observed. This structure, being isomeric with Ia, fits the analytical and molecular



III

weight data, and it also provides a rational basis to explain the formation of 5-aminopyrazoles as derivatives. In the case of the reduction, conjugate addition of hydrogen may give diacetonitrile phenylhydrazone which is very easily cyclized. In the case of the reaction with the halogen acids, addition of a proton may reasonably give a hybrid cation, IV. Attack of the halide ion on this would be expected to give the observed 4-halogeno-5-amino-1-phenylpyrazole, which, of course, can exist in two tautomeric forms.



IV

Analogous ring closures have been reported with ethyl 3-(phenylazo)-crotonate: reductive ring closure by means of ammonium sulfide[8,9] or aluminum amalgam in alcohol[10] to form 3-methyl-1-phenyl-5-pyrazolone and reaction with ethereal hydrogen chloride to form 4-chloro-3-methyl-1-phenyl-5-pyrazolone.[11,12]

Erickson[3] has pointed out that the Michaelis formulation for azipyrazoles is inconsistent with the fact that in the presence of free halogen the phenyl group does not become halogenated, as might be expected by analogy with aniline. The new structure III is consistent with this observation, of course, because of the electron-withdrawal properties of the unsaturated nitrile side chain, due to resonance effects.

At this point it was discovered that 3-(phenylazo)-crotononitrile (III) previously had been reported in the literature as having properties distinctly different from those found for azipyrazole (orange-red color, m.p. 81°). This substance had been obtained by degradation of eulite[13] and had been synthesized also by treating the chlorination product of 5-methylisoxazole with sodium ethoxide and then with phenylhydrazine.[14] The structure III for the product of this sequence seems probable, but it was not confirmed by any supplementary work. Its *p*-nitro analog, however, was stated to react with boiling hydrochloric acid to form a compound considered to be 3-(2-chloro-4-nitrophenylhydrazino)-crotonitrile. The latter could well have been the isomeric 5-amino-4-chloro-3-methyl-1-(4-nitrophenyl)-pyrazole, which would be consistent with an azo-nitrile structure for its precursor.

It is, of course, feasible that both azipyrazole and this red compound are geometrical isomers of 3-(phenylazo)-crotononitrile, there being four such isomers theoretically possible. The lighter color of azipyrazole could reasonably be due to its configuration being more *cis* than that of the other compound, as it has been shown for polyenes that the *cis* arrangement of conjugated double bonds causes the light absorption to be less intense and to be shifted toward the low wave lengths.[15] The *cis*-configuration might be expected for azipyrazole due to its formation from a cyclic compound.

It appears that the red isomer is formed also to slight extent in the oxidation of II; it was apparently isolated, though in very small amount, and its presence would account for the orange-red color of the reaction mixture. Possibly it arises from a rearrangement of azipyrazole, though this has not been demonstrated yet.

While the discrepancy between the two reports of 3-(phenylazo)-crotononitrile thus may be due to geometrical isomerism, it seemed desirable to substantiate the structure III for azipyrazole by means of two independent syntheses. In the first of these, ethyl 3-(phenylazo)-crotonate, prepared by the mercuric oxide oxidation of the phenylhydrazone of acetoacetic ester,[9] was treated with ammonia to form 3-(phenylazo)-crotonamide (V). The reaction of this with phosphoric anhydride gave a brown solid, from which a white crystalline solid was obtained by sublimation. This proved identical with azipyrazole.

(7) Also absent from the spectrum was any band in the 5.5 μ region, which is reported (D. J. Cram and M. J. Hatch, *ibid.*, **75**, 33 (1953)) to be characteristic of the azirine ring. The azirine ring is present, fused to the pyrrolidine ring, in the Michaelis structure.

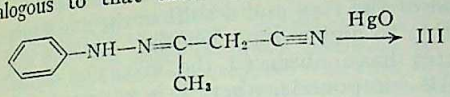
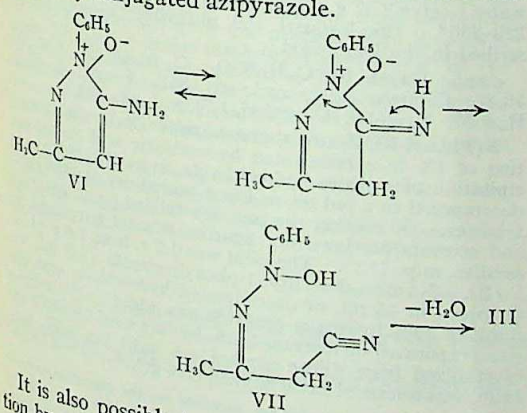
The second confirmatory synthesis of azipyrazole consisted of oxidizing diacetonitrile phenylhydrazone with mercuric oxide in alcohol. This reaction, analogous to that used for the preparation of



ethyl 3-(phenylazo)-crotonate, gave two crystalline products: one tan colored, m.p. 105–107°, and the other red, m.p. 82–83°. The former was identical to the azipyrazole previously obtained, and the latter appears to be the isomer described by Quilico and Justoni.[14] In view of so much evidence, there can hardly be any doubt that azipyrazole is one geometrical isomer of 3-(phenylazo)-crotononitrile.

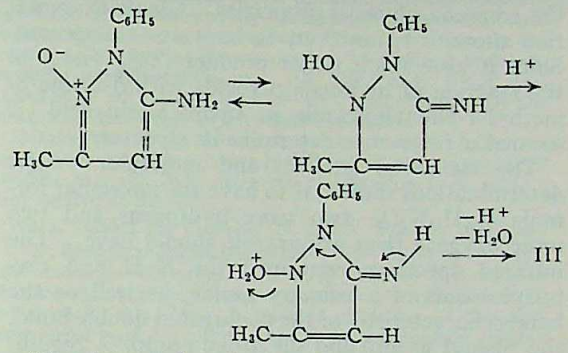
Since oxidative cleavage of the pyrazole ring to form an unsaturated azo compound appears to be novel, one is tempted to speculate on the course of the reaction. 1-Phenylpyrazoles being actually cyclic phenylhydrazones, a formal similarity to the recently studied per-acid oxidation of acyclic phenylhydrazones is evident. The elegant study of this reaction by Lythgoe and co-workers[16] indicates that the first step in the oxidation of aldehyde phenylhydrazones is coördination of oxygen at the phenyl-substituted nitrogen, forming an N-oxide. This is followed by a tautomeric shift of hydrogen, giving the final product, an azoxy compound.

In the present case formation of the analogous pyrazole-1-oxide (VI) could be followed by an easy shift of a proton from the amino or imino group to the electro-negative oxygen and the shift of an electron pair as shown. The resulting hydroxyhydrazononitrile (VII) would be unstable in the acidic medium, losing the elements of water to form the completely conjugated azipyrazole.

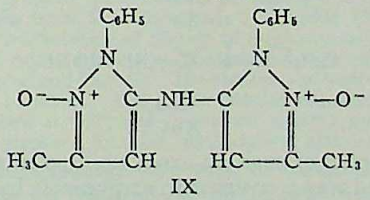


It is also possible to explain azipyrazole formation by a smooth mechanism starting with formation of the pyrazole-2-oxide (VIII).[17]

Other Products from Oxidation of II.—In the reaction of 5-amino-3-methyl-1-phenylpyrazole with hydrogen peroxide in acetic acid under all conditions used, a white crystalline compound melting at 229–230° separated quickly and could be isolated in 70% yield (pure). It seems peculiar that it was not mentioned by Michaelis and co-workers.[1] Because of its possible role as an intermediate in azipyrazole formation, its structure was investigated.



The elemental analysis and molecular weight determinations for this compound indicated an empirical formula of $C_{20}H_{19}N_5O_2$. Its infrared spectrum contained strong bands at 6.82 and 10.70 μ characteristic of the pyrazole ring,[6] at 2.85 μ characteristic of a secondary amine[5] and at 6.85 μ characteristic of an N-oxide or azoxy structure.[18,19] These data suggested that the compound was di-(3-methyl-1-phenyl-5-pyrazolyl)-amine 2,2′-dioxide (IX) or the corresponding 1,1′-dioxide.



IX

This product may be formed by condensation of two molecules of the aminopyrazole and N-oxide formation. Although the sequence of these two steps is unknown, the presence of the N-oxide function suggests that the first reaction of the pyrazole with hydrogen peroxide is transfer of an oxygen to the ring nitrogen, just as in the case of pyridine and other nitrogen heterocycles.

The 2,2′-dioxide structure is favored over the 1,1′-analog, because the ultraviolet spectrum of the compound has its maximum at 247 mμ. This is practically the same as for 5-amino-3-methyl-1-phenylpyrazole (II) (246 mμ). If the oxygen were at N-1, there would be no unshared pairs of electrons on the nitrogen to conjugate with the benzene ring, and the bond maximum should be observed at a shorter wave length; also the N–H bond in the infrared spectrum should be shifted to a higher wave length, because of the possibility of strong hydrogen bonding to a 1-oxide function.

The 2-oxide structure for IX favors the second mechanism postulated for azipyrazole formation,

(16) J. N. Brough, B. Lythgoe and P. Waterhouse, *J. Chem. Soc.*, 4969 (1954).

(17) It is, of course, possible to postulate other mechanisms for azipyrazole formation. A Referee has pointed out that it is conceivable that azipyrazole is formed by oxidation of the phenylhydrazone of diacetonitrile, which may be present in very small concentrations in tautomeric equilibrium with the pyrazole (II). We are planning to do further experimental work on the mechanism of oxidative cleavage of pyrazoles.

(18) B. Curnutte, Jr., S. Searles, Jr., and W. R. Hine, Jr., to be published.

(19) Another strong band at 7.76 μ was in the region for symmetric stretching of the $N{=}\overset{+}{N}{-}O^-$ group, as assigned by B. W. Langley, B. Lythgoe and L. S. Reyner, *J. Chem. Soc.*, 419 (1952).

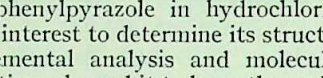
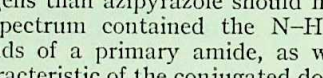
Digitized by Arya Samaj Foundation Chennai and eGangotri

because the intermediate VIII for the latter could give rise to IX by means of self-condensation. It is uncertain whether IX is an intermediate in azipyrazole formation, but several experiments were attempted to see if it could be converted to azipyrazole. The most interesting one was that in which the hydrochloride of IX was heated at 160°, giving a material closely resembling azipyrazole in the common physical properties. Closer examination showed it, however, to be a new compound. Since it also was a major product (38% yield) of the reaction of hydrogen peroxide with 5-amino-3-methyl-1-phenylpyrazole in hydrochloric acid, it seemed of interest to determine its structure.

The elemental analysis and molecular weight determinations showed it to have the molecular formula $C_{10}H_{11}N_3O_2$—two more hydrogens and two more oxygens than azipyrazole should have. The infrared spectrum contained the N–H and carbonyl bands of a primary amide, as well as the bands characteristic of the conjugated double bond, the phenyl group[5] and the azoxy group.[18] Significantly, the pyrazole bands were completely absent. The two oxygens are thus accounted for by the amide and the azoxy functions. It will be recognized that all the structural features, as well as the analytical data, fit 3-(phenyl-NON-azoxy)-crotonamide (Xa) as well as 3-(phenyl-NNO-azoxy)-crotonamide (Xb).[20]



Xa



Xb

In support of such an azoxyamide structure, the compound was converted to azipyrazole by heating with phosphorus trichloride in chloroform.[21] Furthermore, the reaction of 3-(phenylazo)-crotonamide (V) with perphthalic acid gave the same azoxyamide, thus providing an independent synthesis.

Comparison of the ultraviolet spectra of V and the azoxyamide then permitted assignment of the position of the N-oxide oxygen atom in the latter. The maximum for the azoamide was at 250 mμ while that for the azoxyamide was 244. This shift to shorter wave length indicates less conjugation of the benzene ring in the azoxyamide. Such would be the case with the oxygen on the phenyl-substituted nitrogen, since the oxygen would compete with the benzene ring to supply electrons to the carbonyl group. If the oxygen were on the other nitrogen, however, its unshared electrons would be able to conjugate with the benzene ring and would not compete with the latter in resonance with the conjugated chain; the result would be more conjugation of the ring and a shift of the maximum absorption to higher wave lengths. Lythgoe and associates have observed the maximum in ArN=N(O)R compounds, where R is saturated, to be at 292–300 mμ.[16] Similarity of the ultraviolet spectrum to that of nitrobenzene (λ_{max} 260 mμ) also may be used as an indication of the ArN(O)=NR structure.[25] Thus structure Xa is indicated for the azoxyamide, rather than Xb.[22]

The formation of this compound from II probably proceeded *via* azipyrazole. It is well known that hydrogen peroxide is able both to oxidize the azo group to azoxy and (due to its superior nucleophilic property)[23] to hydrolyze the nitrile group to the amide group. The formation of the azoxyamide from the (probably hydrated) hydrochloride of IX suggests that it may have first hydrolyzed to VIII and the corresponding pyrazolone-2-oxide, with VIII cleaving to azipyrazole which was subsequently oxidized by hydrogen peroxide from the pyrazolone-2-oxide and water.

Experimental[24]

5-Amino-3-methyl-1-phenylpyrazole was prepared in 75% yield by cyclizing diacetonitrile phenylhydrazone[26] with dry hydrogen chloride in absolute ethanol and treating the intermediate hydrochloride with ammonia in aqueous solution. The product was obtained as white needles from toluene, m.p. 112–114° (lit.[26] m.p. 115–116°).

Di-(3-methyl-1-phenyl-5-pyrazyl)-amine 2,2′(?)-Dioxide (IX).—A solution of 3.0 ml. of 30% hydrogen peroxide and 5.0 g. of 5-amino-3-methyl-1-phenylpyrazole in 50 ml. of 50% aqueous acetic acid was heated on a steam-bath for 5 hr. A red color developed in a few minutes and after about 30 minutes a yellow precipitate began to separate. It was removed by filtration and recrystallized from pyridine-water to give 3.57 g. (70%) of a white crystalline solid, m.p. 229–230°. The infrared and ultraviolet spectra are described in the Discussion.

Anal. Calcd. for $C_{20}H_{19}N_5O_2$: C, 66.48; H, 5.26; N, 19.39; C-methyl, 2.0; mol. wt., 361. Found: C, 66.47; H, 5.30; N, 19.38; C-methyl, 1.7; mol. wt., 339.

3-(Phenyl-NON-azoxy)-crotonamide (Xa). (A).—Addition of IX to concentrated hydrochloric acid caused precipitation of a white hydrochloride, m.p. 178–180°, which decomposed to a red oil on being heated dry at 160° for 15 minutes. On cooling the red oil solidified (m.p. 109–113°) and recrystallization from aqueous ethanol gave light tan needles, m.p. 113°. The yield was 0.2 g. from 1.0 g. of IX.

(B).—5-Amino-3-methyl-1-phenylpyrazole (5.0 g.) was dissolved in 35 ml. of concentrated hydrochloric acid, and 3 ml. of 30% hydrogen peroxide was added. The solution was evaporated on a steam-bath, leaving a red oil which was crystallized from dilute alcohol. A light tan solid, m.p. 113°, was obtained in 38% yield (2.4 g.).

(20) According to a new method of naming azoxy compounds suggested by J. N. Brough, B. Lythgoe and P. Waterhouse (ref. 16), Xb would be termed 3-(phenylazoxy)-crotonamide and Xa would have to be named 1-carbamoylpropen-2-ylazobenzene. Because the latter name seems cumbersome and screens the α,β-unsaturated amide structure, we feel the NON and NNO designation of the oxide function, used by C. S. Stevens, B. T. Gillis, J. C. French and T. H. Haskell (THIS JOURNAL, **78**, 3229 (1956)), is preferable.

(21) Use of phosphorous trichloride here was suggested by its demonstrated ability to convert pyridine N-oxides to the corresponding pyridines (E. Ochiai, *J. Org. Chem.*, **18**, 534 (1953)). The phosphorous oxychloride formed in removing the oxygen from the azoxy group may then dehydrate the [illegible]

(22) The attack of hydrogen peroxide on the phenyl-substituted nitrogen seems contrary to expectation, since the reagent should be electrophilic in this reaction and the other nitrogen of the azo group should have the higher electron density. A similar result, however, has been observed on oxidation of aryl alkyl azo compounds (ref. 16).

(23) K. B. Wiberg, THIS JOURNAL, **75**, 3961 (1953). In the coiled form of the azipyrazole molecule these two groups are in close proximity, perhaps permitting both processes to go on almost simultaneously and explaining why neither azoamide nor azoxynitrile was found.

(24) Carbon–hydrogen microanalyses were performed by Weiler and Straus, Oxford, England. Melting points are uncorrected. Nitrogen analyses were by the Dumas method; molecular weight determinations by the Rast method; and C-methyl numbers by the Kuhn-Roth method (E. J. Eisenbraun, S. M. McElvain and B. F. Aycock, THIS JOURNAL, **76**, 607 (1954)).

(C).—Five drops of concentrated sulfuric acid was added to a solution of 5 g. of 5-amino-3-methyl-1-phenylpyrazole and 1 ml. of 90% hydrogen peroxide[27] in 30 ml. of glacial acetic acid, cooled in ice so that the temperature remained below 40° (otherwise the reaction is very exothermic). The deep-red solution was evaporated *in vacuo*. Extraction of the red oil with 95% alcohol left a residue of 1.8–2.0 g. of compound IX. The sticky red-brown semi-solid left on evaporation of the alcohol was extracted with ether to give 0.1 g. of tan needles, m.p. 113°; mixed m.p. with products from (B) and (C) undepressed. (In one experiment 0.2 g. of orange-red needles, m.p. 70–80°, was obtained from this ether solution (lit. m.p. for Quilico and Justoni's isomer,[14] 81°). On recrystallization from dilute ethanol it was converted to light tan needles, m.p. 103–106°.) The infrared spectrum was characterized by prominent bands at 2.96, 3.15, 3.28, 3.42, 3.53, 5.9, 6.1, 6.18, 6.25, 6.54, 6.66, 6.76, 6.87, 7.18, 7.63, 10.1, 10.9, 11.9 and 13.1 μ.

Anal. Calcd. for $C_{10}H_{11}N_3O_2$: C, 58.53; H, 5.40; N, 20.5; C-methyl, 1.0; mol. wt., 205. Found: C, 58.22; H, 5.42; N, 19.8; C-methyl, 0.96; mol. wt., 188.

In the early stages of this work, when this compound was thought possibly to be "azipyrazole," its dipole moment was determined to check the possibility of a mesoionic structure. The dielectric constant of benzene solutions was determined by the standing microwave technique.[28] The calculated dipole moment was 0.86 *D*.

3-(Phenylazo)-crotononitrile (Azipyrazole). (A).—To 0.05 g. of 3-(phenyl-NON-azoxy)-crotonamide dissolved in 15 ml. of chloroform at 0°, 0.05 ml. of phosphorus trichloride was added, and the solution was refluxed 1 hr. After cooling, 25 ml. of water was added and the mixture was made alkaline with sodium hydroxide. The chloroform layer was dried with sodium sulfate and the solvent then was removed *in vacuo*. The light brown residual solid was sublimed at 90° (0.05 mm.) to give 10 mg. (30%) of ivory-white needles, m.p. 109°. The m.p. was unchanged after recrystallization from dilute alcohol.

(B).—Vacuum sublimation of the red oil described in (C) for the azoxy compound gave 20 mg. of the same product.

(C).—To a solution of 1.0 g. of diacetonitrile phenylhydrazone in 35 ml. of absolute alcohol was added 2 g. of yellow mercuric oxide, and the mixture was refluxed for 2 hr. The free mercury was filtered off and most of the alcohol distilled off, leaving a red oil. This was partially soluble in light petroleum ether; the insoluble part was then dissolved in ethyl ether. Evaporation of the solvent from the ethyl ether solution gave 0.3 g. of tan needles, m.p. 105–107°. Vacuum sublimation as described above gave 0.20 g. (26%) of ivory-colored needles, m.p. 109°. The mixed melting points of the 109° products from these three methods were undepressed and all had the same infrared spectrum. The latter was characterized by prominent bands at 4.45, 6.20 and 6.25 μ, as well as at 3.53, 3.44, 5.80, 5.87, 5.93, 6.07, 6.31, 6.65, 6.73, 7.31, 7.95 and 8.25 μ.

Anal. Calcd. for $C_{10}H_9N_3$: N, 24.55. Found: N, 24.22.

Derivatives were prepared as follows: **5-amino-3-methyl-1-phenylpyrazole**, m.p. 113–115° (lit.[26] m.p. 115–116°), when azipyrazole was boiled a few minutes in 10% sodium hydrosulfite solution and filtered. **5-Amino-4-iodo-3-methyl-1-phenylpyrazole**, m.p. 75° (lit.[1a] m.p. 75°), when azipyrazole was warmed a few minutes with concentrated hydriodic acid, followed by saturating the solution with sodium hydroxide, extracting with ether and removing the ether from the extract by evaporation. **5-Amino-4-bromo-3-methyl-1-phenylpyrazole**, m.p. 105° (lit.[1a] m.p. 106.5° and mixed m.p. with azipyrazole 83–99°), was obtained by the same procedure using 48% hydrobromic acid.

Evaporation of the solvent from the petroleum ether extract of the reaction mixture in (C) left 50 mg. of stout red needles, m.p. 73–76°; after recrystallization from alcohol they melted at 82–83°.

Anal. Calcd. for $C_{10}H_9N_3$: N, 24.55. Found: N, 24.83.

3-(Phenylazo)-crotononamide (V).—Ethyl 3-(phenylazo)-crotonate was prepared in 10% yield by the reaction of mercuric oxide on ethyl acetoacetate phenylhydrazone[9]; red crystals, m.p. 50°. A solution of 80 mg. of this azoester and 2 g. of dry ammonia in 10 ml. of absolute ethanol was heated in a sealed tube 10 hr. at 110°. On subsequent evaporation of the solvent 60 mg. (90%) of a black crystalline solid, m.p. 74°, remained. (In another run the yield on this reaction was 60%.)

Anal. Calcd. for $C_{10}H_{11}N_3O$: N, 22.22. Found: N, 21.92.

The above amide (40 mg.) was added to 5 ml. of an ether solution of monoperphthalic acid,[29] containing 1×10^{-3} mole of the latter. After standing two days, sodium bicarbonate was added to neutralize the acid present. The ether solution was separated, dried and evaporated *in vacuo*, leaving tan needles, melting at 113°, identical with the 3-(phenyl-NON-azoxy)-crotonamide previously described.

Azipyrazole from V.—Phosphoric anhydride (100 mg.) was added to a solution of 50 mg. of 3-(phenylazo)-crotonamide in 15 ml. of benzene. The mixture was refluxed 30 minutes, cooled and filtered. The solvent was removed from the filtrate *in vacuo*. The white needles obtained (about 15 mg.) melted at 109° and the mixed melting point with azipyrazole prepared by other methods was also 109°.

Acknowledgments.—We wish to thank Dr. John G. Erickson for his kind encouragement and valuable comments, Dr. Louis D. Ellsworth for his aid with the dipole moment measurement and Dr. Basil Curnutte for his assistance in selecting the N–O bands in the infrared spectra of the azoxy compounds.

Preparation and Thermal Rearrangement of Several Dicyclopentadiene Derivatives

BY MYRON ROSENBLUM[1]

RECEIVED DECEMBER 20, 1956

Oxidation of dicyclopentadiene with selenium dioxide in aqueous dioxane solutions has been shown to yield 1-dicyclopentadienol. The oxidation of this alcohol under Oppenauer conditions affords 1-dicyclopentadienone, and its pyrolysis leads to the formation of cyclopentadiene and 2-cyclopentenone. Treatment of 1-dicyclopentadienone with both methyl and phenyl Grignards leads to the formation of the corresponding tertiary alcohols, 1-methyldicyclopentadiene-1-ol and 1-phenyldicyclopentadiene-1-ol. Pyrolysis of 1-acetoxydicyclopentadiene, prepared by acetylation of 1-dicyclopentadienol, affords azulene in low yield.

The synthesis of oxygenated derivatives of dicyclopentadiene has hitherto been confined to the di- and tetrahydro members of the parent diene,[2] although a considerable number of polyalkyl,

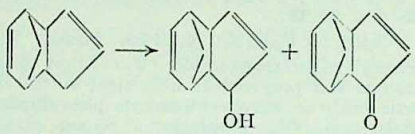
polyaryl and polyhalo dicyclopentadienes possessing oxygen functions at either or both positions 1 and 8 of the tricyclic system are known.[3,4]

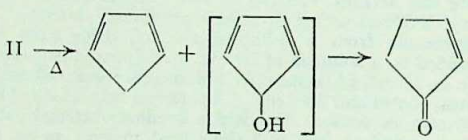
The present paper describes the preparation of several new oxygenated derivatives of dicyclopentadiene and includes a preliminary account of the behavior of some of these on pyrolysis.

Oxidation of dicyclopentadiene (I) with selenium dioxide in dioxane–water solutions afforded 1-dicyclopentadienol (II) in 57% yield, together with a small amount of 1-dicyclopentadienone (III). This alcohol had previously been prepared by Vanelli[5] by hydrolysis of 1-acetoxydicyclopentadiene (IV), obtained by treatment of dicyclopentadiene with selenium dioxide in acetic acid medium.



I II III

Slow distillation of II at atmospheric pressure gave cyclopentadiene and 2-cyclopentenone (V) in 42% yield, while vapor phase pyrolysis at reduced pressures resulted in an essentially quantitative conversion of II to V and cyclopentadiene. The formation of V may be viewed as proceeding *via* an initial reverse Diels–Alder reaction followed by isomerization of the transient 2,4-cyclopentadienol (VI).



VI V

The reaction sequence I → II → V constitutes a useful procedure for the preparation of 2-cyclopentenone which has heretofore been obtained either by allylic oxidation of cyclopentene[6] or by dehydrohalogenation of 1-halocyclopentanone.[7] Of these methods only that of Treibs[6b] and of Corey[7c] are of preparative value.

Oppenauer oxidation of II, employing *p*-quinone as oxidant, gave 1-dicyclopentadienone (III) in 79% yield.[8] Attempts to effect the thermal reversal of III to cyclopentadiene and the unknown cyclopentadienone were unsuccessful. Unlike II, the ketone III resisted pyrolysis at temperatures well above those sufficient to effect reversal of II to its diene and dienophile components.

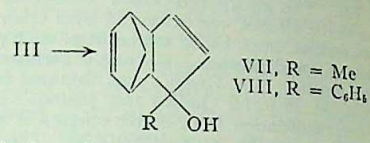
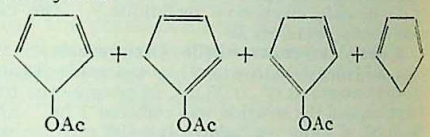
(8) H. Hock and F. Depke, *Ber.*, **84**, 356 (1951), have reported the isolation of a ketone $C_{10}H_{10}O$ from the air oxidation of dicyclopentadiene to which they ascribe the structure of 1-dicyclopentadienone (III). However, their observation that the substance was an oil which resisted crystallization must cast doubt upon its identity, since the ketone prepared as described in this report is a readily crystallizable solid melting at 59°.

Treatment of II with both methyl and phenyl Grignards afforded the corresponding tertiary alcohols, 1-methyldicyclopentadiene-1-ol (VII) and 1-phenyldicyclopentadiene-1-ol (VIII). The pyrolysis of these compounds has not as yet been explored.



Pyrolysis of 1-acetoxydicyclopentadiene, prepared by acetylation of II, led to the formation of cyclopentadiene and a mixture of acetoxycyclopentadienes (IX, X, XI).[5] When this mixture was heated at 150° for 3 hr. and then repyrolyzed at atmospheric pressure, acetic acid was evolved and azulene, identified by its melting point and its ultraviolet absorption spectrum,[9] was isolated in low yield.



IX X XI

The identity of the isomer, present in the complex mixture of diacetoxydicyclopentadienes formed by dimerization of IX, X and XI, which on rearrangement gives rise to azulene, is being investigated.

Acknowledgment.—We are indebted to Professor R. B. Woodward, who suggested this problem, for many valuable discussions during the course of the investigation.

Experimental

1-Dicyclopentadienol (II).—Freshly distilled dicyclopentadiene, 185 g. (1.4 moles), was dissolved in a mixture of 500 ml. of dioxane and 50 ml. of water. Selenium dioxide, 66.5 g. (0.6 mole), was added, and the solution was stirred and heated under reflux for 3 hr. The resulting dark brown mixture was then filtered from selenium and poured into two liters of water. The heavy dark oil was drawn off and the aqueous solution was extracted with 600 ml. of ether in three portions. The organic solutions were combined, washed with water and dried over magnesium sulfate. Removal of solvent, followed by fractionation of the crude product, gave 1-dicyclopentadienol as a pale yellow, viscous oil; yield 100.2 g. (57%), b.p.'s 84° (3 mm.), 90° (5 mm.) and 106° (7 mm.). Redistillation resulted in a colorless product whose infrared spectrum was identical with that of II prepared earlier by Vanelli[5] by hydrolysis of 1-acetoxydicyclopentadiene.

1-Dicyclopentadienone (III).—A mixture of 52.5 g. of 1-dicyclopentadienol (0.36 mole), 48.0 g. of *p*-quinone (0.45 mole) and 87.0 g. of aluminum *t*-butoxide (0.36 mole) in 650 ml. of dry benzene was stirred at 50° for 6 hr. At the end of this period, the dark purple solution was allowed to cool and was decomposed with water. Aluminum hydroxide was filtered off and washed thoroughly with ether. The combined benzene–ether solution was extracted five times with 100-ml. portions of 5% sodium hydroxide solution, washed with water to neutrality and finally dried over magnesium sulfate. After evaporation of solvent, the product was distilled at 82–87° (4 mm.) as a pale yellow oil, which crystallized on being cooled to room temperature; yield 41.0 g. (79%). A portion was recrystallized several times from low boiling petroleum ether to give the pure ketone as colorless plates, m.p. 59.0–59.5°.

Anal. Calcd. for $C_{10}H_{10}O$: C, 82.16; H, 6.90. Found: C, 82.67; H, 7.18.

A 2,4-dinitrophenylhydrazone derivative, crystallized from ethyl alcohol, melted at 203.5–204.0°.

Anal. Calcd. for $C_{16}H_{14}N_4O_4$: C, 58.89; H, 4.32; N, 17.17. Found: C, 58.71; H, 4.54; N, 17.13.

1-Acetoxydicyclopentadiene (IV).—1-Dicyclopentadienol, 50 g., was dissolved in 130 ml. of pyridine containing 100 ml. of acetic anhydride. After standing at room temperature for 12 hr., the solution was poured onto ice and the heavy dark oil was separated. The aqueous solution was extracted twice with 100-ml. portions of ether, and these extracts were combined with the oil. The organic solution was washed several times with dilute hydrochloric acid and then with water to neutrality. After drying the solution over Drierite, solvent was evaporated and the residue was fractionated. The ester distilled at 118.5–120.5° (14.5 mm.), yield 55.6 g. (87%). Its infrared spectrum was identical with that of 1-acetoxydicyclopentadiene prepared earlier by Vanelli.[6]

2-Cyclopentenone (V). By Pyrolysis of 1-Dicyclopentadienol at Atmospheric Pressures.—1-Dicyclopentadienol, 48.85 g., was placed in a 250-ml. claisen flask having a six-inch side arm. The flask was heated over a free flame as a slow stream of dry nitrogen was passed through the alcohol. The distillate temperature was maintained at 140–150°. A slower rate of distillation resulted generally in greater polymerization of the material in the distilling flask. The distillate, containing unchanged alcohol, cyclopentadiene and 2-cyclopentenone, was fractionated to give 8.29 g. of ketone V, b.p. 50° (15 mm.), $n^{25}D$ 1.4753 (lit.[7c] b.p. 53° (16 mm.), $n^{18.2}D$ 1.4780), and 13.13 g. of unchanged 1-dicyclopentadienol. The yield of 2-cyclopentenone, corrected for recovered alcohol, was 42%. Its dinitrophenylhydrazone derivative, m.p. 169–171°, was identical by mixed m.p. determination with that prepared from an authentic sample of 2-cyclopentenone.

2-Cyclopentenone (V). By Vapor Phase Pyrolysis of 1-Dicyclopentadienol at Reduced Pressures.—The apparatus used in these and later experiments consisted of a 25-ml. round-bottom flask, surmounted by a small addition funnel. One of two side-arm tubes joined to the flask served as an inlet for nitrogen while the other led directly to the pyrolysis chamber. The latter consisted of a horizontally mounted Pyrex tube, 30 cm. in length and 1.8 cm. in diameter, heated by means of a multiple unit electric furnace. The pyrolysis tube was connected to a receiver flask, vacuum gage and pump. Temperatures within the pyrolysis chamber were measured by means of an iron–constantan thermocouple.

With the apparatus evacuated to a pressure of 5–7 mm. (nitrogen atmosphere) and the pyrolysis tube heated to a temperature of 450°, the alcohol was allowed to drop slowly from the addition funnel into the distilling flask, heated by means of a oil-bath to 200°. The alcohol was thus immediately volatilized and swept into the pyrolysis chamber by the nitrogen stream and thence into the receiver flask cooled in a Dry Ice–acetone-bath. Infrared spectra taken of the products of several runs, after allowing the cyclopentadiene to evaporate, failed to reveal the presence of any unchanged alcohol and were essentially identical with that of 2-cyclopentenone obtained by pyrolysis of II at atmospheric pressures. Polymeric residues in the distillation flask and the pyrolysis chamber were negligible.

Attempted Pyrolysis of 1-Dicyclopentadienone (III).—When small amounts of the ketone III were heated in a distilling flask at 200–250° in an attempt to effect a reverse Diels–Alder reaction, a part of the ketone distilled unchanged while the remainder polymerized in the distilling flask.

1-Methyldicyclopentadiene-1-ol (VII).—1-Dicyclopentadienone, 10.0 g. (0.069 mole), dissolved in 20 ml. of anhydrous ether, was added dropwise to a stirred solution of methylmagnesium iodide prepared from 1.75 g. (0.069 mole) of magnesium turnings and 12.0 g. (0.085 mole) of methyl iodide in 40 ml. of anhydrous ether. The solution was refluxed on the steam-bath for 30 minutes following addition of the ketone and was then cooled and decomposed with saturated ammonium chloride solution. The aqueous phase was separated, extracted several times with ether, and the ethereal extracts were combined, washed to neutrality with water and dried over calcium sulfate. Evaporation of solvent left 7.85 g. (70%) of pale yellow oil which solidified on cooling. A portion of this material, after several recrystallizations from low boiling petroleum ether, followed by sublimation, yielded pure 1-methyldicyclopentadiene-1-ol as fine colorless needles, m.p. 49.0–49.5°.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.50; H, 8.70. Found: C, 81.50, 80.71; H, 9.08, 8.77.

1-Phenyldicyclopentadiene-1-ol (VIII).—1-Dicyclopentadienone, 2.0 g. (0.014 mole), dissolved in 10 ml. of anhydrous ether, was added dropwise to a stirred solution of phenylmagnesium bromide prepared from 2.15 g. (0.14 mole) of bromobenzene and 0.38 g. (0.016 mole) of magnesium turnings in 45 ml. of anhydrous ether. The solution was refluxed on the steam-bath for 30 minutes following addition of the ketone and was then cooled and decomposed with saturated ammonium chloride solution. The aqueous phase was separated and extracted several times with ether. The ether solutions were combined, washed to neutrality and dried over calcium sulfate. The crude solid, isolated on evaporation of solvent, was recrystallized twice from low boiling petroleum ether to give 0.75 g. (33%) of 1-phenyldicyclopentadiene-1-ol, m.p. 65.5–66.5°.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.67; H, 7.19. Found: C, 86.28, 85.76, 85.79; H, 7.33, 7.39, 7.22.

Azulene. By Pyrolysis of 1-Acetoxydicyclopentadiene.—The apparatus described above in the pyrolysis of 1-dicyclopentadienol was employed in this experiment. The acetate, 10.4 g., was allowed to drop slowly into the distilling flask which was heated to a temperature of 190–200°. A pressure of 5–7 mm. (nitrogen atmosphere) was maintained during the course of the pyrolysis, and the pyrolysis chamber was heated to 440–475°. At the end of 1 hr. addition of the acetate was complete, and 10.4 g. of orange oil had been collected in the receiver flask. The product was heated in an atmosphere of nitrogen at a temperature of 150° for 3 hr. A portion of this material, 7.8 g., was placed in a short path distillation flask containing 1.95 g. of calcium oxide powder, and the flask was immersed in a Woods metal-bath preheated to 240°. A slow stream of nitrogen was bubbled through the mixture during the course of the pyrolysis. After the contents of the flask had been heated for 15 minutes and the bath had reached a temperature of 255°, vacuum was applied, and 1.70 g. of pale blue distillate was collected. Following another brief period of heating, when the bath temperature had risen to 265°, vacuum was again applied, and an additional 1.12 g. of dark blue liquid was collected. The two distillate fractions were combined and placed on a chromatographic column prepared from 16 g. of alumina. On elution with low boiling petroleum ether, the blue component moved rapidly down the column as a well defined zone. This material was rechromatographed three times on 8-g. alumina columns, and in this manner 2.5 mg. of dark blue crystalline material, m.p. 92–95° (with sublimation), was isolated after removal of solvent. The ultraviolet spectrum of the product, taken in 95% ethanol solution, was identical with that of azulene reported by Plattner and Heilbronner.[9]

Kolbe Electrolyses[1] of Perhydrodiphenic Acids

BY C. G. OVERBERGER AND PETER KABASAKALIAN[2]

RECEIVED JANUARY 7, 1957

The Kolbe electrolysis of *cis–syn–cis*-, *trans–anti–trans*- and *trans–syn–trans*-perhydrodiphenic acids in anhydrous methanol is described. In all cases, the principal product was a γ-lactone. The structure of the γ-lactone was established by chemical synthesis. The formation of the γ-lactone may involve a hydrogen radical transfer reaction.

The electrolysis of dibasic acids (from malonic to sebacic) in aqueous media have been reported[3] to yield olefins and alcohols, containing two carbons less than the starting material. The structures of the olefins and the alcohols obtained were both the expected ones as well as their isomers. The latter may have been formed by migration of hydrogen atoms in the originally formed radicals.

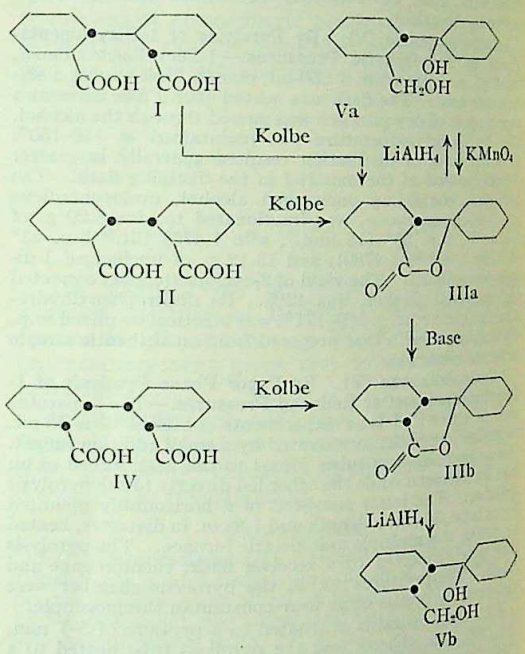
Although all attempts to isolate the coupled product, cycloalkanes, have not been successful, Vanzetti[3d] has reported the formation of a small amount of lactone during the electrolysis of suberic acid. This paper describes an initial phase of the study of Kolbe electrolyses of dibasic acids in anhydrous methanol.

The Kolbe electrolysis products from the perhydrodiphenic acids were separated into a steam-distillable fraction (monomeric) and a non-steam-distillable fraction (polymeric). The non-steam-distillable fractions account for about 20–25% of the product and were presumed to be made up of polymeric material. The steam-distillable fractions, which account for about 60% of the product, contain about 20% of non-lactonic material which was not identified.

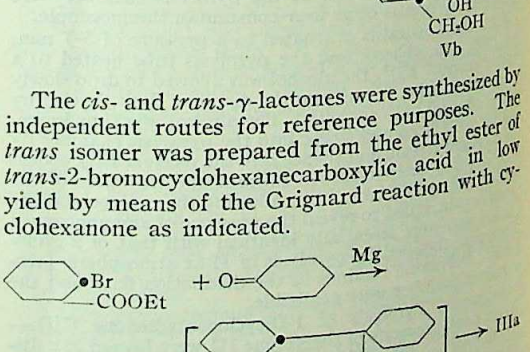
The Kolbe electrolysis of the three perhydrodiphenic acids studied here gave as a minor product (about 5%) δ-lactones. These probably were formed by the intramolecular coupling of the primary and the secondary radicals formed at the anode and were identified only by their infrared spectrum. Their infrared absorption band at 5.76 μ is indicative of a saturated six-membered lactone, but an open chain ester[4] cannot be excluded.

The electrolysis of *trans–anti–trans* (I) and *trans–syn–trans* (II) perhydrodiphenic acids gave as the major product (about 45%) the *trans*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid (IIIa), while the electrolysis of *cis–syn–cis* (IV) perhydrodiphenic acid gave the *cis*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid (IIIb). These isomeric γ-lactones from the Kolbe electrolyses could not be obtained stereochemically pure since isomerization conditions prevailed during their preparation.

The structure of the *trans*-γ-lactone was verified in the following way. Reduction with lithium aluminum hydride gave the *trans*-glycol (90%). This product was found to have only one hydroxyl group which could be acetylated easily. The *trans*-γ-lactone (37%) was regenerated when the *trans*-glycol was oxidized with alkaline potassium permanganate.



The *cis*- and *trans*-γ-lactones were synthesized by independent routes for reference purposes. The *trans* isomer was prepared from the ethyl ester of *trans*-2-bromocyclohexanecarboxylic acid in low yield by means of the Grignard reaction with cyclohexanone as indicated.



The cylization of the initial Grignard product of this type also has been reported by Cason, Adams, Bennett and Register[5] who prepared γ-substituted γ-lactones by the action of Grignard reagents on levulinic esters.

The *cis* isomer was prepared by two methods. The first method[6] involved a Diels–Alder reaction

between butadiene and the methyl ester of β-(1-hydroxycyclohexyl)-propiolic acid to give the lactone of 2-(1-hydroxycyclohexyl)-1,4-cyclohexadiene-1-carboxylic acid (68%). Catalytic reduction with the aid of Adams catalyst eliminated the isolated double bond to form the lactone of 2-(1-hydroxycyclohexyl)-1-cyclohexene-1-carboxylic acid (89%). Further reduction with the aid of Raney nickel and high pressure yielded the *cis*-γ-lactone (82%).

The second method for the preparation of the *cis* isomer used 2-(1-hydroxycyclohexyl)-cyclohexanone as starting material. Two methods are reported for the preparation of this compound and different melting points are recorded. Colonge's[7] method involved treating cyclohexanone with the reaction product from methyl Grignard reagent and N-methylaniline (m.p. 56°). Stanek's[8] method involved the self-condensation of cyclohexanone with ethanolic potassium hydroxide as the basic catalyst (m.p. 160°). The first step in this route involved the formation of cyanohydrins, which immediately cyclized to form probably five-membered cyclic imidic acid esters. These were not purified and on hydrolysis gave hydroxy-γ-lactones. Although Stanek's β-ketol gave a hydroxy-γ-lactone, the carbon and hydrogen analyses of the β-ketol and the hydroxy-γ-lactone were not in agreement with the proposed structure.

Colonge's β-ketol gave two isomeric hydroxy-γ-lactones (89%). One was a solid which is presumed to be the *trans* form from the stereochemistry of the subsequent dehydration step. It accounted for 20% of the total hydroxy lactone. The major fraction was a liquid and is presumed to be the *cis* form from the stereochemistry of the following dehydration step.

Parham, Moulton and Zuckerbraun[9] have reported that the dehydration of 2-phenylcyclohexanone cyanohydrin with thionyl chloride in pyridine is kinetically controlled, resulting in the *trans* elimination of the hydroxyl group. Using the same reaction conditions, thionyl chloride in pyridine, each of the isomeric hydroxy-γ-lactones was dehydrated and found to yield a different unsaturated lactone. The *trans* isomer gave the $\Delta^{1,2}$-product (90%) while the *cis* isomer gave the $\Delta^{1,6}$-product (72%). High pressure reduction, using Raney nickel catalyst, of the $\Delta^{1,6}$-unsaturated lactone also gave the *cis*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid (75%). The *cis*-γ-lactone was reduced with lithium aluminum hydride to give the *cis*-glycol (98%).

Both the *cis*- and *trans*-γ-lactones were isomerized separately with sodium methoxide in anhydrous methanol. Identical equilibrium mixtures were obtained from both; the equilibrium mixture from the *cis* isomer was found to contain 90% *cis*- and 10% *trans*-γ-lactone while the equilibrium mixture from the *trans* isomer was found to contain 91% *cis*- and 9% *trans*-γ-lactone. Thus, the *cis* isomer seemed to be the most stable one at equilibrium.

The melting points of various pairs of isomers obtained in this study are listed in Table I.

TABLE I

ISOMERIC PAIRS

Compound	Isomer	M.p., °C.
Lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid	*cis*	55–56
	trans	99–99.5
2-(1-Hydroxycyclohexyl)-cyclohexanemethanol	*cis*	117–118
	trans	92.5–93
Lactone of 2-(1-hydroxycyclohexyl)-1-hydroxycyclohexanecarboxylic acid	*cis*	?
	trans	159–161
Lactone of 2-(1-hydroxycyclohexyl)-cyclohexene-1-carboxylic acid	$\Delta^{1,2}$	79–80
	$\Delta^{1,2}$	71–72

A possible mechanism for the formation of the γ-lactones may involve a hydrogen radical transfer at the location of the secondary radical, followed by an intramolecular coupling of the rearranged radical and the primary radical formed at the anode.

Urry[10] and Muhs,[11] who studied the alcoholic electrolyses of monocarboxylic acids which generated radical intermediates containing a quaternary carbon adjacent to a primary carbon that was the original radical site, found that of the products formed only those from a single radical showed rearrangement. The products formed from two radicals (coupled and ester products) were unrearranged.

The possibility of other mechanisms to explain the five-membered lactone cannot be excluded. Thus, lactonization could have occurred by ionic processes involving addition of a radical or an ion derived from one carboxyl group to an olefin linkage in the adjacent ring formed from radical disproportionation. The possibility that hydrogen migration occurred by an ionic transfer to a carbonium ion formed by oxidation of the radical at the anode also cannot be discounted completely until further evidence is obtained.

Acknowledgment.—We wish to thank the Schering Corporation for the generous use of their laboratory facilities in this work.

Experimental[12]

Absorption Spectra.—The ultraviolet absorption spectra were measured in 1-cm. quartz cells in methanol solutions using a Cary model 11 recording spectrophotometer. Infrared absorption spectra were obtained with a Perkin–Elmer model 21 double beam recording spectrophotometer with a sodium chloride prism.

Electrolyses.—The electrolysis equipment, conditions and electrode preparation were identical to those reported by Overberger and Kabasakalian.[1]

Kolbe Electrolysis of *trans–syn–trans*-Perhydrodiphenic Acid[13] (II).—A solution of 1.7 g. (0.050 mole) of II in 60 ml. of anhydrous methanol and 10 ml. of 0.20 *N* sodium methoxide was electrolyzed. The electrolysis required about 6 hr. (the current continually decreased and the anode became coated with insoluble material). The electrolyzed solution which was almost neutral was distilled under atmospheric pressure until the distillation temperature started to rise above 70° and most of the methanol was removed. The reaction mixture was then subjected to steam distillation; 6.0 l. of distillate was collected and extracted with ether. The extracts were dried over calcium chloride and concentrated to give 6.46 g. of liquid, fraction A, from which 0.63 g. of solids crystallized, m.p. 87–90°. This sample contained a small amount of the isomeric γ-lactone which could not be separated. Most of fraction A is a mixture of the isomeric γ-lactones (see later Experimental). The infrared spectrum of this solid in a Nujol mull indicated a γ-lactone.[4] Subsequently, this spectrum was found to be identical with the spectrum of the *trans*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid (IIIa).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68; mol. wt., 208. Found: C, 75.04; H, 9.62; mol. wt., 213 (cryoscopic).

The non-steam-distillables amounted to 1.95 g. The infrared spectrum of fraction A in carbon disulfide indicated approximately 70% γ-lactone[4] and 10% δ-lactone.[4]

Kolbe Electrolysis of *trans–anti–trans*-Perhydrodiphenic Acid[13] (I).—A solution of 1.27 g. (0.0050 mole) of I in 70 ml. of anhydrous methanol and 1 ml. of 0.20 *N* sodium methoxide was electrolyzed. The electrolyzed solution was treated as described above to give 0.605 g. of liquid, fraction A, from which 0.138 g. of solid crystallized, m.p. 84–86°. This sample contained a small amount of the isomeric γ-lactone which could not be separated. Most of fraction A is a mixture of the isomeric γ-lactones. The infrared spectrum of this solid in a Nujol mull was identical with the spectrum of the *trans*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid (IIIa). It was not possible to remove all traces of the *cis*-lactone in this synthetic product also (see later Experimental).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.78; H, 9.64.

Fraction B, the non-steam-distillables, amounted to 0.197 g. The infrared spectrum of fraction A in carbon disulfide indicated approximately 70% γ-lactone and 10% δ-lactone.

Kolbe Electrolysis of *cis–syn–cis*-Perhydrodiphenic Acid[13] (IV).—A solution of 1.27 g. (0.0050 mole) of IV in 70 ml. of anhydrous methanol and 5 ml. of 0.20 *N* sodium methoxide was electrolyzed. The electrolyzed solution was treated as described above to give 0.479 g. of liquid, fraction A, from which 0.1 g. of solid crystallized, m.p. 48–52°. This sample contained a small amount of the isomeric γ-lactone which could not be separated. Most of fraction A is a mixture of the isomeric γ-lactones. The infrared spectrum in Nujol mull was identical with the spectrum of the *cis*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid (IIIb).

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 75.14; H, 9.68.

Fraction B, the non-steam-distillables, amounted to 0.139 g. The infrared spectrum of fraction A in carbon disulfide indicated approximately 70% γ-lactone and 10% δ-lactone.

Preparation of *trans*-2-(1-Hydroxycyclohexyl)-cyclohexanemethanol (Va).—To 0.40 g. (0.10 mole) of lithium aluminum hydride suspended in 50 ml. of anhydrous ether, a solution of 1.00 g. (0.0048 mole) of IIIa, from the Kolbe electrolysis, in 50 ml. of ether, was added dropwise according to the general procedure of Nystrom and Brown.[14] The mixture was refluxed for 1 hr., cooled and 10% sodium hydroxide was added. The ether was decanted and the precipitate which had formed was triturated with more ether. The combined ether extracts were dried over calcium chloride and concentrated to give 0.918 g. (90%) of the glycol. Recrystallization from pentane yielded a solid, m.p. 92.5–93°.

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39; primary OH equiv., 212. Found: C, 73.40; H, 11.32; primary OH equiv., 233.[15]

The infrared spectrum of a Nujol mull indicated the OH frequency.[16] The quantitative determination of total primary and secondary hydroxyls was made according to the method of Ogg, Porter and Willits.[15]

Oxidation of *trans*-2-(1-Hydroxycyclohexyl)-cyclohexanemethanol (Va).—To a mixture of 0.100 g. (0.00047 mole) of Va, 0.150 g. of potassium hydroxide and 7.5 ml. of water, was added 5 ml. of aqueous potassium permanganate (1:15) according to the general procedure of Billman and Parker.[17]

The mixture was stirred for 1 hr. and then filtered. Sodium bisulfite was added to the filtrate to remove unreacted potassium permanganate and then the solution was acidified. A cloudy solution was obtained which was placed in the refrigerator. Crystals grew which were filtered and washed with water to give 0.036 g. (37%), 99–99.5°.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.97; H, 9.45.

The infrared spectrum in a Nujol mull indicated a γ-lactone. The spectrum was identical to the spectrum of IIIa.

Preparation of the *trans*-Lactone of 2-(1-Hydroxycyclohexyl)-cyclohexanecarboxylic Acid (IIIa).—To a mixture containing 16 g. (0.67 g. atom) of magnesium turnings, 0.5 g. of mercuric chloride and 100 ml. of dry tetrahydrofuran, was added a solution of 94 g. (0.40 mole) of the ethyl ester of *trans*-2-bromocyclohexanecarboxylic acid[18] and 40 g. (0.41 mole) of cyclohexanone in 100 ml. of tetrahydrofuran according to the general procedure of Miller and Nord.[19] The mixture was refluxed overnight on a steam-bath. After stopping the reaction by addition of dilute hydrochloric acid, the reaction solution was extracted with ether. The ether layer was washed with water, aqueous sodium bicarbonate and water again, dried over calcium chloride and concentrated to an oil. The infrared spectrum of a film showed a small amount of γ-lactone. The oil was saponified with 25% potassium hydroxide solution according to the procedure of Miller and Nord.[19] The basic solution was extracted with ether, then acidified and extracted again. The ether extract of the acid solution was dried over calcium chloride and concentrated to a residue. The infrared spectrum of this acid fraction indicated a small amount of γ-lactone. With the aid of a *p*H meter, this acid, dissolved in methanol, was titrated to an equivalence point with aqueous sodium hydroxide. After the addition of water, the solution was extracted with ether and the extract concentrated to an oil. Steam distillation of this oil gave 3.809 g. (4.6%) of the γ-lactone from which 0.740 g. of solid crystallized, m.p. 86–91°. This sample contained a small amount of the isomeric γ-lactone which could not be separated.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.86; H, 9.69.

The infrared spectrum in a Nujol mull indicated a γ-lactone which was identical to the spectrum of the γ-lactone obtained from the electrolyses of I and II.

Isomerization of the *trans*-Lactone of 2-(1-Hydroxycyclohexyl)-cyclohexanecarboxylic Acid (IIIa).—A solution containing 0.500 g. (0.0024 mole) of IIIa and 10 ml. of 0.20 *N* sodium methoxide in 200 ml. of anhydrous methanol was refluxed for 12 hr. according to the general procedure of Asselineau, Bory and Lederer.[20] The solution was neutralized with acetic acid, the methanol distilled, and the remainder of the reaction mixture was submitted to steam distillation. Ether extraction of the distillate gave 0.319 g. (64%) of liquid. The infrared spectrum in carbon disulfide indicated it to be a mixture consisting of 9% of the *trans*- and 91% of the *cis*-lactones of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid.

Preparation of the Lactone of 2-(1-Hydroxycyclohexyl)-1,4-cyclohexadiene-1-carboxylic Acid (VI).—A solution of 15 g. (0.082 mole) of the methyl ester of β-(1-hydroxycyclohexyl)-propiolic acid[21] and 70 ml. of freshly distilled butadiene in 150 ml. of benzene was heated for 15 hr. at 190–200° in a glass lined bomb according to the general procedure of Joshel and Butz.[22] The benzene was then removed by distillation under reduced pressure to give 46 g. of gummy residue. This material was leached with hot methanol to give 15.47 g. of an oily solid. Recrystallization from petroleum ether (b.p. 30–60°) gave 11.41 g. (68%) of product, m.p. 90–95°. An analytical sample obtained by further recrystallization melted at 96–97°; λ_{max}^{MeOH} 230 mμ, ϵ_{max} 3,800, ε 210 mμ 6,900.[23]

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90. Found: C, 76.45; H, 7.80.

The infrared spectrum in Nujol mull indicated an unsaturated γ-lactone.[24]

Preparation of the Lactone of 2-(1-Hydroxycyclohexyl)-1-cyclohexene-1-carboxylic Acid (IXa).—Using 0.50 g. of Adams catalyst, 0.300 g. (0.00147 mole) of VI in 100 ml. of ethanol was reduced at 25° in a Parr reduction apparatus at 3 atmospheres, overnight. The partially reduced material was isolated to give 0.268 g. (89%), m.p. 70–73°. An analytical sample obtained by recrystallization from petroleum ether (b.p. 30–60°) melted at 79–80°, λ_{max}^{MeOH} 220 mμ, ϵ_{max} 11,200.[25]

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.53; H, 8.58.

The infrared spectrum in Nujol mull indicated an unsaturated γ-lactone.[24]

Preparation of the *cis*-Lactone of 2-(1-Hydroxycyclohexyl)-cyclohexanecarboxylic Acid (IIIb).—A solution of 10.74 g. (0.053 mole) of IXa in 500 ml. of ethanol was reduced at 150° under 100 atmospheres of hydrogen using 10 g. of Raney nickel catalyst. The totally reduced material was recovered to give 9.0 g. (82%) of oil which crystallized on standing, m.p. 50–52°. An analytical sample prepared by recrystallizing from petroleum ether (b.p. 30–60°) melted at 55–56°. This compound showed no appreciable ultraviolet absorption between 400 and 215 mμ.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 74.75; H, 9.70.

The infrared spectrum in Nujol mull indicated a γ-lactone. The spectrum was distinctly different from the spectrum of the *trans* isomer IIIa.

Preparation of the *cis*- *and trans*-Lactone of 2-(1-Hydroxycyclohexyl)-1-hydroxycyclohexanecarboxylic Acid (VIIIa, VIIIb). Using Colonge's β-Ketol.—To a solution of 50 g. (0.252 mole) of 2-(1-hydroxycyclohexyl)-cyclohexanone[7] and 100 g. of potassium cyanide in 500 ml. of ethanol, 100 ml. of glacial acetic acid was added cautiously in a hood according to the general procedure of Boekelheide and Schilling.[26] The mixture was refluxed overnight, the ethanol removed by atmospheric distillation and the remainder of the reaction mixture poured into water. The infrared spectrum of the water-insolubles indicated an imidic acid ester[27] (VII). The aqueous suspension was digested for 3 hr. on a steam-bath and ether extraction of the cooled mixture gave 50 g. (89%) of product. On standing for a week in a refrigerator, 10 g. of a solid, fraction A, m.p. 150–155°, crystallized out. For convenience, the residual liquid will be called fraction B. Fraction A VIIIa was the *trans* isomer; an analytical sample obtained by several recrystallizations from ethyl ether melted at 159–161°. The infrared spectrum in Nujol mull indicated a hydroxyl group as well as a γ-lactone.

Anal. Calcd. for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99. Found: C, 69.86; H, 8.99.

Fraction B (VIIIb) was the *cis* isomer; this liquid could not be induced to crystallize. The infrared spectrum of a film indicated a hydroxyl group as well as a γ-lactone.

Using Stanek's β-Ketol.—The above procedure was repeated using 50 g. (0.252 mole) of Stanek's β-ketol,[8] m.p. 166.5–167°, which had given an incorrect analysis (*Anal.* Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 75.65, 75.75; H, 9.76, 9.82), to give 51 g. (89%), m.p. 173–175°. An analytical sample obtained by several recrystallizations from benzene melted at 183–184.5°, but again gave an incorrect analysis. The structure of this compound was not

determined, but it was obvious that the desired lactone was not obtained.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 69.61; H, 8.99. Found: C, 71.99, 72.16; H, 9.07, 9.16.

The infrared spectrum of a Nujol mull indicated a hydroxyl group as well as a γ-lactone.

Preparation of the Lactone of 2-(1-Hydroxycyclohexyl)-6-cyclohexene-1-carboxylic Acid (IXb) from the Dehydration of the *cis*-Lactone of 2-(1-Hydroxycyclohexyl)-1-hydroxycyclohexanecarboxylic Acid (VIIIb).—To a solution of 50 g. (0.223 mole) of VIIIb in 150 ml. of dry pyridine was added, cautiously, 50 ml. of thionyl chloride according to the general procedure of Boekelheide and Schilling.[26] The mixture was heated overnight on a steam-bath, cooled and poured into ice-water. Ether extraction gave 33 g. (72%) of product, m.p. 67–69°. An analytical sample obtained by several recrystallizations from petroleum ether (b.p. 30–60°) melted at 71–72°, λ_{max}^{MeOH} 220 mμ, ϵ_{max} 11,100. The melting point was depressed, m.p. 63–64°, on admixture with IXa. The infrared spectrum in Nujol mull indicated an unsaturated γ-lactone. The spectrum was distinctly different from IXa.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.90; H, 8.54.

Preparation of the Lactone of 2-(1-Hydroxycyclohexyl)-1-cyclohexene-1-carboxylic Acid (IXa) from the Dehydration of the *trans*-Lactone of 2-(1-Hydroxycyclohexyl)-1-hydroxycyclohexanecarboxylic Acid (VIIIA).—To a solution of 2.0 g. (0.0089 mole) of VIIIa in 10 ml. of dry pyridine was added 4 ml. of thionyl chloride. The reaction was carried out as described above to give 1.65 g. (90%) of product, m.p. 68–75°. An analytical sample obtained by several recrystallizations from petroleum ether (b.p. 30–60°) melted at 79–80°. It was found to be identical (mixed melting point 79–80°, ultraviolet and infrared spectra) with IXa obtained from the reduction of the lactone of 2-(1-hydroxycyclohexyl)-1,4-cyclohexadiene-1-carboxylic acid (VI).

Preparation of the *cis*-Lactone of 2-(1-Hydroxycyclohexyl)-cyclohexanecarboxylic Acid (IIIb) from the Reduction of the Lactone of 2-(1-Hydroxycyclohexyl)-6-cyclohexene-1-carboxylic Acid (IXB).—A solution of 33 g. (0.160 mole) of IXb in 500 ml. of ethanol was reduced, using 10 g. of Raney nickel catalyst at 150° and 100 atmospheres of hydrogen. The totally reduced material was recovered to give 25 g. (75%) of an oil which solidified on standing, m.p. 50–53°. An analytical sample obtained by several recrystallizations from petroleum ether (b.p. 30–60°) melted at 55–56° with no appreciable ultraviolet absorption between 400 and 215 mμ. It was found to be identical (mixed melting point, 55–56° and infrared spectra) with IIIb obtained from the reduction of IXa.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68; mol. wt., 208. Found: C, 74.76; H, 9.52; mol. wt., 213 (cryoscopic).

Preparation of *cis*-2-(1-Hydroxycyclohexyl)-cyclohexanemethanol (Vb).—A solution of 1.00 g. (0.0048 mole) of IIIb was reduced with lithium aluminum hydride as described above to give 1.00 g. (98%) of glycol. Recrystallization from hexane gave a solid, m.p. 117–118°.

Anal. Calcd. for $C_{13}H_{24}O_2$: C, 73.54; H, 11.39. Found: C, 73.42; H, 11.12.

The infrared spectrum in a Nujol mull indicated a hydroxyl group and was distinctly different from the spectrum of the *trans* isomer Va.

Isomerization of the *cis*-Lactone of 2-(1-Hydroxycyclohexyl)-cyclohexanecarboxylic Acid (IIIb).—A solution containing 0.104 g. (0.0005 mole) of the *cis*-lactone of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid was isomerized as described for the *trans* isomer to give 0.047 g. (45%) of liquid. The infrared spectrum in carbon disulfide indicated it to be a mixture consisting of 10% of the *trans*- and 90% of the *cis*-lactones of 2-(1-hydroxycyclohexyl)-cyclohexanecarboxylic acid, identical to that obtained from the isomerization of the *trans*-lactone IIIa.

Antispasmodics. IX. 1-Azaspiro[4.5]decane and Derivatives[1]

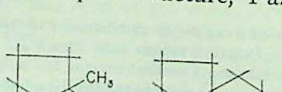
BY ROBERT BRUCE MOFFETT

RECEIVED FEBRUARY 13, 1957

Previous studies in these laboratories have demonstrated that certain compounds containing 2,2-dimethylpyrrolidine (I) are particularly potent anticholinergics. The structurally similar compound, 1-azaspiro[4.5]decane (II), has now been prepared, in which the two methyl groups are joined in a ring. This was incorporated into a variety of compounds of types known to be in general powerful anticholinergics (VIII, IX and XII); however, they had surprisingly little of this type of activity.

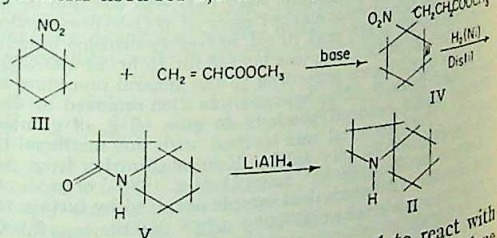
A considerable number of compounds containing the pyrrolidine group have been studied in these laboratories.[2] Of these the 2,2-dimethylpyrrolidine group (I) has been found to be particularly potent when combined, for example, in esters of the type generally used in antispasmodics.[2c]

In extending this work we have investigated the effect of joining the two methyl groups in a ring thus creating the spiro structure, 1-azaspiro[4.5]-decane (II).



I II

This was accomplished by a modification of the synthesis used for 2,2-dimethylpyrrolidine.[2b]



This spiropyrrolidine was allowed to react with ethylene chlorohydrin and with trimethylene chlorohydrin to give the corresponding 1-(hydroxy-

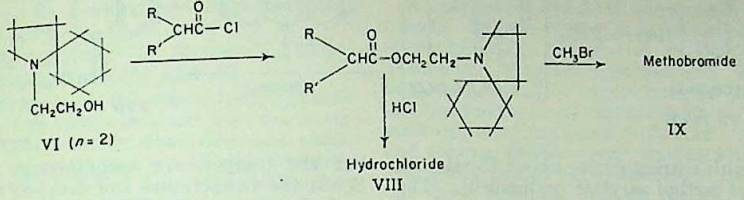
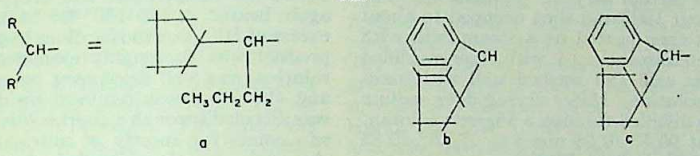
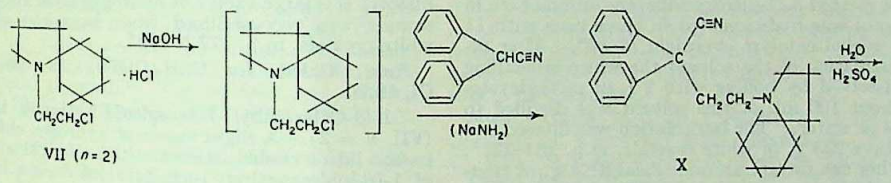
Digitized by Arya Samaj Foundation Chennai and eGangotri

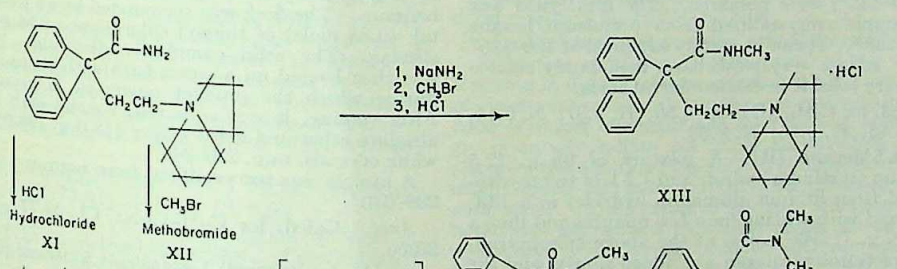
alkyl)-azaspiro[4.5]decane (VI). These in turn were converted to the corresponding chloride hydrochlorides VII with thionyl chloride. The ethanol derivative (VI, $n=2$) was allowed to react with the acid chlorides of several acids which had previously given good anticholinergics.[2c]

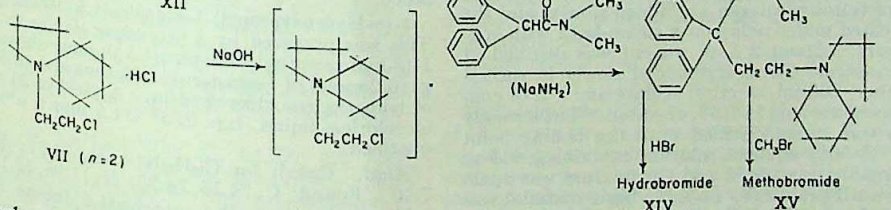




The chlorethyl intermediate was used to alkylate diphenylacetonitrile and the product hydrolyzed to give amides of the type known to include powerful anticholinergics.[3] The mono- and dimethylamides also were prepared.







A few analogs of the phenothiazine antihistamines,[4] antispasmodics[5] and tranquilizing drugs[6] were also prepared.

Pharmacology.—These spiro compounds were tested as anticholinergics both in Thiry-Vella dogs and for their ability to block the depressor response of methacholine in anesthetized dogs. In comparison with structurally related potent anticholinergics such as 2-(2,2-dimethyl-1-pyrrolidyl)-ethyl cyclopentylvalerate hydrochloride (atropine index 1.2)[2c] and α,α-diphenyl-γ-(2,2-dimethyl-1-pyrrolidyl)-butyramide methobromide[7] (atropine index 4), their activities proved to be somewhat lower than anticipated. Compound XII had an atropine index of about 0.5 in Thiry-Vella dogs while the rest had indexes of less than 0.15.

These compounds have been screened in a variety of other pharmacological tests. Preliminary data appear interesting and detailed results will be published elsewhere.

Acknowledgments.—The author is indebted to Dr. Patrick H. Seay, Dr. Walter A. Freyburger and associates of the Department of Pharmacology for the pharmacological results, and to Dr. Richard V. Heinzelman of the Department of Chemistry for guidance.

Experimental[8]

Methyl β-(1-Nitrocyclohexane)-propionate (IV).—To a mixture of 333 g. (2.55 moles) of nitrocyclohexane (du Pont technical grade redistilled), 300 ml. of dioxane (treated with lithium aluminum hydride and redistilled) and 30 ml. of a 35% methanolic solution of benzyltrimethylammonium

hydroxide was added with stirring during about 15 minutes 227.5 g. (2.55 moles) of methyl acrylate (redistilled). The temperature rose to about 100° and then dropped to about 55°. The mixture was then heated on a steam-bath with stirring for 3 hours, diluted to about 1 l. with ether, acidified with dilute hydrochloric acid and washed well with saturated sodium chloride solution. After drying over sodium sulfate the solution was distilled through a Vigreux column. The product distilled at 96.5° (0.05 mm.) to 124.5° (0.35 mm.); yield 532 g. (96.8%); $n^{25}D$ 1.4710.

A sample redistilled through a short packed column gave a middle fraction of colorless liquid; b.p. 96° (0.025 mm.) $n^{25}D$ 1.4711.

Anal. Calcd. for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51. Found: C, 56.05; H, 8.02; N, 6.48.

1-Azaspiro[4.5]decan-2-one (V).[9]—A solution of 453.3 g. (2.11 moles) of methyl β-(1-nitrocyclohexane)-propionate in 1.26 l. of ethanol was hydrogenated in three runs with 11 tsp. of Raney nickel catalyst overnight at 50°. After filtration and distillation of the solvent the white crystalline residue was dissolved by boiling with 2 l. of methylcyclohexane and about 100 ml. of this solvent was distilled to remove alcohol or water. The hot solution was filtered and on cooling it gave 253 g. of white crystals, m.p. 131–133°. By concentrating the filtrate an additional 31.4 g. of crystals, m.p. 129–132°, were obtained. The total yield was 88.2%. A sample recrystallized from petroleum hexane had m.p. 132–133°. It can be readily sublimed at 100–135° (0.012 mm.). It is a very weak base, moderately soluble in water and very soluble in dilute mineral acids.

Anal. Calcd. for $C_9H_{15}NO$: C, 70.55; H, 9.87; N, 9.14. Found: C, 70.45; H, 9.85; N, 9.03.

1-Azaspiro[4.5]decane (II).—A mixture of 95 g. (2.5 moles) of lithium aluminum hydride and 1.5 l. of tetrahydrofuran (distilled from lithium aluminum hydride) in a 12-l. flask was refluxed with stirring for a few minutes and then a solution of 206 g. (1.343 moles) of the above spiropyrrolidone in 1.1 l. of tetrahydrofuran was added slowly, and the mixture was heated under reflux on a steam-bath with stirring for 18 hours. About 2 l. of solvent was distilled at atmospheric pressure. Then were added slowly in succession: 1 l. of ether, 200 ml. of ethyl acetate and 1 l. of concentrated hydrochloric acid in 1.5 l. of water. The strongly acidic solution was steam distilled until the boiling point reached 100°. A 50% aqueous solution containing 680 g. of sodium hydroxide was added and the mixture was again steam distilled until practically no more basic material was coming over. About 4 l. of distillate was collected which separated into two layers. This was extracted twice with ether and then continuously extracted with ether for 6 hours. The ether solutions were well dried by shaking with potassium carbonate. After filtration the solution was distilled through an efficient column. After removing the solvent the fraction boiling at 99–104° (42 mm.) was collected; yield, 84%; $n^{25}D$ 1.4817. A sample was redistilled giving a middle fraction of colorless liquid, b.p. 96° (33 mm.), $n^{25}D$ 1.4814.

Anal. Calcd. for $C_9H_{17}N$: C, 77.63; H, 12.31; N, 10.06; equiv. wt., 139.24. Found: C, 77.95; H, 11.88; N, 9.24; equiv. wt., 140.16.

1-(β-Hydroxyethyl)-1-azaspiro[4.5]decane (VI, $n = 2$).—A mixture of 146.6 g. (1.05 moles) of 1-azaspiro[4.5]decane and 64.6 g. (0.8 mole) of ethylene chlorohydrin was stirred and heated under reflux to 120°. The heating was stopped but the temperature spontaneously rose to about 167°. When the temperature had dropped to 120° the flask was again heated at 130–150° for 15 minutes. After cooling an excess of 50% aqueous sodium hydroxide was added and the product was thoroughly extracted with ether. The ether solution was well dried over potassium carbonate, filtered, and the ether was removed by distillation. The product was distilled through a short column. After removing a forerun consisting mostly of unreacted 1-azaspiro[4.5]decane, the main fraction distilled, b.p. 138° (12 mm.). The yield was 126.2 g. (86.2%) of colorless liquid; $n^{25}D$ 1.5010.

Anal. Calcd. for $C_{11}H_{21}NO$: C, 72.08; H, 11.55; N, 7.64. Found: C, 72.41; H, 11.87; N, 7.66.

Hydrochloride.—Hydrogen chloride gas was passed into a cooled benzene solution of the above free base. The hydrochloride separated in crystalline form but tended to redissolve if a large excess of hydrogen chloride was used. A sample was recrystallized from isopropyl alcohol giving white crystals, m.p. 177.5–179°.

Anal. Calcd. for $C_{11}H_{22}ClNO$: Cl, 16.13. Found: Cl, 16.30.

1-(β-Chloroethyl)-1-azaspiro[4.5]decane Hydrochloride (VII, $n = 2$).—A slight excess of hydrogen chloride gas was passed into a cooled, stirred solution of 121 g. (0.676 mole) of 1-(β-hydroxyethyl)-1-azaspiro[4.5]decane in 250 ml. of benzene. The flask was surrounded by an ice-bath, and 60 ml. (0.88 mole) of thionyl chloride was added slowly with stirring. The solid completely dissolved. The solution was then heated on a steam-bath with stirring for 2 hours during which the product separated in crystalline form. After cooling, it was collected, washed with benzene and absolute ether and dried giving 158.0 g. (98.0%) of nearly white crystals, m.p. 239–240°.

A sample was recrystallized from isopropyl alcohol, m.p. 239–240°.

Anal. Calcd. for $C_{11}H_{21}Cl_2N$: Cl, 29.77. Found: Cl, 29.50.

1-(γ-Hydroxypropyl)-1-azaspiro[4.5]decane (VI, $n = 3$).—This was prepared by a procedure similar to that used for 1-(β-hydroxyethyl)-azaspiro[4.5]decane above using 27.84 g. (0.2 mole) of 1-azaspiro[4.5]decane and 18.9 g. (0.2 mole) of trimethylene chlorohydrin. A yield of 23.43 g. (59.5%) of colorless liquid, b.p. 155° (11.5 mm.), $n^{25}D$ 1.4979, was obtained.

Anal. Calcd. for $C_{12}H_{23}NO$: C, 73.21; H, 11.75; N, 7.10. Found: C, 74.13, 74.35; H, 11.98, 12.13; N, 7.12.

1-(γ-Chloropropyl)-1-azaspiro[4.5]decane Hydrochloride (VII, $n = 3$).—This was prepared by a procedure similar to that used for 1-(β-chloroethyl)-1-azaspiro[4.5]decane hydrochloride above using 22.4 g. (0.1135 mole) of 1-(γ-hydroxypropyl)-1-azaspiro[4.5]decane, 50 ml. of benzene and 15 ml. (0.2 mole) of thionyl chloride. The product consisted of 26.8 g. (93.6%) of white crystals, m.p. 224–226.5°.

A sample was recrystallized from isopropyl alcohol, m.p. 225–227°.

Anal. Calcd. for $C_{12}H_{23}Cl_2N$: Cl, 28.11. Found: Cl, 28.07

Cyclopentyl-*n*-propylacetate Ester of 1-(β-Hydroxyethyl)-1-azaspiro[4.5]decane Hydrochloride (VIIIa).—To a solution of 9.33 g. (0.05 mole) of 1-(β-hydroxyethyl)-1-azaspiro[4.5]decane in 50 ml. of dry benzene was added 11.3 g. (0.06 mole) of cyclopentyl-*n*-propylacetyl chloride.[10] A white

precipitate separated almost immediately but redissolved on heating under reflux for 3 hours. The red solution was treated with 30 ml. of 10% aqueous sodium hydroxide and extracted well with ether. After washing with water the ether was removed and the product was distilled. A middle fraction of 8.34 g., b.p. 146–147° (0.04 mm.), was dissolved in absolute ether, made acidic with ethanolic hydrogen chloride and further diluted with absolute ether. The hydrochloride was obtained as a white crystalline material, m.p. 151–152°; weight 8.2 g.

Anal. Calcd. for $C_{21}H_{38}ClNO_2$: C, 67.80; H, 10.30; Cl, 9.53. Found: C, 68.21; H, 10.16; Cl, 9.53.

Free Base.—The filtrate from the above hydrochloride was reconverted to the free base, combined with the lower and higher boiling fractions from the distillation and redistilled. A yield of 7.0 g. of nearly colorless oil was obtained, b.p. 146° (0.05 mm.); $n^{25}D$ 1.4879. The total yield of hydrochloride and free base amounted to 85.8%.

Anal. Calcd. for $C_{21}H_{37}NO_2$: C, 75.17; H, 11.12; N, 4.17. Found: C, 76.15, 76.53; H, 10.93, 11.16; N, 4.00.

Methobromide (IXa).—To a cold solution of 6.5 g. (0.0194 mole) of the above free base in 25 ml. of methyl ethyl ketone was added 6.2 g. of cold methyl bromide. The flask was stoppered, clamped and allowed to stand at room temperature for 2 days. Crystals separated and were collected, washed with methyl ethyl ketone and dried giving 5.06 g. (60.6%) of product, m.p. 152–153°. A small additional yield was obtained from the filtrate.

Anal. Calcd. for $C_{22}H_{40}BrNO_2$: C, 61.38; H, 9.37; Br, 18.57. Found: C, 61.64; H, 9.34; Br, 18.58.

Phenyl-Δ^2-cyclopentenylacetate Ester of 1-(β-Hydroxyethyl)-1-azaspiro[4.5]decane.—This was prepared by a procedure similar to that used for the above ester using 11.6 g. (0.0634 mole) of 1-(β-hydroxyethyl)-azaspiro[4.5]decane, 50 ml. of dry benzene and 15.5 g. (0.07 mole) of phenyl-Δ^2-cyclopentenylacetyl chloride.[11] The product was distilled giving 22.17 g. (95%) of viscous light yellow liquid, b.p. 163° (0.01 mm.).

Anal. Calcd. for $C_{24}H_{33}NO_2$: C, 78.43; H, 9.05; N, 3.81. Found: C, 78.80; H, 8.88; N, 3.84.

Hydrochloride (VIIb).—To a solution of 16.3 g. (0.0444 mole) of the above free base in absolute ether was added a slight excess of ethanolic hydrogen chloride. Dilution with more ether caused the hydrochloride to separate as an oil. The solvent was removed by distillation under reduced pressure below 90° and the glassy residue was crystallized from ethyl acetate giving 12.7 g. (71%) of white crystals, m.p. 140–142°.

Anal. Calcd. for $C_{24}H_{34}ClNO_2$: C, 71.33; H, 8.48; Cl, 8.78. Found: C, 71.31; H, 8.37; Cl, 8.96.

Methobromide (IXb).—To a cold solution of 4.55 g. (0.0124 mole) of the above free base in 25 ml. of methyl ethyl ketone was added 5 g. of cold methyl bromide. The flask was stoppered, clamped and allowed to stand at room temperature for 5 days. White crystals separated and were collected, washed with methyl ethyl ketone and then with absolute ether and dried; yield 5.0 g. (87.2%); m.p. 167.5–169°.

Anal. Calcd. for $C_{25}H_{36}BrNO_2$: C, 64.92; H, 7.85; Br, 17.28. Found: C, 65.01; H, 7.98; Br, 17.49.

Phenylcyclopentylacetate Ester of 1-(β-Hydroxyethyl)-1-azaspiro[4.5]decane Hydrochloride (VIIIc).—A solution of 9.47 g. (0.0234 mole) of the above hydrochloride in 150 ml. of 95% ethanol was hydrogenated at room temperature and 40 lb. pressure with 0.1 g. of platinum oxide catalyst. The theoretical amount of hydrogen was taken up in 10 minutes. The solution was filtered from the catalyst and distilled nearly to dryness below 40° under reduced pressure. The residue crystallized from ethyl acetate on the addition of ether, giving 7.88 g. (83%) of white crystals, m.p. 152–153.5°.

Anal. Calcd. for $C_{24}H_{36}ClNO_2$: C, 70.99; H, 8.94; Cl, 8.73. Found: C, 71.21; H, 8.99; Cl, 8.77.

α,α-Diphenyl-γ-[1-(1-azaspiro[4.5]decane)]-butyronitrile (X).—A mixture of 38.6 g. (0.2 mole) of diphenylacetonitrile, 300 ml. of dry toluene and 5.06 g. (0.22 mole) of lithium amide was heated under reflux under nitrogen with vigorous stirring for 4 hours.

A solution of 1-(β-chloroethyl)-1-azaspiro[4.5]decane was prepared by shaking 85.9 g. (0.36 mole) of the hydrochloride with ice and 35 ml. of 50% aqueous sodium hydroxide. The mixture was extracted five times with toluene, the toluene solution was well dried over potassium carbonate, and made up to 400 ml.

An aliquot of 244.5 ml. (equivalent to 0.22 mole) of the toluene solution of the chloride was added dropwise with stirring during 30 minutes to the above suspension of lithium salt of diphenylacetonitrile. The mixture was then heated under reflux with stirring for 19 hours. After cooling the mixture was washed with water and the aqueous washings were extracted with ether. The combined ether and toluene solutions were shaken with dilute hydrochloric acid which caused the separation of the hydrochloride as an oily layer insoluble in both the water and toluene. The hydrochloride and aqueous layers were separated, washed with ether and made basic with dilute sodium hydroxide. The free base was extracted with ether and benzene and after washing with water the solvent was removed. The product was distilled giving 46.3 g. of light brown viscous liquid, b.p. 160° (0.02 mm.). On standing, it crystallized and was recrystallized from isopropyl alcohol giving 33.85 g. (47.2%) of white crystals, m.p. 85–90°. A sample was recrystallized again, m.p. 90–92°.

Anal. Calcd. for $C_{25}H_{30}N_2$: C, 83.75; H, 8.44; N, 7.82. Found: C, 83.95; H, 8.45; N, 7.80.

Hydrochloride.—The above moist toluene and ether solutions, from which the oily hydrochloride had separated, on standing deposited white crystals; weight 5.56 g. (7%). This was recrystallized from isopropyl alcohol giving 5.35 g. of white crystals which on slow heating in m.p. tube melted at 123–128° with foaming, then crystallized and remelted at 195–197°. Infrared spectrum and analysis shows this to be a hydrate.

Anal. Calcd. for $C_{25}H_{31}ClN_2 \cdot 2H_2O$: C, 69.67; H, 8.19; Cl, 8.42; N, 6.50; H_2O, 8.36. Found: C, 71.19; H, 8.42; Cl, 8.22; N, 6.80; H_2O (loss of wt. on drying), 8.56.

Calcd. for $C_{25}H_{31}ClN_2$: C, 76.01; H, 7.91. Found (on dried sample): C, 75.74; H, 8.04.

α,α-Diphenyl-γ-[1-(1-azaspiro[4.5]decane)]-butyramide.—A solution of 32.8 g. (0.0915 mole) of the above nitrile free base in 5.5 ml. of concentrated sulfuric acid and 55 ml. of water was heated with stirring on a steam-bath for 4 hours. After standing overnight the solution was poured onto ice giving an oily sulfate salt which dissolved in the aqueous phase on the addition of ether. The aqueous layer was extracted again with ether and the ether solutions were washed with water. The combined aqueous fractions were made basic with ammonium hydroxide giving an oil which soon crystallized. The crude product was recrystallized from 500 ml. of 80% ethanol giving 22.95 g. (66.8%) of crystals, m.p. 169.5–172°.

Anal. Calcd. for $C_{25}H_{32}N_2O$. C, 79.74; H, 8.57; N, 7.44. Found. C, 79.84; H, 8.32; N, 7.40.

Hydrochloride (XI).—A solution of 6.5 g. (0.0173 mole) of the above free base in methanol and 1.6 ml. of concentrated aqueous hydrochloric acid was concentrated on a steam-bath by a stream of nitrogen. Benzene was added and the solution was further concentrated. On cooling it crystallized giving 7.3 g. of white crystalline powder, m.p. 212.5–214.5° (heated slowly in m.p. tube). A sample in a tube placed in the bath at 175° immediately melted, placed in the bath at 160° it partly melted, and placed in the bath at 155° it did not melt.

Anal. Calcd. for $C_{26}H_{33}ClN_2O$: C, 72.70; H, 8.05; Cl, 8.59. Found: C, 72.77; H, 8.12; Cl, 8.63.

Methobromide (XII).—To a cold suspension of 7.53 g. (0.02 mole) of the above free base in 50 ml. of methanol was added 16 g. of cold methyl bromide. The flask was stoppered, clamped and allowed to stand at room temperature for 4 days, during which the starting material completely dissolved. The solution was concentrated and diluted with ether giving a gum. This was dissolved in methanol, filtered, concentrated and diluted with methyl ethyl ketone. On boiling on a steam-bath it crystallized giving 8.84 g. (93.7%) of white crystals, m.p. 200–202°.

Anal. Calcd. for $C_{26}H_{35}BrN_2O$: C, 66.23; H, 7.48; Br, 16.95. Found: C, 66.11; H, 7.52; Br, 16.56.

α,α-Diphenyl-γ-[1-(1-azaspiro[4.5]decane)]-N-methylbutyramide Hydrochloride (XIII).—A suspension of 8.28 g. (0.022 mole) of the above amide free base and 0.97 g. (0.025 mole) of sodium amide in 75 ml. of dry toluene was heated under reflux with stirring for 2 hours. After cooling in an ice-bath, a solution of 2.3 g. (0.024 mole) of methyl bromide in 35 ml. of cold toluene was added dropwise with stirring during 30 minutes. The mixture was stirred at room temperature for 3 hours, cooled and extracted with dilute hydrochloric acid. The solution was made basic with sodium hydroxide giving an oily free base which was extracted out with ether and washed with water, and dried. A slight excess of ethanolic hydrogen chloride was added giving a gummy hydrochloride which crystallized on standing. This was recrystallized from methyl ethyl ketone giving 5.95 g. (63.4%) of white crystals, m.p. 186–188°.

Anal. Calcd. for $C_{26}H_{35}ClN_2O$: C, 73.13; H, 8.26; Cl, 8.30. Found: C, 73.29; H, 7.96; Cl, 8.33.

α,α-Diphenyl-γ-[1-(azaspiro[4.5]decane)]-N,N-dimethylbutyramide.—A mixture of 14.4 g. (0.06 mole) of diphenyl-N,N-dimethylacetamide,[12] 100 ml. of dry toluene and 2.65 g. (0.068 mole) of sodium amide was heated for 2 hours under reflux, under nitrogen with vigorous stirring. After cooling, 72.2 ml. (equivalent to 0.065 mole) of a toluene solution of 1-(β-chloroethyl)-1-azaspiro[4.5]decane (see above under preparation of the nitrile) was added dropwise with stirring during 20 minutes. The mixture was then heated under reflux for 1 hour and allowed to stand overnight. It was washed with water, the washings were extracted with ether, and the ether and toluene solutions were extracted with dilute hydrochloric acid. The extracts were washed with ether and made basic with dilute sodium hydroxide giving a gummy free base which soon crystallized to 23.7 g. of light yellow solid, m.p. 133–145°. This was recrystallized from isopropyl alcohol giving 17.8 g. of nearly white crystals, m.p. 147–152°. Recrystallization from benzene gave 11.32 g. (46.6%) of white crystals, m.p. 149–152°.

Anal. Calcd. for $C_{27}H_{36}N_2O$: C, 80.15; H, 8.97; N, 6.93. Found: C, 80.44; H, 8.93; N, 6.87.

Hydrobromide (XIV).—The filtrates from the recrystallization of the free base were acidified with 48% hydrobromic acid and concentrated. Ether was added giving a gum which solidified on standing. This was dissolved in methyl ethyl ketone and concentrated. Acetone was added and crystals immediately separated. This was recrystallized from methyl ethyl ketone giving 5.7 g. (17.5%) of white crystals, m.p. about 103–110° dec. The total yield of free base and hydrobromide was 64.1%.

This appeared to be a solvate so a 0.1-g. sample in a little ethanol was treated with 2,4-dinitrophenylhydrazine solution giving a 2,4-dinitrophenylhydrazone. This was recrystallized from ethanol, m.p. 116–121°. A mixed melting point with authentic acetone 2,4-dinitrophenylhydrazone (m.p. 125–127°) gave no depression (mixed m.p. 118–124°). A mixed melting point with authentic methyl ethyl ketone 2,4-dinitrophenylhydrazone (m.p. 111–112°) gave a good depression (mixed m.p. 100–102°).

Anal. Calcd. for $C_{27}H_{37}BrN_2O \cdot CH_3COCH_3$: C, 66.28; H, 7.97; Br, 14.70. Found: C, 66.48; H, 7.77; Br, 14.59.

Methobromide (XV).—To a cold suspension of 8.09 g. (0.02 mole) of the free base in 25 ml. of acetone and 40 ml. of methanol was added 10 g. of cold methyl bromide. The flask was stoppered, clamped and allowed to stand at room temperature for 3 days. The starting material completely dissolved. The solution was concentrated on a steam-bath by a stream of nitrogen giving an oil which crystallized. This was triturated with absolute ether, collected and dried giving 9.9 g. of white crystalline product. Recrystallization from methanol gave 9.85 g. (98.8%), m.p. 191–193°.

Anal. Calcd. for $C_{28}H_{39}BrN_2O$: C, 67.32; H, 7.87; Br, 16.00. Found: C, 67.12; H, 8.09; Br, 16.06.

10-[β-(1-(1-Azaspiro[4.5]decane))-ethyl]-phenothiazine Hydrochloride (XVI).—A mixture of 14.0 g. (0.07 mole) of phenothiazine, 100 ml. of dry toluene and 2.93 g. (0.075 mole) of sodium amide was heated under reflux under nitrogen with vigorous stirring for 2 hours. After cooling, 83.3 ml. (0.075 mole) of a toluene solution of 1-(β-chloroethyl)-1-azaspiro[4.5]decane (see above under preparation of the nitrile) was added dropwise with vigorous stirring during 15 minutes. It was then heated under reflux for 19 hours. The mixture was washed with water and then the toluene solution was shaken with 400 ml. of water containing 15 ml. of concentrated hydrochloric acid. An oil separated which soon crystallized. The solid was collected, washed with water and ether and dried, giving 26.8 g. (91.3%) of tan crystals, m.p. 107–130°. This was recrystallized from water giving 25.7 g. of nearly white crystals, m.p. 120–130° dec. Infrared spectrum indicates it is a hydrate.

Anal. Calcd. for $C_{23}H_{29}ClN_2S \cdot H_2O$: C, 65.93; H, 7.46; N, 6.69; Cl, 8.46; S, 7.65. Found: C, 66.10; H, 7.50; N, 6.47; Cl, 8.54; S, 7.96.

10-[γ-(1-(1-Azaspiro[4.5]decane))-propyl]-2-chlorophenothiazine (XVII).—A mixture of 11.7 g. (0.05 mole) of 2-chlorophenothiazine,[13] 2.06 g. (0.053 mole) of sodium amide and 75 ml. of dry toluene was heated under reflux under nitrogen with vigorous stirring for 2 hours.

A mixture of 13.4 g. (0.053 mole) of 1-(γ-chloropropyl)-1-azaspiro[4.5]decane hydrochloride and dilute sodium hydroxide was extracted with 100 ml. of toluene in four portions. The toluene extracts were washed with a little water and well dried over potassium carbonate.

This toluene solution was added slowly during 10 minutes to the suspension of the sodium salt of chlorophenothiazine with vigorous stirring. The mixture was heated under reflux for 8 hours, cooled, washed twice with water and the washings were extracted with ether. The toluene and ether solutions of the free base were shaken with dilute hydrochloric acid. An oily hydrochloride separated insoluble in both layers. The hydrochloride and aqueous layers were separated, washed with ether and made basic with sodium hydroxide. The free base separated as an oil which soon crystallized. The solid was collected, washed with water and dried giving 19 g. of tan solid, m.p. 108–112°. This was crystallized from 100 ml. of ethyl acetate (with treatment with decolorizing charcoal) giving 15.3 g. (74%) of cream-colored crystals, m.p. 114–116°. A small sample recrystallized from acetone gave crystals with the same color and melting point.

Anal. Calcd. for $C_{24}H_{29}ClN_2S$: C, 69.79; H, 7.08; Cl, 8.58. Found: C, 69.83; H, 7.08; Cl, 8.78.

Studies on the Chemical and Enzymatic Oxidation of Lysergic Acid Diethylamide[1]

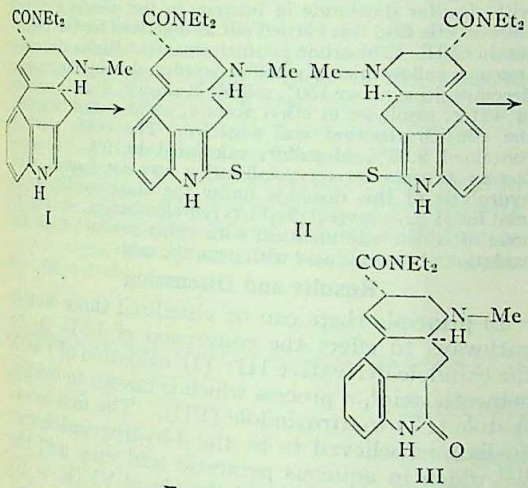
BY K. FRETER, J. AXELROD AND B. WITKOP

RECEIVED OCTOBER 27, 1956

The reaction of the trichloroacetate of lysergic acid diethylamide (I) with disulfur dichloride in benzene yielded the symmetric disulfide II which on reductive acid hydrolysis and purification by multiple countercurrent distribution gave a non-crystalline compound, which was identical in all respects with a product obtained by enzymatic oxidation of I. On the basis of color reactions, alkaline opening to a diazotizable amine and ultraviolet absorption spectrum the oxindole structure III is suggested for this oxidation product.

Introduction

Whereas studies on the metabolic fate of the hallucinogenic (psychotomimetic) lysergic acid diethylamide LSD in intact animals[2-4] have been handicapped by the great potency of I, the formation of a physiologically inactive metabolite (presumably III) was observed in the oxidation by an enzyme present in liver microsomes.[5] This paper describes the formation of III from I by reductive hydrolysis of the disulfide II.



Experimental

Purification of the LSD-Metabolite Obtained by Enzymatic Oxidation.—The solution of the crude metabolite from 5 mg. of LSD[5] in 0.1 *N* hydrochloric acid was evaporated to dryness at 20° in a vacuum desiccator. The residue was taken up in as little methanol as possible and filtered. The concentrated solution was evenly distributed (micropipet) along the starting line of several sheets of Whatman No. 1 filter paper. After completion of the chromatographic process (ascending technique, mixture of 2,4-lutidine–*t*-amyl alcohol, 1:1, saturated with water) the sheets were dried. Stripes of the area corresponding to an R_F-value of 0.85 were cut out under an ultraviolet light and eluted by a descending solvent front of methanol. After evaporation of the solvent there remained about 3 mg. of colorless residue which defied crystallization. No crystalline salts could be obtained. The ultraviolet absorption spectrum showed a sharp peak at 259 mμ.

Conversion of Lysergic Acid Diethylamide (I) to the Disulfide II.—To a suspension of 300 mg. of LSD (I) in 100 ml. of anhydrous benzene was added 500 mg. of anhydrous trichloroacetic acid. A clear solution was obtained by gentle warming. To this solution which was cooled to the point of near-solidification was added within 15 minutes a solution of 69 mg. of disulfur dichloride (S_2Cl_2) in 10 ml. of benzene. After ten more minutes the strongly yellow reaction mixture was poured into 700 ml. of petroleum ether (30–40°). The trichloroacetate of the disulfide II which separated in yellow flakes was collected and washed thoroughly with petroleum ether and ether. The salt was then transferred into a separatory funnel, decomposed with *N* alkali and the free disulfide II exhaustively extracted into ethyl acetate. The orange-colored solution was washed, dried and concentrated. The disulfide was recrystallized for analysis from dioxane–water, m.p. 184°, yield 200 mg. (60% theor.), R_F 0.95 descending technique, 2,4-lutidine–amyl alcohol, 1:1, saturated with water, Fig. 1. The Ehr-

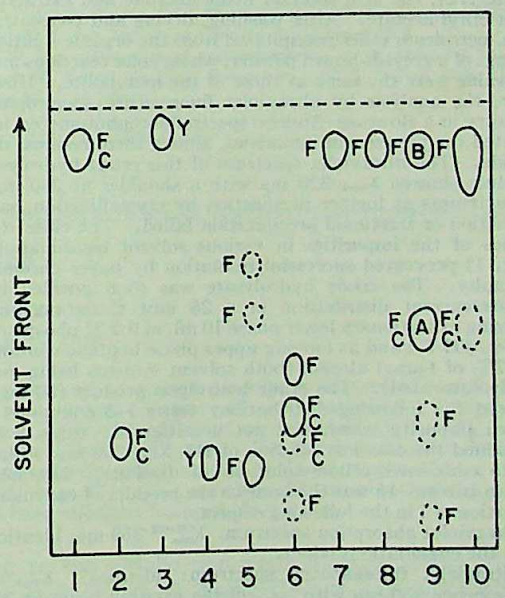


Fig. 1.—R_F-values and analytical determination of the various compounds; solvent system 2,4-lutidine-*t*-amyl alcohol (1:1, saturated with water): 1 = LSD (I); 2 = lysergic acid; 3 = disulfide (II) of LSD; 4 = disulfide of lysergic acid; 5 = hydrolysate of disulfide of lysergic acid; 6 = oxidation of lysergic acid; 7 = hydrolysate of II; 8 = enzymatic oxidation product of I; 9 = oxidation of LSD (I) by peracetic acid to a labile Ehrlich-positive compound A and a stable Ehrlich-negative compound B; 10 = stable Ehrlich-negative oxidation product B of I from Ehrlich-positive oxidation product A by the action of acid. Methods for characterization: F = fluorescence under ultraviolet light; C = color developing after spraying with cinnamaldehyde solution; Y = yellow original color.

lich reaction was negative, the Keller reaction (concentrated sulfuric acid containing a trace of ferric ion) gave a green color, as a result of the combination of the blue color, characteristic of β-substituted indoles, and of the yellow color of the disulfide II. Reduction with zinc dust in pyridine–glacial acetic acid according to Kuhn and Winterstein[6] gave a colorless solution which formed an insoluble red-brown mercaptide with lead acetate and on standing reoxidized to the yellow solution of the disulfide. The ultraviolet spectrum of II showed the expected displacement to longer wave length: $\lambda_{max}^{CH_3OH}$ 324 (log ε 3.54); lysergic acid tartrate, $\lambda_{max}^{CH_3OH}$ 312 (log ε 3.93).

Anal. Calcd. for $C_{40}H_{48}N_6O_2S_2 \cdot 2H_2O$: C, 64.53; H, 6.98; N, 11.31; S, 8.60. Found: C, 64.72; H, 6.79; N, 11.46; S, 8.83.

No weight loss was observed when the material was dried at 100° *in vacuo*.

Dr. A. Hofmann, Sandoz A. G., Basle, Switzerland, had the kindness to inform us that the same disulfide, m.p. 182°, $[\alpha]^{20}D$ −1020° (pyridine), analyzing for $C_{40}H_{48}N_6O_2S_2$ (recrystallized from dioxane–water, dried at 90° *in vacuo*) has been obtained in his laboratory. A direct comparison of our, with his, sample established the identity.

Hydrolysis of the Disulfide II.—Refluxing of II with 20% acetic acid after a short time led to the evolution of hydrogen sulfide which was trapped as lead sulfide. Although the rate of liberation of H_2S decreased markedly it was still noticeable after 6 hr. On a preparative scale, 200 mg. of disulfide II was dissolved in 30% acetic acid and equidistributed into 5 small glass tubes each of which contained 100 mg. of C.P. zinc dust. The tubes were sealed *in vacuo* and heated to 110° for 16 hr. The contents of the tubes was cooled, lyophilized and the residue taken up in a small volume of methanol, filtered, mixed with a fivefold volume of ether, and filtered again. The filtrate was extracted with dilute HCl, the acid solution made alkaline and extracted with ethyl acetate. After washing, drying and concentration, petroleum ether precipitated from the organic solution 30 mg. of a greyish-brown powder, whose color reactions and R_F-value were the same as those of the metabolite. However, the analysis by ultraviolet fluorescence spectrophotometry in a Bowman–Aminco spectrofluorophotometer[7] indicated the presence of impurities, among them residual disulfide. The ultraviolet spectrum of this crude hydrolysis product showed λ_{max} 320 mμ with a shoulder at 260 mμ. All attempts at further purification by crystallization, salt formation or fractional precipitation failed. The close R_F-values of the impurities in various solvent combinations (Fig. 1) prevented successful resolution by paper chromatography. The crude hydrolysate was then purified by countercurrent distribution in a 25 unit Craig machine utilizing as stationary lower phase 10 ml. of 0.2 *M* phosphate buffer, *p*H 7.4 and as moving upper phase heptane containing 7% of *t*-amyl alcohol (both solvent systems being mutually saturated). The crude hydrolysis product (30 mg.) showed the following distribution: tubes 1–5 contained a brown impurity which was not investigated; tubes 8–15 contained the colorless solution of III, λ_{max} 259 mμ; tubes 20–25 contained yellow solutions of disulfide. The solution in tubes 8–15 was the same as the product of enzymatic oxidation of I in the following respects:

Ultraviolet absorption spectrum: $\lambda_{max}^{CH_3OH}$ 259 mμ, identical with the enzymatic product.

Ultraviolet fluorescence spectrum: identical; λ_{max} of fluorescence 430 mμ with λ_{max} of the exciting beam at 335 mμ.

Distribution Coefficients.—The relative concentrations in aqueous solutions of varying *p*H before and after extraction with various organic solvents were determined by measurement of the per cent. transmission of the maximum of fluorescence at 430 mμ in a Bowman–Aminco spectrofluorophotometer,[7] adjusting the transmission to 100 at the beginning of extraction.

Biphasic systems		Relative concn. of metabolite III	
Inorganic	Organic	By hydrolysis of II	By enzymatic oxidation of I
Phosphate buffer *p*H 7.8	Heptane–5% isoamyl alcohol	70	69
Phosphate buffer *p*H 7.8	Ethylene dichloride	14	15
0.1 *N* hydrochloric acid	Ethyl acetate	42	39

R_F-Values: identical, 0.85, *cf.* Fig. 1.

Ehrlich Reaction: both negative.

Azotest.—Both compounds, after treatment with hot aqueous alcoholic alkali, but not before, showed a diazotizable amino group which coupled after diazotization with an alkaline solution of β-naphthol.

Reaction of Folin and Ciocalteu[8]: both positive.

Oxidation of LSD (I) with Peracetic Acid.—Five milligram samples of LSD (I) were oxidized with 1 ml. of a mixture of glacial acetic acid and 30% hydrogen peroxide ("Superoxol," C.P.) in a ratio of 5:1 at room temperature for ten minutes up to one hour. The reaction mixtures were freeze-dried and chromatographed using the usual solvent mixture. Two discrete spots were observed (Fig. 1). The compound A with R_F 0.5 was obtained on brief oxidation. It gave a positive Ehrlich reaction and had $\lambda\lambda_{max}$ 249 and 310 mμ. On standing in solution or, more rapidly on treatment with acid, rearrangement to an Ehrlich-negative compound B, R_F 0.85 occurred.

Similarly, the action of peracetic acid on lysergic acid produced two different compounds with R_F-values of 0.3 (Ehrlich-positive) and 0.4 (Ehrlich-negative, Fig. 1).

Lysergic Acid Disulfide.—The reaction of lysergic acid with disulfur dichloride in benzene in the presence of trichloroacetic acid was carried out as described for the preparation of II. The crude product separated during the reaction as a yellow microcrystalline powder, showing increasing decomposition above 150°, soluble in alcohol, slightly soluble in water, insoluble in ethyl acetate, acetone and benzene; the Ehrlich reaction was negative. The crude product contained 9.66% of sulfur, calculated 10.70%. A satisfactory process for recrystallization was not found. The hydrolysis of this disulfide under the same conditions as used for II gave several products (chromatogram, see Fig. 1) none of which was identical with either product from the oxidation of lysergic acid with peracetic acid.

Results and Discussion

In principle there can be visualized three simple pathways to effect the conversion of LSD (I) to the oxindole derivative III: (1) oxidation of I with peracetic acid[9], a process which is known to oxidize skatole (IV) to atroxindole (VII). The first intermediate is believed to be the β-hydroxyindolenine V[10] which in aqueous peracetic acid may add the elements of water to yield the glycol VI (R = H) which undergoes acid-catalyzed loss of water (*via* a benzylcarbonium ion) to the oxindole VII. With perbenzoic acid in chloroform the common intermediate V may add peracid to form VI (R = $OCOC_6H_5$) undergoing ring-fission with loss of benzoate anion to give VIII.[11] Two products are formed from I and peracetic acid; an Ehrlich-positive compound A rearranging on standing or by the action of acid to an Ehrlich-negative compound B. If the glycol analog of VI in the lysergic acid series were stable one would have to assume that any possible reaction with *p*-dimethylaminobenzaldehyde would be faster than rearrangement catalyzed by the acid present. No stable α-unsubstituted β-hydroxyindolenines are known and so one does not know whether such compounds may give a color with Ehrlich reagent. However, the scheme glycol (VI) → oxindole (VII) seemed unlikely since it was found that the acid-catalyzed rearrangement of the Ehrlich-positive

oxidation product of lysergic acid gave a product whose R_F-value was definitely different from the R_F of the presumable oxindole prepared by a more direct method. Such a distinction by paper chromatography was not possible for the analogous products from LSD.

(2) The attempted solvolysis of the commercially available bromination product of LSD, believed to be 2-bromo-LSD because of the negative Hopkins–Cole and Ehrlich reactions, was without success. Even heating with silver oxide for several hours failed to produce silver bromide.

(3) Finally, the reaction of LSD with disulfur dichloride (S_2Cl_2) was investigated. Pyrroles with free α and β-positions[12] and indoles with free α-position[13] are converted by this reagent to symmetrical disulfides. This procedure was applied to the trichloroacetate of LSD in order to prevent the basic tertiary nitrogen from reacting with the disulfur dichloride. The product obtained in this way had all the properties expected from a compound of the disulfide structure II. II is no longer physiologically active.[14] Whereas hydrolysis of the disulfide from tryptophan proceeds smoothly even with water alone, II had to be heated under fairly vigorous conditions with dilute acetic acid and zinc dust. Mineral acid led to resinification, and base could not be used without the danger of losing the amide group. The purification of the hydrolysis mixture by fractionation and countercurrent distribution finally yielded a pure compound which, though not obtained crystalline, was identical with regard to ultraviolet and fluorescence spectra, color reactions, distribution coefficients and R_F-values with the metabolite obtained by enzymatic oxidation of LSD. In addition to the negative Ehrlich and the positive Folin reactions the formation of a diazotizable amino group on treatment with base and the sharp absorption maximum at 259 mμ[15] support the oxindole structure III for this metabolite.

Quebrachamine. I

BY BERNHARD WITKOP

RECEIVED NOVEMBER 19, 1956

Dehydrogenation of quebrachamine, $C_{19}H_{26}N_2$ (II), furnished a mixture of homologous indoles, a mixture of 3-methyl-5-ethyl- and 3,5-diethylpyridine, a mixture of homologous carbazoles and a propyl derivative of α- or β-carboline. Two major oxidation products, the hydroxy base $C_{19}H_{26}N_2O$, m.p. 188° (V), and an N(a)-acetyldihydroindole base, $C_{21}H_{28}N_2O_2$, m.p. 213° (IV), were obtained on oxidation of II with ozone or hydrogen peroxide in acetic acid. The hydroperoxide VI, formed by catalytic oxygenation of II, on sublimation or warming in polar solvents disproportionated to V and oxygen. V, on catalytic hydrogenation, yielded the hexahydrohydroxy base $C_{19}H_{32}N_2O$, m.p. 177° (IX), which on dehydrogenation with palladium gave a base, $C_{11}H_{17}N$, isolated as the picrate, which also has been obtained from aspidospermine.

Quebrachamine has been isolated from the bark of *Aspidosperma quebracho blanco*,[1] together with aspidospermine and yohimbine or quebrachine, from *Aspidosperma chakensis*, together with spegazzinine,[2] and from the bark of *Gonioma kamassi*.[3,4] It belongs to the small group of crystalline oxygen-free plant bases. It contains an indole system, possibly unsubstituted at the α-position (positive Hopkins–Cole and Ehrlich reactions, red picrate),[5,6] and, judging from its resistance to mild catalytic hydrogenation, no other unsaturation. In addition to the indolic non-basic nitrogen N(a), there is a basic (pK 6.76, Table II) nitrogen N(b) which must be tertiary. The structure of a N-(3-indolylethyl)-1,2,3,4-tetrahydroisoquinoline (I, ring junction *cis* or *trans*)[7] is ruled out for, at least, two reasons: (i) the Hofmann degradation of compounds of type I, *e.g.*, of *chano*desoxyyohimbol[8] gives a volatile base, optically active N-methyl-*trans*-decahydroisoquinoline, in good yield. (ii) Catalytic dehydrogenation of I would lead to isoquinoline. Quebrachamine methiodide gives no easily volatile base on attempted Hofmann degradation, and the dehydrogenation of the free alkaloid does not lead to an isoquinoline.

Dehydrogenation with zinc dust under the conditions applied to yohimbine,[9] C-dihydrotoxiferine-I,[10] gelsemine[11] and aspidospermine[12] yielded four products: (i) The picrate of a base $C_9H_{13}N$. Its melting point (180–181°) was undepressed on admixture with 3,5-diethylpyridine picrate from aspidospermine (m.p. 180–182°).[12] The pyrolytic product apparently contains some 3-methyl-5-ethylpyridine whose picrate (m.p. 191–192°)[13] must be isomorphous with that of the homolog. It is present in an amount small enough not to alter significantly the analysis. The pyrolytic cracking of an ethyl to a methyl side chain is a frequent phenomenon observed also with the indolic degradation products. (ii) The steam-volatile indole fraction yielded a mixture of picrates which were exceedingly difficult to purify. One probably is dealing here with a similar mixture of β-alkylindole picrates as observed in the pyrolysis of yohimbine,[9] C-dihydrotoxiferine[10] and aspidospermine.[12] The non-volatile non-basic fraction formed needles, m.p. 218°, probably a mixture of carbazole and its 2-(or 3-)methyl homolog.[14] Dehydration of quebrachamine with palladium black gave ammonia and, in a yield of 1%, the picrate (m.p. 257°) of a base $C_{14}H_{16}N_2$ (m.p. 202°). Its ultraviolet spectrum (Table I) is suggestive of an α- or β-carboline system of which the dehydrogenation product may be a propyl derivative.

If quebrachamine contains an α-unsubstituted indole system, its formula can be resolved into II. Oxidation by ozone,[15] peracids[16] and oxygen[17] would be expected to lead to a substituted *o*-formaminophenone (III). Ozonization of quebrachamine in 60% acetic acid led, however, to two unexpected products (Chart I): an N(a)-acetyldihydro base IV, $C_{21}H_{28}N_2O_2$ (m.p. 213°), and a base V, $C_{19}H_{26}N_2O$ (m.p. 188°). Both bases are formed in very low yield probably by a secondary decomposition of ozone or ozonides to yield hydrogen peroxide in equilibrium with peracetic acid by interaction with the solvent. The ultraviolet spectra of both compounds ruled out a γ-quinolone system as is sometimes formed from 2,3-disubstituted indoles by intramolecular condensation of the ozonolysis product.[18] The products resulting from prolonged ozonolysis of quebrachamine could not be precipitated by base and were not obtained crystalline. The nature of base IV is disclosed by its spectral resemblance to N-acetylhexahydrocarbazole and by the loss of acetyl on acid hydrolysis to yield a dihydroindole base $C_{19}H_{26}N_2O$ (VII, m.p. 103°) isomeric with the hydroxy base V. The oxygen function in IV is lost on reduction with $LiAlH_4$ and an N(a)-substituted indole base (VIII) is obtained. The unusual N(a)-acetylation in the formation of IV is reminiscent of the acylating power of peracetic acid–sodium bisulfite mixtures[19] and may reflect on the role of quebrachamine as a biogenetic precursor of aspidospermine.

As expected, much higher yields of bases IV and V were observed in the oxidation of quebrachamine with peracetic acid, *i.e.*, mixtures of acetic acid and hydrogen peroxide. By careful control of time and temperature of the reaction (*cf.* Experimental) 90% of base V and 10% of base IV were obtained. With perbenzoic acid only base V was produced.

The infrared and ultraviolet spectra of the base $C_{19}H_{26}N_2O$ (V) suggest a dihydroindole derivative rather than a β-hydroxyindolenine (XII). The second tertiary nitrogen atom N(b) could possibly add to the β-hydroxyindolenine (XII) to form in aqueous or alcoholic solutions a quaternary eseroline type compound XIII. Base V in alcoholic solution does not obey Beer's law and in the determination of the *pK* value (inflection points at 11.9 and 5.65, Table II) which is higher than that of quebrachamine (6.76 in methyl Cellosolve) a marked hysteresis was observed on back-titration indicative of tautomerism (*e.g.*, XII ⇄ XIII). Lithium aluminum hydride reduces base V smoothly to quebrachamine, a type of reduction typical of β-hydroxyindolenines[20] or derivatives such as quinamine,[21] and catalytic reduction of V leads to a hexahydro base IX in which apparently full saturation has been achieved by hydrogenation of

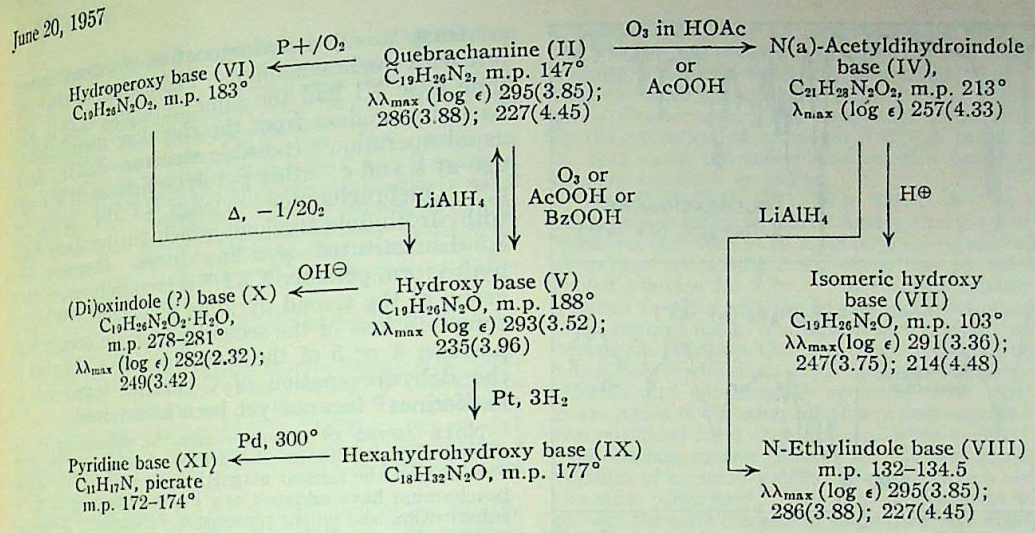

Chart I.—Products obtained in the oxidation of quebrachamine with ozone oxygen and peracids.

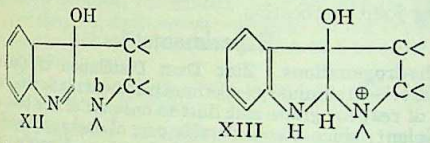
the benzene ring (*cf.* infrared spectra, Fig. 1) but with no loss of the hydroxyl group located initially



probably at a benzyl position. This retention of a hydroxyl group would indicate that the reduction of the aromatic ring is faster than the hydrogenolysis of a substituted benzyl alcohol. Base V is also formed from the hydroperoxide VI, obtained by catalytic oxygenation of quebrachamine, by thermal disproportionation: 2R–OOH → 2R–OH + O_2.[22] The most likely position for the initial attack of oxygen is again the β-indole carbon rather than a methylene group adjacent to the indole system or to N(b). Further evidence for the β-hydroxyindoline nature of V comes from the action of alkali which leads to two fractions, one having oxindole or dioxindole properties, the other displaying the spectral characteristics of indoxyl compounds. The formation of indoxyls under much less vigorous conditions has been observed in the autoxidation and rearrangement of the indole alkaloids

TABLE II

methyl iodide (X = CH_3^+) as indicated by the arrows.[23] A related system XIX would be capable of similar effects. However, the isomeric quebrachamine has a strong narrow NH band in the infrared spectrum (Fig. 1), characteristic of an indole imino group, and its methiodide has an N-methyl and no additional C-methyl group.[25] The expression XX for quebrachamine offers no explanation

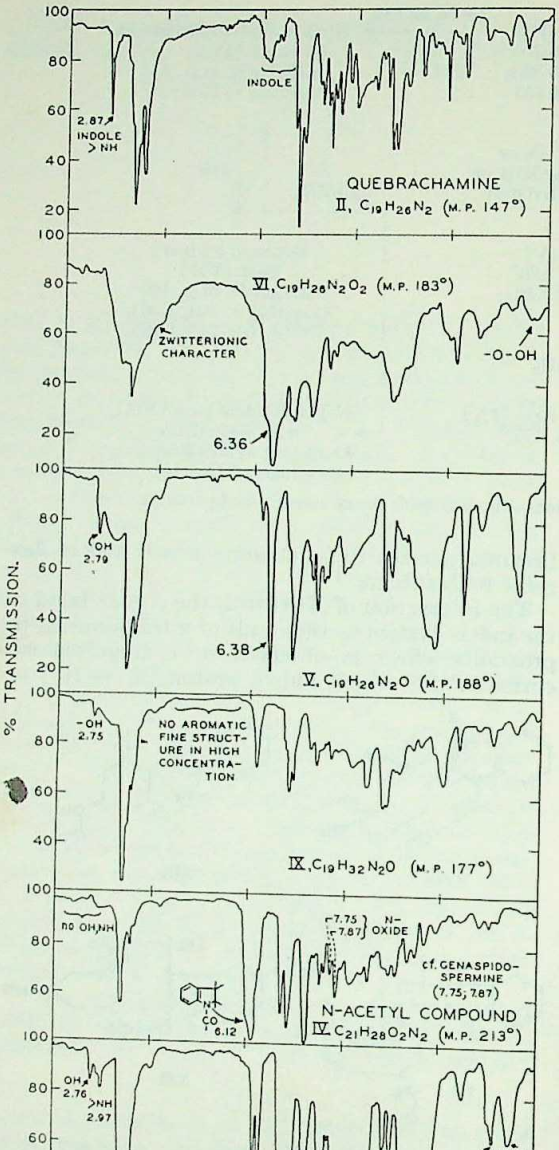

Fig. 1.—Infrared spectra of quebrachamine (II), bases VI, V, IX, IV and VII in chloroform.

for the reactions in chart I but serves as a model to illustrate formally the types of fission observed on dehydrogenation: b → skatol, c → 3-ethylindole + 3,5-diethylpyridine, d → 3-methyl-5-ethylpyridine. Rupture at a would yield indole and 3-ethyl-5 *n*-butylpyridine. The picrate (m.p. 172–174°) of a base of this composition was obtained when the hexahydrohydroxy base, m.p. 177° (IX), was dehydrogenated with palladium. No evolution of ammonia was observed in this dehydrogenation in contrast to all dehydrogenation reactions carried out with quebrachamine. The picrate of the pyridine base XI had the same m.p. and m.m.p. as a basic by-product from the zinc dust distillation of aspidospermine[12] (possible structure XXII, cleavage at a and c; other pyrolytic fissions at b, d and e.[26] Quebrachamine belongs to the family of (dihydro)indole alkaloids which on pyrolysis yield 3,5-disubstituted pyridine bases. Ibogaine (dihydro form possibly XXI)[27] retains only one methyl group of the second pyridine side chain. Whether complete loss of the second side chain occurs from position 4 or 5 of the 3-ethylpyridine obtained in the dehydrogenation of C-curarine[14] and the C-toxiferines[10] has not yet been ascertained.

NOTE ADDED IN PROOF.—Since the submission of this manuscript studies on the deuterium exchange (with K. Freter) and the nuclear magnetic resonance spectra of quebrachamine have adduced new evidence bearing on the α-substitution and on the presence of a N-methyl group. In coöperation with D. H. Conroy, to whom I am most indebted for discussions, NMR spectra and the communication of his results with aspidospermine [H. Conroy, P. N. Brook, K. Rout and N. Silverman, THIS JOURNAL, 79, in press (1957)], formulas for quebrachamine and its transformation products have been postulated which will be discussed in a forthcoming joint publication.

Experimental[28]

Dehydrogenations. Zinc Dust Distillation of Quebrachamine.—Preliminary experiments showed that a ratio of 25 parts of reagent grade zinc dust to one part of free base was insufficient, since a considerable part of unchanged quebrachamine was found in the volatile fraction. For every distillation 50 mg. of quebrachamine was intimately mixed with 7 g. of zinc dust. Fifty such distillations were carried out using the same conditions and equipment as used previously for the dehydrogenations of yohimbine,[9] C-dihydrotoxiferine-I,[10] gelsemine[11] and aspidospermine.[12]

Basic Fraction.—The combined ethereal solutions of the volatile degradation products were concentrated to 50 cc. and extracted with dilute hydrochloric acid. The free bases were liberated from the solution of their hydrochlorides with base and taken up into ether. The more volatile bases were separated from the dark colored residue by steam distillation. The volatile bases were obtained from the steam distillate by salting out with ammonium chloride and extraction with ether. After evaporation of the ether there remained a few drops of a colorless oil with a strong collidine-like odor. The base was dissolved in 2 cc. of dilute hydrochloric acid, and excess aqueous picric acid solution was added. After 1 hr. the supernatant was clear and the flocculent picrate was collected and washed with water. The dry picrate crystallized on trituration with 0.5 cc. of cold acetone. The acetone washing was separated from the residue which on recrystallization from 1 cc. of acetone appeared in fine glistening needles, m.p. 179°. One more recrystallization raised the m.p. to 180–181°, undepressed on admixture with the 3,5-diethylpyridine picrate from aspidospermine.[12]

Anal. Calcd. for $C_9H_{13}N \cdot C_6H_3N_3O_7$: C, 49.45; H, 4.39; N, 15.38. Found: C, 49.23; H, 4.15; N, 15.21.

The basic residue from the steam distillation was taken up into ether. On slow evaporation, or on rubbing the residue with methanol, unchanged quebrachamine (m.p. 144°) was obtained.

Non-basic Fraction.—The ethereal solution from which the bases had been extracted with hydrochloric acid was evaporated and separated into a steam-volatile and non-volatile part. The volatile part had a strong indolic odor and was purified further by distillation *in vacuo*. This purified fraction was dissolved in petroleum ether and con-

verted into the picrate free of excess picric acid by cautious addition of a warm solution of anhydrous picric acid in petroleum ether (b.p. 60°). Not until after three recrystallizations from benzene–petroleum ether had the picrate lost its stickiness. Four more recrystallizations from benzene raised the m.p. as follows: 104°, 128°, 132°. From the last fraction which was just sufficient for C and H analysis, there was obtained after one more recrystallization a small sample, m.p. 143°, mixed m.p. with the isomorphous mixture of β-methyl- and β-ethylindole picrates (m.p. 154°) from yohimbine, 135–140°. The analysis was done on the picrate, m.p. 132°, and points to the presence of higher homologs of ethylindole.[29]

Anal. Calcd. for $C_{11}H_{13}N \cdot C_6H_3N_3O_7$: C, 52.58; H, 4.15. Found: C, 52.48; H, 4.15.

The analysis of a picrate from mother liquor, m.p. 128°, gave: C, 53.63; H, 4.31. From 3.64 mg. of this picrate there was obtained 0.713 mg. of AgI under the conditions of the Zeisel determination (2.57% "OCH_3") but no AgI under the conditions of the Herzig–Meyer determination.[8] This excludes methylation of the indole imino group in the course of dehydrogenation.[30]

The dark residue of the steam distillation of the volatile indoles was distilled at 140° (0.01 mm.). The colorless crystalline distillate on recrystallization from benzene appeared as sheaves of fine needles, m.p. 218°. The compound has all the properties of the product from the zinc distillation of C-dihydrotoxiferine-I[10] and is probably a mixture of carbazole and some homolog.[14] The Hopkins–Cole reaction is negative, the Ehrlich reaction gives a light-red color in the cold, dark-red on warming, fading on cooling, changing to dark blue-violet on addition of a trace of potassium nitrite.

Anal. Calcd. for $C_{13}H_{11}N$: C, 86.16; H, 6.07; N, 7.73. Found: C, 85.86; H, 5.86; N, 7.51.

Dehydrogenation of Quebrachamine with Palladium Black.—A mixture of 0.5 g. of quebrachamine and 0.5 g. of freshly prepared palladium black was heated in a metal-bath to 320° for 4 hr. At 220° the odor and alkaline reaction (litmus paper) of ammonia was distinctly noticeable and persisted for about 3 hr. The crude dehydrogenation product was taken up in ether and separated from the palladium. The bases were extracted with dilute hydrochloric acid, liberated with alkali and again extracted into ether. After evaporation of the ether the brown semi-solid residue was freed of pyridines at 100° (1 mm.). Subsequent distillation at 180° (0.01 mm.) gave a droplet of a light-yellow oil, solidifying in the cold, which was dissolved in 1.0 *N* HCl and converted into the picrate. The dry picrate was triturated with 0.2 cc. of glacial acetic acid which dissolved dark-colored impurities. The yellow residue was freed of acetic acid with ether. The purified picrate was recrystallized from acetone, in which it is moderately soluble, yielding clusters of needles, m.p. 257° dec. On slow crystallization from more dilute solutions in acetone the picrate appeared in short prisms with the same m.p.

Anal. Calcd. for $C_{14}H_{16}N_2 \cdot C_6H_3N_3O_7$: C, 54.67; H, 3.87. Found: C, 54.83; H, 3.73.

By comparison the picrate of β-carboline (norharman) showed a similar dimorphism: from acetone it crystallized in light-yellow fine needles or yellow-red prisms, m.p. 265°, crystalline transformation at 220°, mixed m.p. with picrate from quebrachamine 240°.

Hydrochloride.—The solution of the picrate in acetone was acidified with 4 *N* hydrochloric acid and the picric acid extracted into ether. The solution of the base in hydrochloric acid shows in great dilution the same blue fluorescence as harman or norharman. The dry hydrochloride was recrystallized from ethanol–ether in sheaves of colorless needles, m.p. 210°.

Free Base.—The free base was liberated from the aqueous solution of its hydrochloride by the addition of alkali and extracted into ether. It crystallized from ether in colorless needles, m.p. 202°, mixed m.p. with norharman (m.p. 200°) 186°. For the ultraviolet spectrum *cf.* Table I.

Dehydrogenations of quebrachamine with selenium at 300° led to the evolution of ammonia and yielded, besides volatile products, a neutral compound whose solution in benzene after filtration through alumina showed a strong green fluorescence. The dehydrogenation with sulfur led to the evolution of ammonia and H_2S beginning at 150°. In both cases the amorphous reaction products seemed to contain selenium or sulfur.

Base $C_{21}H_{28}N_2O_2$ (IV), M.p. 213°. A. By Ozonization of Quebrachamine in Acetic Acid.—One gram of quebrachamine was dissolved in 10 cc. of 60% acetic acid and a stream of oxygen containing 2.5% ozone was passed through the cooled solution for 2 hr. The reaction mixture was made alkaline to *p*H 8 and the base which precipitated collected. One obtained 0.4 g. of a light-brown powder, which showed a negative Hopkins–Cole reaction and did not react with dinitrophenylhydrazine. This material was placed in a filter thimble and continuously extracted with ether. On slow evaporation of the ether solution prisms appeared which were recrystallized from acetone in colorless needles, m.p. 213°. The viscous mother liquors on micro-sublimation in the vacuum of a mercury diffusion pump gave a second crop of the same compound. Whereas, on treatment with hot acid or base the pure compound showed no diazotizable aromatic amino group, the same test was positive with the crude ozonization product.

Anal. Calcd. for $C_{21}H_{28}N_2O_2$: C, 74.2; H, 8.29; N, 8.23. Found: C, 74.74; H, 8.37; N, 7.68.

B. By Oxidation with Peracetic Acid.—A solution of 0.5 g. of quebrachamine in a mixture of 3 cc. of glacial acetic acid and 3 cc. of 30% hydrogen peroxide (Superoxol) was left for 40 hr. at 20°. The slightly pink solution was cooled and brought to a *p*H of 7.5–8.0 with alkali.

The precipitated base, after collecting, washing and drying, 45 mg. of a pink powder, was easily soluble in ether, methanol, acetone, etc. The solution in acetone on slow concentration deposited long glistening needles which were washed with little ice-cold acetone; m.p. 213°. The substance sublimed in high vacuum at 180–200° (bath). The reactions according to Ehrlich and Hopkins–Cole were negative. The azo test for aromatic NH_2 was ambiguous: By the short action of 2 *N* mineral acid on the steam-bath, a diazotizable amine seemed to be formed whereas longer action of 4 *N* hydrochloric acid led to the new base $C_{19}H_{26}N_2O$, m.p. 103° (see below). When analytically pure, negative diazo tests were given regardless of short or prolonged action of acid or alcoholic alkali.

Anal. Calcd. for $C_{21}H_{28}N_2O_2$: C, 74.2; H, 8.29; N, 8.23; N–$COCH_3$, 12.64; mol. wt., 340.4. Found: C, 74.98, 74.84; H, 8.40, 8.26; N, 8.08; N–CO–CH_3,[31] 11.4; mol. wt., 351, 357 (Rast), 358 (Signer[32]).

Infrared Spectrum ($CHCl_3$).—No band in the OH, NH region; strong and broad band at 6.12 μ (*cf.* aspidospermine 6.13 μ, but N-acetyltetrahydrocarbazole, 5.91 μ); shoulders at 6.20, 6.26; 6.72s; 6.85s; 6.93sh; 7.22s; 7.51w; 7.60w; 7.75w; 7.87m; 8.15w; 8.37vw; 8.50w; 8.95w; 9.08w; 9.33w; 9.49w; 9.68w; 9.92w; 10.29vw; 10.83vw; 11.0w.

Ultraviolet Spectrum (95% EtOH).—λ_{max} (log ε) 257 mμ (4.33); 220 (4.52) end absorption; $\lambda_{min.}$ (log ε) 235 (3.94); *cf.* N-acetylhexahydrocarbazole, λ_{max} (log. ε) 254 (4.21).[33]

Microtitration (Table II, Fig. 2).[34]—The basicity of a $^1/_{250}$ *M* solution of the base in 60% ethanol–water was 9.1 *p*H units at 20°. The microtitration with glass electrode according to Ingold[35] carried out under nitrogen gave *pK* 7.85.[36]

Base VIII, M.p. 132–134.5°, by Reduction of IV with $LiAlH_4$.—When a solution of 80 mg. of base IV in ether was treated with excess $LiAlH_4$ there was a distinct reaction. After the usual work-up an oily reduction product was obtained which crystallized on rubbing with methanol. A still somewhat sticky sample of these crystals showed m.p.

132–134.5°. The infrared spectrum of the crude material has no bands in the OH–NH region, 6.22m; 6.72vs; 6.83–6.86s; 7.24–7.26m. The ultraviolet spectrum ($\lambda\lambda_{max}$ (log ϵ) 294 (3.83); 288 (3.85); 231 (4.55)] was almost identical with that of quebrachamine [$\lambda\lambda_{max}$ (log ϵ) 295 mμ (3.85); 286 (3.88); 227 (4.45)]. An analysis of the best crystalline fraction obtained (Found: C, 80.03; H, 12.34) gave a surprisingly high value for hydrogen (Calcd. for $C_{21}H_{26}N_2$: C, 79.68; H, 11.46). The hydrochloride was precipitated from ethereal solution with gaseous HCl as a hygroscopic powder, unsharp m.p. 155–165°; Hopkins–Cole and Ehrlich reactions essentially negative. By carrying out the Ehrlich directions according to Dutcher[37] with material from mother liquors, no color was observed until nitrite was added which produced a dark purple color.

Base VII, $C_{19}H_{26}N_2O$, M.p. 103°, by Acid Hydrolysis of IV.—A solution of 50 mg. of base IV in 4 cc. of 4 *N* HCl was left on the steam-bath for 3 hr. and then taken to dryness in a desiccator at room temperature. The colorless residue was easily soluble in water. From this solution alkali precipitated the flocculent base. The dry base, after two recrystallizations from ether, formed fine colorless needles, m.p. 103°.

Anal. Calcd. for $C_{19}H_{26}N_2O$: C, 76.47; H, 8.78; N, 9.39. Found: C, 76.58; H, 8.61; N, 9.14.

Infrared Spectrum ($CHCl_3$).—2.76, 2.96 (NH and OH); 6.18s; 6.27s; 6.73vs; 6.85vs; 6.93sh; 7.21m; 7.27sh; 7.53m; 9.67s; 10.48m; 11.12m; 11.45m.

Ultraviolet Spectrum (95% ethanol).—$\lambda\lambda_{max}$ (log ϵ) 291 (3.36); 247 (3.75); 214 (4.48); $\lambda\lambda_{min}$ (log ϵ) 271 (3.12); 234 (3.65); 222 (4.09). A comparable dihydroindole, *e.g.*, deacetylaspidospermine, shows $\lambda\lambda_{max}$ (log ϵ) 291 3.48); 245 (3.77); 215 (4.42).

Base $C_{19}H_{26}N_2O$ (V), M.p. 188°. A. By Ozonization of Quebrachamine.—The solution from the ozonization of 1 g. of quebrachamine from which the base m.p. 213° had been precipitated at *p*H 8 was made very strongly alkaline with excess 50% NaOH and extracted with ether. On slow evaporation of the ether extract colorless clear prisms were obtained, m.p. 188°.

Anal. Calcd. for $C_{19}H_{26}N_2O$: C, 76.47; H, 8.78; N, 9.39. Found: C, 76.82; H, 9.01; N, 9.49.

The ozonization of quebrachamine, even with less than the calculated amount of ozone, invariably led to water-soluble or acidic compounds which were no longer precipitated with base of any strength. When 1 g. of quebrachamine in 15 cc. of methanol was treated with excess 3% ozone under ice cooling, on evaporation 1.3 g. of a light-brown powder was obtained, insoluble in ether, easily soluble in alkali, which did not blue potassium iodide–starch paper. The reaction product with dinitrophenylhydrazone could not be crystallized.

B. By the Action of Perbenzoic Acid on Quebrachamine.—The solution of 184 mg. of quebrachamine in chloroform was left for 24 hr. with 140 mg. of perbenzoic acid in chloroform. The red solution was extracted with dilute alkali to remove the benzoic acid. After evaporation of the solvent the residue was taken up in 2 *N* HCl, brought to *p*H 8, and a small amount of basic material (starting material) removed by extraction with ether. On addition of strong alkali and extraction with ether, 110 mg. of the base $C_{19}H_{26}N_2O$, m.p. 186–188°, was obtained on recrystallization from ether.

C. By the Action of Peracetic Acid on Quebrachamine.—From the filtrate, *p*H 8, of the preparation of the base m.p. 213°, strong alkali precipitated more of a colorless base which on dilution with water went into solution again but which could be extracted with ether. The residue of the dried ether extract weighed 450 mg. Table III lists the yields of the two bases from quebrachamine as function of the time the peracetic acid is allowed to react.

Two recrystallizations from ether furnished large glass-clear prisms, m.p. 188°. After reaction with excess acetic anhydride at room temperature for 24 hr. unchanged starting material was recovered.

Anal. Calcd. for $C_{19}H_{26}N_2O$: C, 76.47; H, 8.78; N, 9.39. Found: C, 76.75; H, 8.86; N, 9.68.

On slow recrystallization from acetone clusters of needles were obtained, m.p. 115°. The material gave an insoluble dinitrophenylhydrazone which indicates an acetone adduct. The compound was dried for two days at 100° *in vacuo* and then melted at 178–180°. The analysis was performed on material dried at 20°.

TABLE III

YIELDS OF THE TWO BASES V (M.P. 188°) AND IV (213°) IN THE REACTION OF 500 MG. OF QUEBRACHAMINE WITH A MIXTURE OF 3 CC. OF GLACIAL ACETIC ACID AND 3 CC. OF 30% HYDROGEN PEROXIDE FOR VARIOUS LENGTHS OF TIME AT 20°

Time of reacn., 20° hours	Recovd. quebrachamine, mg.	Base (V) $C_{19}H_{26}N_2O$ m.p. 188°, mg.	Base (IV) $C_{21}H_{28}N_2O_2$ m.p. 213°, mg.	Acidic products not pptd. by base, %
14	200	290	..	...
24	..	470	35	...
40	..	450	45	Little
100	..	..	..	>90

Anal. Calcd. for $C_{19}H_{26}N_2O \cdot CH_3COCH_3$: C, 74.12; H, 9.05; N, 7.86. Found: C, 74.52; H, 8.53; N, 8.26.

Rapid recrystallization from acetone led to pure base, m.p. 186–188°, which was used for rotation: $[\alpha]^{20}D$ −504° (*c* 1.0 in 50% aqueous EtOH).

Color Reactions.—Quebrachamine gives a lasting strong purple color in the Hopkins–Cole test; the base m.p. 188° gives a red color (fading to blue-green after 20 hr.) similar to that shown by quebrachamine in high dilution. The Ehrlich reaction gives a pink color in the cold, which becomes red on warming. Samples recrystallized from acetone showed weak or no color in these tests.

Infrared Spectrum ($CHCl_3$).—Distinct sharp band at 2.78, broad and flat band at 3.15, characteristic C–H doublet at 3.42 and 3.57; slight but distinct dip at 4.04 (zwitterionic ammonium structure), very weak aromatic band at 6.20; 6.38vs; 6.86vs; 7.26m; 7.40s; 7.54w; 7.80m; 8.76s; 8.90m; 9.80vs; 10.39s; 10.71m; 11.17vw; 11.54s.

Ultraviolet Spectrum (95% EtOH).—$\lambda\lambda_{max}$ (log ϵ): 293 mμ (3.52); 235 (3.96) at a molar concentration of 1.57×10^{-5}; 294 (3.48) at *c* 1.57×10^{-4}; at *c* 1.57×10^{-3} only linear absorption is observed which at 340 mμ has log ϵ 2.90 and at 360 mμ, 2.0; Beer's law is *not* obeyed.

Microtitration.—The basicity of a 0.01 *M* solution in water was 11.36 *p*H units at 20°. On titration with 0.01 *N* HCl two points of inflection were found: pK 10.57 and 7.43. On back-titration with 0.01 *N* NaOH a marked hysteresis was observed indicating rearrangement during titration.[37] In 80% methyl Cellosolve the *p*H of comparable solutions at the starting point was: quebrachamine 8.53; base V, 12.62. While quebrachamine gave a distinct pK of 6.76, only inflection points at 11.9 and 5.65 were observed for base V. The observed neutralization equivalent was within 3% of the calculated value. The maximum change in *p*H was observed after the addition of the amount of 0.01 *N* HCl in 80% methyl Cellosolve corresponding to 60% of the neutralization equivalent.

Hydrochloride.—The hydrochloride was prepared from ethereal solution with gaseous HCl. It formed a crystalline powder which appeared from chloroform solution on slow concentration in colorless clear prisms, m.p. 285–287° (sublimation 200–240°). Found: C, 65.44; H, 8.54; N, 8.12; Cl, 10.85. Calcd. for $C_{19}H_{26}N_2O \cdot HCl \cdot {}^3/_4H_2O$: C, 65.52; H, 8.25; N, 8.04; Cl, 10.3.

Infrared Spectrum ($CHCl_3$).—2.73vw; 3.14 (broad and strong band); 4.07 (saturated ammonium); 4.27vw, 4.93vw; 6.19m (phenyl or protonated azomethine?), 6.37sh; 6.80vs; 7.25m.

Picrate.—From the solution of the hydrochloride, aqueous picric acid precipitated the amorphous picrate which after collecting, washing and drying crystallized from aqueous acetone in glistening yellow scales, m.p. 173° (clear yellow melt).

Anal. Calcd. for $C_{19}H_{26}N_2O \cdot C_6H_3N_3O_7$: C, 56.02; H, 5.54; N, 13.28. Found: C, 56.49; H, 5.86; N, 13.04.

Hydriodide.—The addition of excess methyl iodide to an ethereal solution of base V led after a few minutes to the precipitation of a crystalline powder which was recrystallized from methanol–ether as needles, m.p. 280° (dec., darkening The reduction of the hydriodide

with lithium aluminum hydride or sodium borohydride yielded quebrachamine in good yield.[38]

Anal. Calcd. for $C_{19}H_{26}N_2O\cdot HI$: C, 53.52; H, 6.38; N, 6.58. Found: C, 53.62; H, 6.91; N, 6.88.

The picrate from this hydriodide melted at 172°, the free base, after recrystallization from hexane, melted at 186°, undepressed on admixture with the starting material.

Ultraviolet Spectrum (95% EtOH).—$\lambda\lambda_{max}$ (log ϵ): 291 (3.50); 285 (3.51); 220 (4.38). The solutions obeyed Beer's law.

Reduction of Base V to Quebrachamine with $LiAlH_4$.—To a solution of 200 mg. of base V in ether was added excess $LiAlH_4$. After the reaction had subsided the mixture was left for 1 hr. at room temperature. After the usual work-up the ether-soluble fraction was dissolved in 0.1 *N* HCl and brought to *p*H 7.5. The precipitated base was recrystallized from methanol as colorless prisms, m.p. 145–147°, undepressed on admixture with quebrachamine. The comparison was confirmed by infrared analysis and by conversion to the picrate, red prisms from methanol, m.p. 194°, undepressed on admixture with authentic quebrachamine picrate. A by-product of this reduction was isolated when the aqueous solution was brought from *p*H 8 to 11. In addition to about 60 mg. of an oily ether-soluble base (picrate yellow prisms from MeOH, m.p. 170–172°) 10 mg. of a flocculent ether-insoluble product separated at the interface between water and ether; it formed short prisms from chloroform, m.p. 183–186° (yellow melt). The analysis (C, 66.79; H, 8.57) is reminiscent of the hydrochloride of base V. There was insufficient material for investigation. The infrared spectrum was that of an indole and very similar to, though not identical with, that of quebrachamine. Quebrachamine itself was recovered unchanged after refluxing for 1 hr. with excess $LiAlH_4$ in tetrahydrofuran.

Catalytic Hydrogenation of Base V.—A solution of 0.3 g. of base V in 4 cc. of glacial acetic acid was allowed to take up to 2 equivalents of hydrogen in the presence of 100 mg. of PtO_2. The uptake of hydrogen was slow (10, decreasing to 4 cc./hour). The reduction mixture after separation from the catalyst was brought to *p*H 8. A flocculent base (about 40 mg.) separated which formed beautiful prisms from acetone, m.p. 165°, after two recrystallizations 177°. The mixed m.p. with the starting base was 135–155°. The compound gave negative Hopkins-Cole and Ehrlich tests. Its solution in 95% ethanol had only end absorption in the ultraviolet. A highly concentrated saturated solution in chloroform showed no aromatic fine structure, a narrow band at 2.80 μ, 2.86sh; 3.05sh; 3.12sh; 3.17 (broad band), 6.16m; 6.84s; 6.92sh; 7.27w; 7.41m; 7.70w; 8.85m; 10.05m; 10.37w; 11.05.

Anal. Calcd. for $C_{19}H_{32}N_2O$: C, 74.95; H, 10.59; N, 9.20. Found: C, 74.78; H, 10.47; N, 8.91.

Further addition of 50% alkali to the aqueous reaction mixture precipitated two additional basic fractions at *p*H 12 and 14, which were taken up in ether separately. Slow crystallization of the latter fraction from acetone overnight at 0° yielded cushions of colorless needles, m.p. 136–138°. The Ehrlich reaction gave a wine-red color.

Anal. Calcd. for $C_{19}H_{28}N_2O$: C, 75.95; H, 9.39; N, 9.33. Found: C, 76.38; H, 9.48; N, 9.15.

The ultraviolet and infrared spectra of this "dihydro base" were practically identical with those of the starting material.

Further hydrogenation of the "dihydro base" m.p. 138° gave in the usual work-up at *p*H 8 some hexahydro base (m.p. 175°; C, 74.29, H, 10.45) and at *p*H 14 crystals from acetone, m.p. 141–145° (loss of acetone), resolidification at 165°, second m.p. 175°, mixed m.p. with starting base (m.p. 188°) 135–170°. Found: C, 74.11; H, 9.48; N, 8.65. Calcd. for $C_{19}H_{28}N_2O\cdot CH_3COCH_3$: C, 73.70; H, 9.56; N, 7.81.

Palladium Dehydrogenation of Hexahydrohydroxy Base IX.—In a preliminary experiment *no odor of ammonia* was noticeable when equal parts of base V and palladium black were heated to 300°. The same absence of ammonia was noticed when 500 mg. of the hexahydro base IX and 300 mg. of palladium black were heated in a Späth tube to 300–320° (metal-bath). During the course of 2 hr. 120 cc. of hydrogen was evolved. The dehydrogenation mixture was extracted with ether and the oily bases (104 mg.), after distillation at 150° (14 mm.), extracted into 0.1 *N* HCl. The picrate was made in aqueous solution and recrystallized from methanol; yellow needles were obtained, m.p. 168–170°, recrystallized from acetone, m.p. 172–174°, undepressed on admixture with "picrate A," m.p. 168–172° from aspidospermine.

Anal. Calcd. for $C_{11}H_{17}N\cdot C_6H_3N_3O_7$: C, 52.04; H, 5.14; N, 14.28. Found: C, 51.64; H, 5.43; N, 13.88.

Action of Potassium Hydroxide in Refluxing Amyl Alcohol on V.—A solution of 0.3 g. of the base V and of 1 g. of KOH in 5 cc. of amyl alcohol was refluxed for 1 hr. and then taken to dryness *in vacuo*. In the usual manner the mixture was separated into acidic, neutral and basic fractions. The acid fraction amounted to a few mg. of an ether-soluble oily product with a strong odor reminiscent of butyric or hexahydrobenzoic acid and showed a strong infrared band at 5.85 μ. The ether-soluble neutral fraction was negligible. The ether-soluble basic fraction (120 mg.) was slightly yellow with a powerful green fluorescence. It was purified on a small column of alumina. By careful elution with 10-cc. portions of chloroform–benzene (1:1), the *indoxyl fraction* was obtained pure enough for spectral characterization.

A crystalline fraction from ether, m.p. 142°, was analyzed: C, 67.19; H, 8.33 (Calcd. for $C_{19}H_{26}N_2O_2\cdot 1^1/_2H_2O$: C, 66.83; H, 8.56).

Infrared Spectrum of Indoxyl Fraction ($CHCl_3$).—2.88 μ (NH); 3.05; 4.07 (ammonium); 5.89s (CO of indoxyl); 6.15s (phenyl); 6.72–6.78 (sharp doublet); 7.23w; 7.45m; 7.55m; 8.57m; 9.07s; 10.35m; 11.25w; 11.57w.

Ultraviolet Spectrum of Indoxyl Fraction (95% EtOH).—$\lambda\lambda_{max}$ 392, 290, 234 mμ (log ϵ was not determined because there was not enough material to make a solution of known concentration); *cf.* isoquinamine: $\lambda\lambda_{max}$ (log ϵ): 397 (3.51); 255 (4.0); 232 (4.46).

Oxindole Fraction.—Elution with pure chloroform gave a colorless fraction whose spectral characteristics agree with an oxindole or dioxindole structure. Analysis of a sample, obtained crystalline on trituration with ether (m.p. 295–315° dec.) showed C, 68.65; H, 8.69 (Calcd. for $C_{19}H_{26}N_2O_2\cdot H_2O$: C, 68.64; H, 8.49. Calcd. for $C_{19}H_{26}N_2O\cdot HCl$: C, 68.26; H, 8.14). There was insufficient material for a chlorine determination. The high m.p. and part of infrared data support the salt, the method of preparation and the ultraviolet spectrum and oxindole band do not.

Infrared Spectrum ($CHCl_3$).—2.89 (sharp and narrow NH); 3.13 (broad on band); 3.98 (zwitterion or salt?), 5.84vs (CO of oxindole); 6.15s; 6.80s; 7.25m; 7.37m; 7.53s; 8.52w; 8.72w; 8.88w; 9.08s; 9.34w; 9.55w; 9.82m; 10.05m; 10.19m; 11.20w; 11.58m. By comparison dioxindole showed the following bands (Nujol): 2.92; 3.15; 5.85s; 6.13s; 6.80s; 7.14m; 7.39m; 7.65w; 7.82m; 7.89m; 8.12w; 8.35s; 8.48s; 8.68w; 9.01s; 9.35m; 9.86w; 10.70w; 10.96vw; 11.52w.

Ultraviolet Spectrum (95% EtOH).—$\lambda\lambda_{max}$ (log ϵ): 282 (2.32); 249 (3.42); *cf.* gelsemine: 282 (2.69); 252 (3.33).

A similar compound had been obtained before from a preparation of 2 g. of base V, when the latter was not extracted immediately with ether but left in contact with strong alkali overnight. Most of the collected product was easily soluble in ether. However, there remained a small part which was almost insoluble in ether but soluble in chloroform. On slow evaporation from acetone it formed buttons of birefringent needles, showing a crystalline transformation into slim rods at 212–240°, 273° subliming, 278–281° melting with decomposition. Found: C, 68.57; H, 8.65; N, 8.14. For calcd. values see above.

The infrared spectra of this oxindole (or dioxindole) fraction showed the following bands ($CHCl_3$): 2.70w; 2.78sh; 3.15 (broad); 4.05w; 5.83vs; 6.18s; 6.37vs; 6.84vs; 7.25vw; 7.37s; 7.55m; 7.67w; 7.88w; 8.76w; 8.84–8.88m; 9.24w; 9.81m; 10.15w; 10.38m; 10.70m; 11.55m.

Catalytic Peroxidation of Quebrachamine to the Hydroperoxy Base VI.—A solution of 300 mg. of quebrachamine in 5 cc. of glacial acetic acid was added to a suspension of platinum, obtained by reduction of 100 mg. of PtO_2 in 3 cc. of glacial acetic acid, and shaken under oxygen. One molar equivalent of oxygen (25.5 cc.) was taken up in 90 minutes.

(38) Originally the hydriodide was considered to be the methiodide and the $LiAlH_4$ reduction erroneously interpreted to involve loss of a methyl group; *cf.* B. Witkop and J. B. Patrick, THIS JOURNAL, **75**, 4474 (1953).

No oxygen uptake was observed when ethyl acetate served as the solvent. The solution was filtered from the catalyst and brought to *p*H 9 by adding 4 *N* KOH at 0°. A negligible amount of basic material separated and was discarded. Concentrated alkali was added at 0°. The resulting base was extracted into ether, in which it was not very soluble. Some of the base crystallized at the interface and was collected by filtration. The residue from the ether extract as well as the crystals from the interface were recrystallized from acetone. Short colorless needles were obtained, m.p. 183° (yellow melt, evolution of gas). The compound turned starch–iodide paper blue.

Anal. Calcd. for $C_{19}H_{26}N_2O_2$: C, 72.58; H, 8.34; N, 8.91. Found: C, 73.08; H, 8.04; N, 9.24.

Infrared Spectrum ($CHCl_3$).—2.84 μ (weak, broad band); 3.16 (shallow, broad band); 3.98 (shoulder); 4.35vw; 6.20vw; 6.36s; 6.85vs; 7.26w; 7.9w; 7.52w; 8.76m; 8.90m; 9.88w; 10.40m; 11.55m. When VI was left in chloroform solution for two days, a strong new band at 3.17 and a weak band at 5.74 μ developed.

Microtitration.—A 0.01 *M* solution in 50% water–alcohol showed 12.3 *p*H units at 20°. The microtitration gave values of *pK* 12.13 and 9.65. In 80% methyl Cellosolve (starting *p*H 12.28) *pK* inflection points at 11.0 and 5.5 were observed on titration with 0.01 *N* HCl. The neutralization equivalent was within 2% of theory.

Hydrochloride.—The addition of HCl gas to a chloroform solution of the hydroperoxide yielded tufts of needles, sintering and partial melting 180–185°, subliming in needles at 210°, melting again at 275–278°. Found: C, 61.76; H, 7.49; N, 7.33. (Calcd. for $C_{19}H_{26}N_2O_2 \cdot HCl \cdot H_2O$: C, 61.95; H, 7.93; N, 7.60.)

Conversion of the Hydroperoxide VI into the Base V.

A. By Sublimation *in Vacuo*.—A small sample of the hydroperoxide was warmed in a molecular still to 180° (0.001 mm.). The crystalline material, washed down from the "cold finger," crystallized from ether in prisms, m.p. 188°, undepressed on admixture with base V, m.p. 188. The picrate was prepared (m.p. 172°) and identified with the picrate of base V by mixed m.p. and analysis.

B. By Rearrangement of the Hydroperoxide in Chloroform.—A solution of 0.5 g. of hydroperoxide VI in 40 cc. of chloroform, containing a few drops of a 4 *N* solution of HCl in ether, was refluxed until the test with potassium iodide-starch paper was negative. This took 50 minutes. From the chloroform solution there crystallized on cooling clear colorless prisms of a hydrochloride, m.p. 285–287° (sublimation 200–240°). Found: C, 65.68; H, 8.71; N, 8.12; Cl, 11.51. Calcd. for $C_{19}H_{26}N_2O \cdot HCl \cdot {}^3/_4H_2O$: C, 65.52; H, 8.25; N, 8.04; Cl, 10.6.

The infrared spectrum of this hydrochloride was practically identical with that of base V (2.73; 3.14; 4.06w; 6.18vs).

The mother liquors were fractionated on a column of 20 g. of alumina using 10-cc. portions of chloroform for elution. Fractions 4 and 5 (24 mg.) were ether-soluble, gave an ether-insoluble hydrochloride and showed the following bands in the infrared; 3.05 (broad); 5.98vs; 6.21s; 5.97vs; 6.01vs; 6.21s; 6.37m; 6.73vs. The ultraviolet spectrum showed only very weak absorption at 310 mμ where *o*-acylaminophenones absorb. A later fraction 13 (5 mg.) showed the following infrared bands: 3.10 (broad); 5.73s; 6.18s; 6.34s.

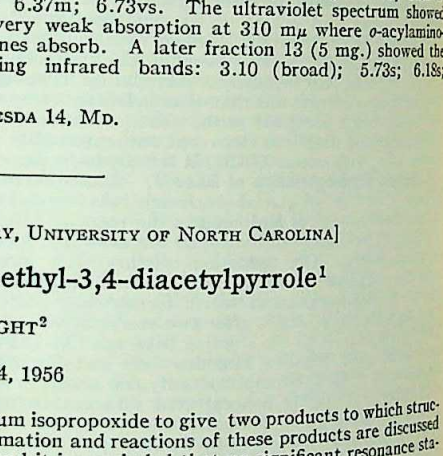
The Self-condensation of 1,2,5-Trimethyl-3,4-diacetylpyrrole[1]

BY D. BRUCE BRIGHT[2]

RECEIVED NOVEMBER 24, 1956

1,2,5-Trimethyl-3,4-diacetylpyrrole condenses in the presence of sodium isopropoxide to give two products to which structures VIII and IX have been assigned as the most probable. The formation and reactions of these products are discussed in connection with the possible aromaticity of the pentalene system, and it is concluded that no significant resonance stability of the pentalene type is present in an apparently favorable case.

With the exception of a few dibenzo-derivatives,[3] previous attempted syntheses of the pentalene system[4] (I) have been unsuccessful. The present work is concerned with the attempted synthesis of an azapentalene. This plan was chosen because the nitrogen analog would be expected to have about the same resonance energy as the carbocycle and the fact that suitable starting materials were readily available. The scheme adopted was to start with a suitably substituted pyrrole nucleus and to form the second five-membered ring by a cyclization reaction. The attempted cyclization of 2,5-dimethyl-3,4-diacetylpyrrole (II) with several basic catalysts was unsuccessful, presumably because of the initial formation of the salt from the acidic N–H group rather than an active methyl group.



Such a cyclization would have resulted in the formation of the bicyclic product IV or its enol VI, a hydroxytrimethylazapentalene. To test the feasibility of this type of cyclization, 1,2,5-trimethyl-3,4-diacetylpyrrole (III), in which the N–H group is substituted, was subjected to treatment with sodium isopropoxide in isopropyl alcohol. The expected product (V) was not obtained but instead two isomeric compounds (A and B) whose analyses

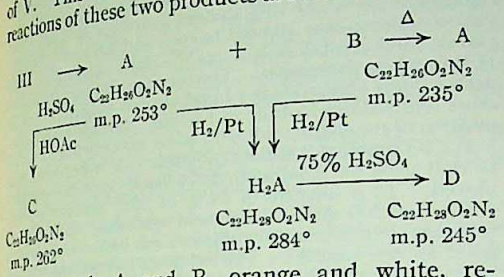
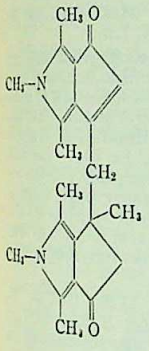
and molecular weights indicated them to be dimers of V. This reaction and some of the subsequent reactions of these two products are shown



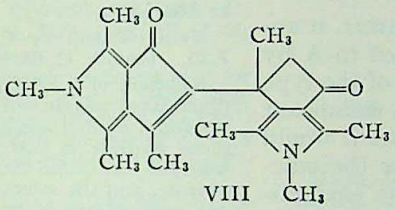
Compounds A and B, orange and white, respectively, could be separated by fractional recrystallization. From a rough separation of A and B from the reaction mixture, it is estimated that A is formed in about 45% yield and B in about 15%. Compound B when heated at its melting point underwent considerable decomposition but was in part converted to its isomer, A. It was observed that A is very sensitive to acids, a fact which hindered the formation of carbonyl derivatives. From the treatment of A with acidic solutions, a light yellow compound (C), isomeric with A and B, was formed in low yield in addition to considerable tar. The hydrogenation of both A and B proceeded readily with platinum oxide catalyst to give the same dihydro-derivative (H_2A). In view of this fact and the marked difference in the ultraviolet spectra of the compounds (see Experimental), it can be concluded that A and B differ only in the position of a double bond. Since compound C is difficult to obtain in a pure state, it proved unfeasible to obtain its hydrogenation product. However, the striking similarity in the ultraviolet spectra of B and C suggests that they have closely related or identical electronic systems. The infrared spectra of both A and B and their derivatives indicated in the above chart all exhibit carbonyl absorption at 5.96–6.01 μ and no absorption in the N–H or O–H regions (see Experimental).

The evidence is fairly conclusive that compound A does not have an acetyl group. The compound is recovered unchanged when treated with sodium hypoiodite while an acetylpyrrole would be expected to undergo the iodoform reaction or suffer replacement of the acetyl group.[5] Furthermore, treatment of H_2A with 75% sulfuric acid, a method for removing acyl and ester groups from a pyrrole nucleus,[6] results only in the isomerization of H_2A to D. The ultraviolet spectra of H_2A and D are essentially identical, suggesting that the conversion may involve only a stereochemical change. The product obtained from the lithium aluminum hydride reduction of A proved to be too unstable to be isolated in a pure state. The attempted oxidation of A with potassium permanganate also was unsuccessful.

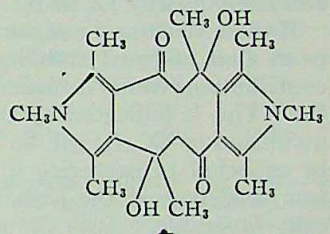
Of the possible structures for A consistent with these data and which might logically be formed from III, the most likely appear to be VII and VIII. Their formation can be visualized as an initial cyclization to form V, followed by a Michael reaction with another molecule of V or the intermediate



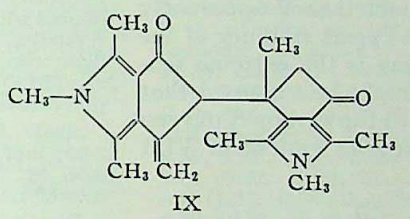
VII



VIII



X



IX

hydroxyketone. An initial intermolecular condensation to form a compound such as X, which might conceivably react further undergoing cyclization and dehydration to form a product with only one double bond outside of the pyrrole rings, appears unlikely since a preparation of A using the dilution technique gave essentially the same results as the normal procedure. Furthermore, the presence of methyl groups in the 1-, 2- and 5-positions of the starting pyrrole (III) would be expected to favor an initial intramolecular condensation.

The experimental facts can be accounted for more readily on the basis of structure VIII rather than VII. Thus if compound A is VIII, B must be IX, since no other position of the double bond is possible. Catalytic hydrogenation of both these structures would be expected to give the same dihydro-derivative with the adjacent substituents on the five-membered ring in a *cis* configuration. The observed isomerization with strong acid may involve conversion to the more stable *trans* isomer. It would be predicted that the dimerization of V *via* a Michael reaction would give VIII (through the intermediate IX) rather than VII, by analogy to the fact that the alkylation of γ-extended enolate ions takes place preferentially in the α-position.[7]

A definite decision between the possible structures VII and VIII for A can be made on the basis of whether or not a methylene group is present in

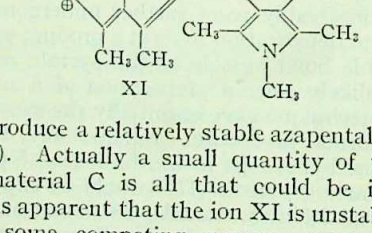
its double bond isomer B. This group would be present in B (IX) if A is correctly formulated as VIII but absent if A is VII. A clear-cut distinction between these two possibilities could not be made by an examination of the infrared spectrum of B. Although the spectrum shows a strong band characteristic of a methylene group[8] (11.47 μ), it is also consistent with a structure containing a trisubstituted ethylene group (the group which would be present in B if A were VII) having an absorption band at 12.06 μ.[8a] However, the presence of a methylene group in B was confirmed readily by ozonolysis of the material, from which formaldehyde was obtained, isolated as its demethone derivative. Thus VII is eliminated as a possibility leaving VIII as the most probable structure for A and consequently IX as B.[9]

If these structural assignments are correct, it appears that no great stability is conferred to A by contributions from resonance structures of the type Va. This is indicated by the fact that significant quantities of IX (B) can be isolated, since it would be expected to isomerize to VIII under the reaction conditions if the isomerization were energetically favorable. Also, the fact that V apparently dimerizes readily indicates no great stability of the system. Especially surprising is the extreme sensitivity of A to acids, as it might be supposed that the attachment of a proton to the carbonyl oxygen of the more unsaturated bicyclic system in VIII



XI

would produce a relatively stable azapentalene cation (XI). Actually a small quantity of the isomeric material C is all that could be isolated. Thus it is apparent that the ion XI is unstable relative to some competing process—presumably a carbonium ion rearrangement. In contrast to this behavior the stability of the more saturated compound D to strong acids should be noted. Thus it appears that these results offer no evidence for the formation of a resonance-stabilized system of the pentalene type in a case which otherwise appears favorable.

(9) The referee has pointed out an apparent inconsistency in the ultraviolet spectra of the products with the proposed structures; namely, that the spectrum of A should exhibit absorption bands at approximately 255 and 310 mμ as found in the spectra of B, C, H_2A and D, since the proposed formulation contains one β-acylpyrrole portion. Two such isolated portions would be present in H_2A and D as formulated. Taking into account the factor of 1/2, the contribution of one acylpyrrole system to the log ϵ values for A is calculated to be 4.11 and 3.64 at 258 and 305 mμ, respectively (using the spectrum of H_2A as a basis). The actual spectrum of A is characterized by lack of fine structure, and the log ϵ values found at these wave lengths are 4.26 and 3.78, respectively. Thus, the spectrum of A is consistent with structure VIII.

Experimental[10]

Attempted Cyclization of 2,5-Dimethyl-3,4-diacetylpyrrole.—One gram of 2,5-dimethyl-3,4-diacetylpyrrole[11] was refluxed in 20 ml. of 10% sodium hydroxide for 1 hr. The yellow solution was allowed to cool, and 0.8 g. of a slightly yellow solid crystallized, m.p. 177–180°; mixed m.p. with II showed no depression. The reaction also was attempted with sodium *t*-butoxide in *t*-butyl alcohol, sodium hydride in ether and sodium hydride in toluene. In each case decomposition of the sodium salt with water gave starting material.

1,2,5-Trimethyl-3,4-diacetylpyrrole.—A procedure similar to that used for 2,5-dimethyl-3,4-diacetylpyrrole[11] was employed. To a mixture of 64 g. of 25% aqueous methylamine and 200 ml. of acetic acid was added 50 g. of *sym*-tetraacetylethane, and the mixture was heated at its boiling point for ten minutes. The red-black solution was allowed to cool and was then basified with an excess of saturated sodium carbonate solution. The solid was removed by filtration and recrystallized from a water–ethanol mixture; yield 29.5 g. (60%)' m.p. 138–140°. A sample purified for analysis by four recrystallizations from dilute ethanol melted at 143–144°.

Anal. Calcd. for $C_{11}H_{15}O_2N$: C, 68.36; H, 7.83; N, 7.25. Found: C, 68.68; H, 7.78; N, 7.18.

Reaction of 1,2,5-Trimethyl-3,4-diacetylpyrrole with Sodium Isopropoxide.—A solution of sodium isopropoxide in isopropyl alcohol was prepared by dissolution of 8 g. of sodium hydride in 800 ml. of isopropyl alcohol. To this solution was added 29.5 g. of 1,2,5-trimethyl-3,4-diacetylpyrrole, and the solution was refluxed for 4 hr. The dark red solution was concentrated at water-pump pressure and diluted with water to precipitate an orange solid. After recrystallization from 95% ethanol, about 11 g. (41%) of a light orange product (A) was obtained, m.p. 247–252° with considerable darkening. A sample was recrystallized four times from 95% ethanol; m.p. 251–253°.

Anal. Calcd. for $C_{22}H_{26}O_2N_2$: C, 75.39; H, 7.48; N, 8.00; mol. wt., 350. Found: C, 75.60; H, 7.49; N, 7.91, mol. wt. (cryoscopic in camphor), 306, (ebullioscopic in chloroform), 362.

From a collection of residues from the recrystallization of different fractions of A, recrystallization from 95% ethanol resulted in the separation of two types of crystals: the small orange crystals (A) described above and also some large light yellow crystals with hexagonal faces. Mechanical separation and repeated recrystallization of the yellow crystals from 95% ethanol with treatment with decolorizing charcoal finally gave a white crystalline product (B), m.p. 231–235°.

Anal. Found: C, 74.98, 74.87; H, 7.68, 7.57; N, 7.73, 7.80.

In another experiment a solution of 10 g. of III in 50 ml. of benzene and 250 ml. of isopropyl alcohol was added dropwise to a refluxing stirred solution of the catalyst over a period of 24 hr. The reaction mixture was neutralized with concentrated hydrochloric acid, the sodium chloride removed and the black solution evaporated to dryness *in vacuo*. A rough separation of the products was effected by extraction of B with small portions of 95% ethanol, crystallization of the extract, concentration and further recrystallization. By this procedure a portion of 6.5 g. of the residue gave 3 g. (46%) of crude A, 1.2 g. (18%) of crude B and a tar-like black material (36%) from which no crystalline substance could be isolated. Compound A did not give a positive 2,4-dinitrophenylhydrazine test but apparently underwent the change caused by the acidic solution (see below). Compound A was recovered unchanged when subjected to the iodoform test.

Conversion of B to A.—Two hundred milligrams of B was heated in a test-tube at approximately 230° for five minutes. During this time the material melted and turned black. After cooling, the contents of the tube was dissolved in hot 95% ethanol and allowed to cool. The small quantity of dark orange solid which separated was recrystallized and shown to be A by the identity of its infrared spectrum with that of another sample of A.

(10) Melting points are corrected. Microanalyses were carried out by Weiler and Strauss Microanalytical Laboratory, Oxford, England, and Micro-Tech Laboratories, Skokie, Ill.

Conversion of A to C.—One gram of A was dissolved in 10 ml. of acetic acid, and 1 ml. of concentrated sulfuric acid was added at room temperature. The solution immediately turned dark green. The temperature was prevented from rising by cooling in an ice-bath. After five minutes of swirling, the mixture was poured into ice-water from which an oil separated which solidified after a few minutes. Four recrystallizations from absolute ethanol and two from 95% ethanol gave a small amount of light yellow crystals, m.p. 258–262° with darkening.

Anal. Calcd. for $C_{22}H_{26}O_2N_2$: C, 75.39; H, 7.48; N, 8.00; mol. wt., 350. Found: C, 75.17; H, 7.50; N, 8.18; mol. wt. (cryoscopic in camphor), 306.

Hydrogenation of A.—A solution of 2 g. of A in 100 ml. of 95% ethanol with 0.2 g. of Adams catalyst was hydrogenated at about three atmospheres pressure at 55° for 4 hr. After removal of the catalyst, the yellow solution was concentrated and cooled to give 0.8 g. of white solid, m.p. 274–278°, and a second crop of 0.3 g., m.p. 265–270°. Combination and recrystallization raised the melting point to 276–284°. An analytical sample melted at 281–284°.

Anal. Calcd. for $C_{22}H_{28}O_2N_2$: C, 74.97; H, 8.01; N, 7.95. Found: C, 74.94, 75.09; H, 7.78, 7.92; N, 7.65, 7.79.

Hydrogenation of B.—Employing the conditions used for A, 430 mg. of B gave 320 mg. of white crystals which after one recrystallization from 95% ethanol melted at 280–284°. The infrared spectrum of this product was identical with that of the hydrogenation product of A; mixed m.p. 280–283°.

Conversion of H_2A to D.—A mixture of 400 mg. of H_2A and 2.7 ml. of 75% sulfuric acid was heated at approximately 100° for 30 minutes. The solution turned dark red during this period. A solid separated when the mixture was poured into ice-water. Two recrystallizations from 95% ethanol gave 140 mg. of white solid, m.p. 240–243°. An analytical sample melted at 241–243°.

Anal. Calcd. for $C_{22}H_{24}O_2N_2$: C, 74.97; H, 8.01; N, 7.95; mol. wt., 352. Found: C, 74.79, 75.03; H, 7.79, 7.89; N, 7.9, 8.25; mol. wt. (cryoscopic in camphor), 310, 303.

Ozonolysis of B.—A solution of 290 mg. of B in about 100 ml. of ethyl acetate was treated with ozone for 30 minutes after which time the absorption of ozone ceased. The solution was evaporated to dryness under reduced pressure to give a yellow oil. The oil was treated with 75 ml. of 10% sulfuric acid, and about 50 ml. of the mixture was collected by distillation. To the distillate was added a solution of 125 mg. of methone in a few cc. of 95% ethanol followed by a few drops of piperidine. After the solution had been allowed to stand, about 140 mg. of solid separated which after one recrystallization from dilute ethanol melted at 187–188°; mixed m.p. with an authentic sample of the dimethone derivative of formaldehyde showed no depression.

Ultraviolet Spectra.—All the spectra were determined in 95% ethanol.

	λmax, mμ	log ε	λmin, mμ	log ε

Analogs of Tetracycline. I. Preparation of 1-(2-Hydroxyphenyl)-3-(2-ketocyclohexyl) Propane-1,3-dione and 1-(2-Hydroxyphenyl)-3-(2-ketocyclohexyl)-3-keto-1-propene

BY EDWARD E. SMISSMAN AND R. BRUCE GABBARD

RECEIVED DECEMBER 3, 1956

A method for the preparation of A and D ring analogs of tetracycline is discussed. This method, the reaction of coumarins with cyclohexanone, gave rise to 1-(2-hydroxyphenyl)-3-(2-ketocyclohexyl)-3-keto-1-propene and 1-(2-hydroxyphenyl)-3-(2-ketocyclohexyl)-propane-1,3-dione. A preparation for ethyl-2,2-ethylenedioxycyclohexane-carboxylate is given.

We have initiated a study of A-D ring analogs of the tetracycline molecule, I. Our interest was directed toward the preparation of a molecule having the same four oxygen functions as are present in position 1, 10, 11 and 12 of the parent compound.

We decided to investigate the possible formation of our desired system by the reaction of the sodio derivative of cyclohexanone, III, and the properly substituted coumarin, II. The reaction between coumarin and sodio-organic compounds other than sodium alkoxides[1] has not been reported.

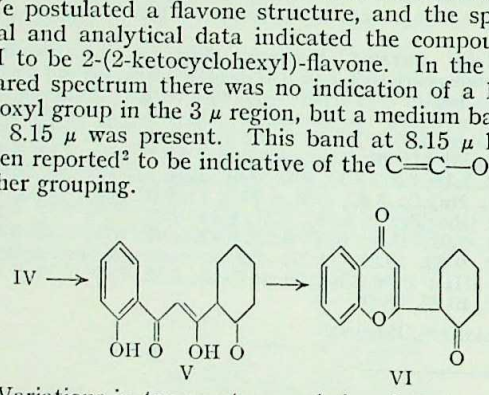
The initial reaction in the series was between coumarin (IIA) and cyclohexanone (III). This reaction was carried out in the presence of sodium ethoxide and gave a 19% yield of 1-(2-hydroxyphenyl)-3-(2-ketocyclohexyl)-3-keto-1-propene (IVA). The reaction was then extended to the use of 4-hydroxycoumarin (IIC), but insolubility of the sodium salt in the reaction solvent prevented it from condensing with the cyclohexanone anion. Logically, we protected the enolic hydroxyl group as the enol ether, and using 4-ethoxycoumarin (IIB), in the reaction with cyclohexanone we obtained 1-(2-hydroxyphenyl)-1-ethoxy-3-keto-3-(2-ketocyclohexyl)-1-propene (IVB). We acidified this product during the workup and the enol ether, IVB, produced 1-(2-hydroxyphenyl)-3-(2-ketocyclohexyl)-propane-1,3-dione (V) in 6% yield. After standing in a 10% aqueous hydrochloric acid solution, V formed a compound VI, which was soluble in 10% sodium hydroxide but not in saturated sodium bicarbonate solution. This compound gave a deep-red color with sulfuric acid. We postulated a flavone structure, and the spectral and analytical data indicated the compound VI to be 2-(2-ketocyclohexyl)-flavone. In the infrared spectrum there was no indication of a hydroxyl group in the 3 μ region, but a medium band at 8.15 μ was present. This band at 8.15 μ has been reported[2] to be indicative of the C=C—O-R ether grouping.



V VI

Variations in temperature and time failed to increase the poor yield of V. We attempted to use sodamide, triphenylmethylsodium and sodium dispersion as catalysts but to no avail.

A second method of preparing the desired compound V was tried. The condensation of 2-hydroxyacetophenone (VII) with ethyl 2,2-ethylenedioxycyclohexanone carboxylate (VIII) would give a product IX, which on acidification should lead to V. The synthesis of ethyl 2,2-ethylenedioxycyclohexanecarboxylate had not been reported, and we were successful in preparing this compound. However, the condensation, using sodium ethoxide as a catalyst, did not take place in amounts great enough to allow us to isolate the desired compound. We did not attempt the condensation using other catalysts.

Experimental

1-(2-Hydroxyphenyl)-3-(2-ketocyclohexyl)-3-keto-1-propene (IVA).—A solution of 6 ml. of absolute ethanol in 100 ml. of dry toluene was placed in a 500-ml. three-necked flask. In the presence of a nitrogen blanket, dispersed sodium[3] was added (CARE!) until the toluene solution turned gray (excess sodium). One to two ml. of absolute ethanol was added to discharge the gray color of the suspension. A solution of 9.8 g. (0.1 mole) of cyclohexanone and 14.6 g. (0.1 mole) of coumarin in 100 ml. of dry toluene was added to the contents of the flask. The stirred suspension, initially yellowish-white in color, immediately changed to dark brown and considerable heat was evolved. The solution was stirred for 4 hr. The mixture was shaken with 200 ml. of water and the non-aqueous layer discarded. The aqueous layer was acidified to *p*H 2 with concd. HCl. The milky suspension was extracted twice with ether and on evaporation the ether extracts gave a dark brown viscous oil. This oil was dissolved in 50 ml. of ethanol and a saturated solution of cupric acetate was added until precipitation was complete. The greenish precipitate of the cupric complex was collected and placed in a separatory funnel containing 100 ml. of H_2O and 50 ml. of ether; 25 ml. of concd. HCl was added. The funnel was shaken occasionally to facilitate the decomposition of the copper complex. The ether layer on evaporation gave a brown viscous oil. The oil was dissolved in saturated sodium bicarbonate solution. On acidification, a solid product, 1-(2-hydroxyphenyl)-3-(2-ketocyclohexyl)-3-keto-1-propene monohydrate, separated. It required three to four repetitions of the procedure of dissolving the original material in sodium bicarbonate and acidifying to convert all of the material to the tan monohydrate; yield 5 g. (19%), m.p. 127° dec.

Anal. Calcd. for $C_{15}H_{16}O_3 \cdot H_2O$: C, 68.75; H, 6.88; neut. equiv., 262. Found: C, 68.80, 69.04; H, 6.49, 6.94; neut. equiv., 259.

4-Ethoxycoumarin (IIB).—The method of Anschütz[4] was followed; 4-hydroxycoumarin was treated with equal molar quantity of sodium ethoxide and then allowed to react with ethyl iodide. From 48.6 g. (0.3 mole) of 4-hydroxycoumarin, 25 g. (44%) of colorless prisms of 4-ethoxycoumarin was obtained, m.p. 136–138° (lit. 136°).

1-(2-Hydroxyphenyl)-3-(2-ketocyclohexyl)-propane-1,3-dione (V).—A solution of 3 ml. of absolute ethanol in 100 ml. of dry xylene was placed in a 500-ml. three-necked flask. The procedure was identical to that described for the preparation of IVA using a solution of 9.5 (0.05 mole) of 4-ethoxycoumarin and 5.3 g. (0.5 mole) of cyclohexanone in 100 ml. of dry xylene. The ether extract of the copper complex decomposition gave 0.80 g. of a brownish yellow oil. One hundred mg. of the compound was treated with a solution of 2,4-dinitrophenylhydrazine as described by Shriner and Fuson.[5] Orange needles were obtained from chloroform–alcohol recrystallization, m.p. 206–208°.

Anal. Calcd. for $C_{27}H_{24}N_8O_{10}$: C, 52.26; H, 3.87. Found: C, 52.20; H, 3.89.

2-(2-Ketocyclohexyl)-flavone (VI).—Two hundred milligrams of 1-(2-hydroxyphenyl)-3-(2-ketocyclohexyl)-propane-1,3-dione was allowed to stand in 50 ml. of 10% HCl. The oil solidified to a yellow amorphous mass within two days. After recrystallization from acetic acid–water, 150 mg. (80%) of a yellowish amorphous powder, m.p. 102–104°, was obtained.

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.06; H, 6.26. Found: C, 73.72; H, 6.40.

Ethyl 2,2-Ethylenedioxycyclohexanecarboxylate (VIII).—A homogenous, clear solution was prepared by mixing 50 ml. of thiophene-free benzene, 50 ml. of ethylene glycol and 100 ml. of 1,4-dioxane. To 125 ml. of this solution was added 17.6 g. (10.1 moles) of ethyl 2-cyclohexanone carboxylate and 20 mg. of *p*-toluenesulfonic acid monohydrate. The flask containing this mixture was connected to a mois-

ture trap and the mixture refluxed until water no longer separated in the trap. The time required was 18 hr. The benzene and dioxane were distilled and the residue was treated with 100 ml. of 1% aqueous sodium hydroxide and the solution extracted twice with 50-ml. portions of ether. The ether was evaporated leaving a liquid which was distilled to give 13 g. (60%) of a colorless material, b.p. 259–261° (atmosphere); 170–174° (14 mm.); $n^{25}D$ 1.4640.

Anal. Calcd. for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47. Found: C, 61.12; H, 8.24.

Polyazobenzenes. III. Infrared Absorption Spectra of Some Polyazobenzenes

BY KEIHEI UENO

RECEIVED DECEMBER 26, 1956

Infrared absorption frequencies from 4000 to 650 cm.$^{-1}$ are reported for seventeen polyazobenzenes including their nitro, amino and hydroxy derivatives. Frequencies are assigned in most cases to bond or group vibrations, and the results are discussed in relation to their structure. Tentative assignment was made for the N=N bond at 1400 and 1455 cm.$^{-1}$.

Introduction

Le Fèvre and his co-workers[1] have investigated some 43 aromatic diazonium and azo compounds and found common absorption bands at around 1406 and 1577 cm.$^{-1}$. However, their result was not conclusive, and more fundamental information on the infrared absorption spectra of aromatic azo compounds is badly needed from both theoretical and practical standpoints. It is the purpose of this investigation to analyze the infrared absorption spectra of polyazobenzenes and their nitro, amino and hydroxy derivatives, as well as polyazostilbenes, which can be considered as model structures of commonly used azo dye molecules. The result of such a study should be of importance in connection with the infrared analysis of azo dyes of more complicated structures.

Experimental

Compounds chosen for this investigation are identical with those which were previously synthesized for our ultraviolet absorption study, and details of their syntheses have been described.[2] Since it was almost impossible to prepare solid samples of stereochemically pure isomers for most of the compounds, the infrared absorption measurements were carried out on samples neglecting their stereochemical purity, although they are believed to consist mainly of *trans* isomers.

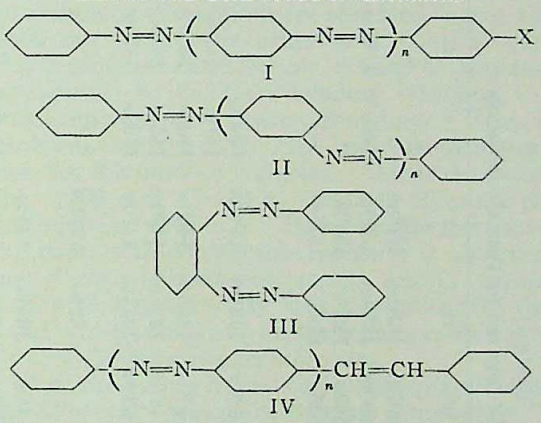
A Perkin-Elmer model 21 double beam spectrophotometer equipped with sodium chloride optics was used for the measurements, and samples were run both as Nujol mulls and as potassium bromide disks. For most of the samples, the Nujol run and the potassium bromide disk run gave almost the same absorption spectra; however, better resolution was observed in the latter technique, and additional bands were found in the region where the Nujol bands overlap.[3]

Result and Discussion

The significant absorption bands observed below 1650 cm.$^{-1}$ are presented in Table II, along with the assignments to the group vibrations wherever possible.

TABLE I

LIST OF THE COMPOUNDS INVESTIGATED



Compound no.	Name of compound	Structural description: Type	n	X
1	Azobenzene	I	0	H
2	4-Phenylazo-azobenzene	I	1	H
3	4,4′-Bis-(phenylazo)-azobenzene	I	2	H
4	4-Hydroxy-azobenzene	I	0	OH
5	4-Hydroxy-4′-phenylazo-azobenzene	I	1	OH
6	4-Phenylazo-4′-(*p*-hydroxyphenylazo)-azobenzene	I	2	OH
7	4-Aminoazobenzene	I	0	NH_2
8	4-Phenylazo-4′-aminoazobenzene	I	1	NH_2
9	4-Phenylazo-4′-(*p*-aminophenylazo)-azobenzene	I	2	NH_2
10	4-Nitroazobenzene	I	0	NO_2
11	4-Phenylazo-4′-nitroazobenzene	I	1	NO_2
12	4-Phenylazo-4′-(*p*-nitrophenylazo)-azobenzene	I	2	NO_2
13	3-Phenylazo-azobenzene	II	1	
14	3,3′-Bis-(phenylazo)-azobenzene	II	2	
15	2-Phenylazo-azobenzene	III		
16	4-Styryl-azobenzene	IV	1	
17	4-Styryl-4′-phenylazo-azobenzene	IV	2	

In general, the absorption patterns of each set of polyazobenzenes are found to be almost identical but become broader and more diffuse when the number of azo linkages increases. The same tendency was reported for the amino acids and the corresponding polypeptides.[4]

(2) K. Ueno, THIS JOURNAL, **74**, 4508 (1952); K. Ueno and S. Akiyoshi, *ibid.*, **76**, 3667 (1954).

(3) Infrared absorption spectra of some of these compounds have been published in the Sadtler Infrared Catalog; however, their spectra were taken by the Baird double beam spectrophotometer of linear wave length on Nujol mull samples. Since our spectra were recorded in linear wave number with potassium bromide technique, more precise investigation was possible, especially in the 3000 and 1600 cm.$^{-1}$ regions.

[a] Compound number refers to Table I.

As would be expected, there are several strong absorptions arising from the phenyl rings, which are indicated in the table. For the *p*-hydroxy, *p*-amino and *p*-nitro compounds, there are additional bands due to these substituents. Of these absorption bands, the hydroxy and the amino groups should give rise to absorptions in the 3300 cm.$^{-1}$ region.

For *p*-hydroxyazobenzene, an O–H stretching absorption band is found at 3140 cm.$^{-1}$ [5]; however, for the corresponding polyazo compounds no well defined absorption band can be observed. The bathochromic shift of this band from the normal position of the 3590–3650 cm.$^{-1}$ region is due to the intermolecular hydrogen bonding as was indicated by Hadzi.[6]

The hydroxy group is also expected to give absorptions at the lower frequency regions which are caused by the O–H bending and C–O–H deformation vibrations. For the compounds investigated, two common absorptions are observed, one at 1378–1380 cm.$^{-1}$ and the other at 1240–1288 cm.$^{-1}$. Hadzi assigned the 1280 cm.$^{-1}$ band of *p*-hydroxyazobenzene to the O–H bending vibration which was confirmed by a deuteration study.[6] Thus it is probable that the 1240–1288 cm.$^{-1}$ band is responsible for this mode of vibration. Hadzi also assigned the 1230 cm.$^{-1}$ band to the C–O–H in-the-plane deformation vibration. However, the corresponding band with comparable intensity is observed in many other polyazo compounds, and it cannot be said with any certainty that the 1230-1212 cm.$^{-1}$ band of *p*-hydroxypolyazobenzene is caused purely by C–O–H deformation vibration.

It is interesting to find three absorption bands in the 3300 cm.$^{-1}$ region for *p*-amino compounds. The frequencies of these bands are listed in Table III.

TABLE III

ABSORPTION BANDS OF *p*-AMINOPOLYAZOBENZENE IN 3300 CM.$^{-1}$ REGION

	Frequencies in cm.$^{-1}$		
	Overtone	$-NH_2$ stretch.	
Monoazo	3220	3400	3510
Disazo	3220	3350	3440
Trisazo	3210	3380	3480
Aniline		3395	3481

The bands are clear in the monoazo compound, but they become broader and more diffuse in polyazo compounds. The primary amine usually gives rise to two absorption bands in this region; for instance, aniline gives absorptions at 3481 and 3395 cm.$^{-1}$ [7a] which are assigned to the N–H stretching modes of vibration. Thus, of the three absorption bands of aminoazo compounds, two corresponding bands at the higher frequency side can be assigned to the N–H stretching vibration. With regard to the remaining band at 3220 cm.$^{-1}$, which is the weakest in intensity of these three bands, one can reasonably explain it as an overtone of the 1620

(5) No corresponding band can be observed for *o*-hydroxyazobenzene, where strong intramolecular hydrogen bonding exists; *cf.* K. Ueno, THIS JOURNAL, **79**, 3066 (1957).

cm.$^{-1}$ band. Since this strong band at 1620 cm.$^{-1}$ is characteristic of the aminoazo compound and since the frequency is in a region where the N–H deformation band of primary amines appears, this band can be assigned to N–H deformation mode of vibration. In this connection, it is noteworthy that the trisazo compound (compound 9) which has the lowest N–H deformation band (1613 cm.$^{-1}$) also has the lowest overtone band at 3210 cm.$^{-1}$. An additional band at the lower frequency region of 1300–1273 cm.$^{-1}$ can likewise be assigned to the C–N stretching vibration of the *p*-amino group.

For the nitro derivatives, two strong bands at 1525 and 1345 cm.$^{-1}$ are observed in addition to the absorption bands of the non-substituted polyazobenzenes, and these two bands are, without doubt, due to the NO_2 group.[7b]

With regard to the absorption bands due to the azo linkage, no conclusive result has been reported, although Le Fèvre and his co-workers assigned two bands near 1406 and 1577 cm.$^{-1}$ to the —N=N— linkage.[1] The main difficulty is that the azo absorptions are expected to appear in the double bond region, so that they may well be merged with the stronger aromatic ring absorptions. For the compounds under investigation, two common absorption bands at around 1455 and 1400 cm.$^{-1}$ are observed. The former band probably was overlooked by Le Fèvre, because the region is overlapped by a Nujol band. Although it is not clear which band is responsible for which mode of vibration of —N=N— bonding, these two bands can tentatively be assigned to the azo linkage.

Azo compounds are also expected to give rise to other bands at lower frequency regions, which originate in the C—N= linkage. The assignments for these bands in the literature are rather confusing, spreading over the range of 900–1325 cm.$^{-1}$.[8]

(8) H. W. Thompson, *J. Chem. Soc.*, 328 (1948); N. V. Colthup, *J. Opt. Soc. Amer.*, **40**, 397 (1950); W. West and R. B. Killingsworth, *J. Chem. Phys.*, **6**, 1 (1938); S. Imanishi and Y. Kanda, *J. Sci. Res. Inst. Tokyo*, **43**, 17 (1949); H. Stammreich, *Experientia*, **6**, 225 (1950); W. J. C. Thomas, *Chemistry & Industry*, **23**, 567 (1953).

However, according to Le Fèvre, three bands of aromatic azo compounds in the regions of 900, 1150 and 1300 cm.$^{-1}$ were assigned to the C–N linkage. For the polyazobenzenes under investigation, three bands at 920, 1140 and 1300 cm.$^{-1}$ regions correspond to those assigned by Le Fèvre, and these three bands are tentatively assigned to the —C—N= linkage.

As was reported in the previous papers,[2] the frequencies of absorption maxima in the ultraviolet region were related to the number of azo linkages and with the relative position of azo linkages against the phenyl ring. However, there is no simple relationship between the infrared absorption frequencies of the —N=N— or —C—N= linkage and the number of azo groups. Although some differences in the double bond region of the infrared spectra of *p*-, *m*- and *o*-polyazobenzenes were observed, no clear-cut rule was found for these absorption spectra.

For the polyazostilbenes, the steric configuration of the C=C bond is understood to be *trans*,[2,9] so that the C=C stretching absorption would be too weak to be observed, and moreover it may well overlap with the aromatic ring vibrations. Thus, the only characteristic absorptions of these compounds are to be observed in the —CH=CH— deformation region, and the C–H out-of-plane deformation vibration is expected to appear in a region of 970–960 cm.$^{-1}$.[7c] The observed band of the polyazostilbenes at 960–962 cm.$^{-1}$ can accordingly be assigned to this mode of vibration.

Acknowledgment.—The author is grateful to Prof. A. E. Martell of Clark University for the use of the facilities for measuring the infrared absorption spectra. He is also grateful to Prof. S. Akiyoshi of Kyushu University, Fukuoka, for his inspiring discussion during the course of this investigation.

Interactions of Homologs of Carcinogenic Azo Dyes and Proteins[1-3]

BY R. K. BURKHARD, ROGER BAUER AND R. M. GROSSMAN

RECEIVED JANUARY 19, 1957

The interactions of 4-aminoazobenzene, 3′-methyl-4-aminoazobenzene, 4′-methyl-4-aminoazobenzene with bovine serum albumin and the proteins contained in rat liver extracts have been studied by the equilibrium dialysis technique at 0° and *p*H 6.8. The interaction between methyl orange and bovine serum albumin was repeated as a reference interaction. The data suggest the following order among the quantities of these dyes bound to bovine serum albumin: 3′-methyl-4-aminoazobenzene (greatest), 4′-methyl-4-aminoazobenzene, 4-aminoazobenzene, methyl orange (least). However, only in certain cases were the differences between these quantities found to be statistically significant at the 5% level. The data also suggest that the interaction of 4′-methyl-4-aminoazobenzene with bovine serum albumin is less temperature dependent than the interactions involving the other two uncharged dyes and this protein. The methylated aminoazobenzenes bind to the proteins in the rat liver extracts in larger quantities than aminoazobenzene and these quantities are about one third to one half as large as those observed with bovine serum albumin when both sets of data are expressed in terms of moles of dye bound per milligram of nitrogen.

It has been suggested that in the interaction of an uncharged azo dye such as 4-aminoazobenzene with bovine serum albumin cationic sites from the lysine residues and phenolic hydroxyl groups from the tyrosine residues in the protein engage in hydrogen bonding to the amino group of the dye.[4] Subsequent to this report it was found that the differences observed in the interactions of 4-aminoazobenzene, 3′-methyl-4-aminoazobenzene and 4′-methyl-4-aminoazobenzene with bovine serum albumin at 25° could not be accounted for solely by differences in basicities of the three dyes and it was suggested that factors other than basicity could be of major importance in interactions of this type.[5] In order to gain further insight into the nature of these protein–dye interactions it was thought desirable to study their temperature dependences for which the temperature of 0° was selected for additional studies. Along with these studies it was also thought desirable to repeat earlier studies involving the interactions between the proteins in rat liver extracts and azo dyes at 0°[6] and thus establish a firmer foundation for further studies involving the interactions of rat liver proteins and dyes. This paper reports the results obtained from these two lines of investigation.

Experimental

Sources of Dyes and Proteins.—The dyes used in these studies were prepared as previously outlined.[5] The serum protein was Crystallized Bovine Plasma Albumin (referred to as bovine serum albumin in this paper) as obtained from the Armour Laboratories. The albumin was dried over P_2O_5 *in vacuo* prior to its use. The rat liver extracts were prepared by the extraction of a dried blood-free rat liver homogenate with phosphate buffer near 0°. The livers used in this preparation were obtained by the *in situ* perfusion of these organs with cold 0.89% saline during anesthesia followed by extirpation and quick freezing. These livers were then pooled, homogenized near 0° in a Waring Blendor, dialyzed near 0° against distilled water until the resistance of the dialyzate matched that of the distilled water and the resultant material lyophilized. This dried homogenate was then examined for the presence of carbohydrates, blood and lipids. The di-*o*-anisidine test was used to test for carbohydrates[7]; the benzidine test (after a short period of boiling) was used to test for blood[8]; exhaustive extraction with chloroform by use of a Soxhlet extractor followed by gravimetric determination of the chloroform soluble material was used to test for lipids. These tests indicated that carbohydrates, blood and lipids were not present in detectable quantities in this rat liver homogenate. The quantity of nitrogen in each extract prepared from this homogenate was determined by the micro-Kjeldahl method of Stover and Sandin[9] using the mixed indicator of Sobel, *et al.*[10] Crushed ice-water baths were used to maintain the desired temperature during the preparation of the homogenate and extracts.

Interactions.—The equilibrium dialysis technique as developed by Klotz and his co-workers was used for these studies.[11] The fact that the optical densities of solutions containing dyes and rat liver extracts did not change over a 24-hour period was considered as evidence that the dyes were not undergoing metabolic changes during this period and that differences in optical densities observed during equilibrium dialysis studies were due to protein–dye interactions. All spectral data were obtained by use of a Beckman model DU spectrophotometer. A crushed ice-water bath was used to maintain the temperature for the equilibrium dialysis experiments. The dye solutions used varied in concentration from approximately 3×10^{-6} to 10×10^{-6} moles per liter. The protein solutions involving serum albumin were 0.2% by weight. The rat liver extracts contained approximately 0.1 mg. of nitrogen per ml. The exact nitrogen content of each extract was determined and was taken into consideration when computations were made. All interactions and extractions made use of a phosphate buffer (*p*H 6.8) which contained 0.055 mole of Na_2HPO_4 and 0.044 mole of KH_2PO_4 per liter of solution.

Treatment of Data.[12]—The data obtained from studies involving bovine serum albumin were converted into values for $1/r$ (the reciprocal of the moles of dye bound per mole of protein) and $1/A$ (the reciprocal of the free dye concentration). The method of least squares was then used to calculate the intercepts and slopes for the equations having the form[13]

$$\frac{1}{r} = \frac{1}{n} + \frac{1}{nkA}$$

The correlation coefficients for these lines were then calcu-

lated to establish the validity of such treatment. The data were also converted into values of r/A and the method of least squares again used to calculate the intercepts and slopes for the equations having the form[14]

$$r/A = nk - kr$$

Correlation coefficients were then calculated for the lines obtained from these plots but it was found in all cases that much higher correlation coefficients were obtained by the first method of analysis. The reason for this was probably due to the fact that when the Klotz type of plot was used each set of experimental points was almost equally spaced along the abscissa but when the Scatchard type of plot was used each set of experimental points formed a cluster. Since statistical analysis of the data ultimately was used it was felt that the precision of any calculated value could still be represented adequately even though the Klotz type of plot was used. Thus all values reported in this paper regarding bovine serum albumin were obtained by the method introduced by Klotz.[13] Estimated values for $1/r$ and the corresponding 95% confidence intervals were then calculated at selected values for $1/A$. The t-test was then used to determine the significance of the differences between these values and between the slopes of the least squares lines. The 5% probability level was used as the criterion for significance in all such comparisons. Thermodynamic quantities were then calculated from the slopes of the least squares lines obtained at 0° and 25°.[5] In the case of the free energy data calculations also were made from the 95% confidence limits to indicate the precision of each calculation but this treatment was not extended to the enthalpy and entropy calculations.

Results and Discussion

The values for $1/n$, $1/nk$ and the correlation coefficients associated with each least squares line involving bovine serum albumin interactions are listed in Table I. Estimated values for $1/r$ and the corresponding 95% confidence intervals are listed in Table II. From these data it was concluded that in the majority of the cases an excellent linear relationship existed between $1/r$ and $1/A$. Even though the correlation coefficient associated with 4′-methyl-4-aminoazobenzene was small it still indicated a linear relationship did exist between $1/r$ and $1/A$. Statistical analysis of the data revealed that over the common free dye concentration range 3′-methyl-4-aminoazobenzene was bound in significantly larger quantities than 4-aminoazobenzene, however, in the case of 3′-methyl-4-aminoazobenzene and its 4′-isomer only at concentrations less than 6×10^{-6} mole per liter were significantly larger quantities of the 3′-substituted dye bound. It was also found that over the common range examined no significant differences were found in the amounts of binding of 4′-methyl-4-aminoazobenzene and 4-aminoazobenzene. These results again suggest[5] that factors other than basicity are of major importance in determining the abilities of these uncharged dyes to complex to bovine serum albumin.

It has been reported that 4-aminoazobenzene binds to bovine serum albumin in somewhat smaller quantities than methyl orange at *p*H 6.9 and 25°.[4]

TABLE I

VALUES FOR $1/n$, $1/nk$ AND CORRELATION COEFFICIENTS ASSOCIATED WITH LEAST SQUARES LINES (0°) AND THE THERMODYNAMIC FUNCTIONS FOR THE BINDING OF THE FIRST DYE MOLECULE OR ION TO BOVINE SERUM ALBUMIN

Dye[a]	No. of detn.	$1/n$	$1/nk \times 10^5$	Cor. coeff.	$-\Delta F_1°$ (0°) (kcal./mole) From slope	$-\Delta F_1°$ (0°) (kcal./mole) From 95% limits	$-\Delta F_1°$ (25°)[b] (kcal./mole) From slope	$-\Delta F_1°$ (25°)[b] (kcal./mole) From 95% limits	$-\Delta H_1°$ (kcal./mole)	$\Delta S_1°$ (cal./mole/deg.)
AB	10	0.050	14.9	0.99	6.03	5.97–6.10	6.30[c]	6.19–6.44	3.3[c]	11[c]
3′-Me-AB	11	.432	8.87	.99	6.31	6.30–6.32	6.47	6.38–6.57	4.6	6
4′-Me-AB	9	− .0856	13.8	.85	6.07	5.87–6.55	6.44	6.34–6.56	2.0	15
MO	10	− .183	17.3	.94	5.95[d]	5.80–6.16	..	.....	..	..

[a] Abbreviations: AB, (4-aminoazobenzene); 3′-Me-AB, (3′-methyl-4-aminoazobenzene); 4′-Me-AB, (4′-methyl-4-aminoazobenzene; MO, (methyl orange). [b] The 25° values were obtained from data of Burkhard and Moore.[5] [c] Literature values for these thermodynamic functions are −6150 cal./mole for the free energy change at *p*H 6.9, −3700 cal./mole and 11 cal./mole/deg. for the enthalpy and entropy changes, respectively, at *p*H 9.2.[4] [d] Literature value for this free energy change is −6049 cal./mole.[17]

The data obtained from studies involving the rat liver extracts were converted into units of the percentage of total dye bound per milligram of nitrogen in the extract. These rather unusual units were used in reporting these data since it was felt that a preparation such as this type of rat liver extract was too heterogeneous to allow a rigorous analysis of the data. Correlation coefficients relating these percentages to the total dye concentrations were calculated and it was found that over the concentration range studied these percentages were independent of the total dye concentration. Thus these percentages were merely averaged and the arithmetic means and standard deviations reported. The F-test was used to determine whether significant differences existed among these means. The t-test was then used to locate wherein these differences lay. The 5% probability level was again used as the criterion for significance in these comparisons. For the purpose of comparing these data to the data associated with bovine serum albumin certain of both sets of data were selected and converted into units of moles of dye bound per milligram of nitrogen. To achieve this conversion the value of 16.07[15] was used for the percentage of nitrogen in bovine serum albumin.

Burgert also has studied these interactions at 25° but at *p*H 7.3.[16] He obtained the same results that Klotz and Ayers did in that at a free dye concentration of 1×10^{-5} mole per liter, for example, the amount of methyl orange bound to the protein was 0.40 mole per mole of protein and with 4-aminoazobenzene the amount was 0.35. Thus while there appears to be greater binding of methyl orange at 25° it does not appear to be true at 0° and *p*H 6.8. The data in Table II even suggest that methyl orange is bound in smaller quantities than 4-aminoazobenzene but statistical analysis of these data revealed that the differences between these amounts were not significant. Comparison of methyl orange to 3′-methyl-4-aminoazobenzene, however, revealed that over the entire common range the unchanged dye was bound in larger quantities, but in the case of 4′-methyl-4-aminoazobenzene *versus* methyl orange the uncharged dye was bound in significantly larger quantities only at concentrations lower than 6×10^{-6} mole per liter.

Comparison of these results with those obtained

TABLE II

ESTIMATED VALUES AND 95% CONFIDENCE INTERVALS FOR $1/r$ AT GIVEN VALUES OF $1/A$ FOR BINDING OF DYES TO BOVINE SERUM ALBUMIN

$1/A$ (L/mole $\times 10^{-5}$)	Dye[a]	$1/r$	95% Confidence interval
1.67	AB	2.54	2.30–2.78
	3′-Me-AB	1.91	1.88–1.94
	4′-Me-AB	2.26	1.58–2.94
	MO	2.71	2.41–3.01
2.00	AB	3.03	2.80–3.26
	3′-Me-AB	2.20	2.17–2.23
	4′-Me-AB	2.70	2.20–3.20
	MO	3.28	3.00–3.56
2.50	AB	3.77	3.35–4.19
	3′-Me-AB	2.65	2.60–2.70
	4′-Me-AB	3.33	2.94–3.72
	MO	4.14	3.69–4.59
2.86[b]	3′-Me-AB	2.97	2.94–3.00
	4′-Me-AB	3.80	3.31–4.29

[a] Abbreviations: same as in Table I. [b] Values for AB and MO systems are not listed at 2.86×10^5 due to the fact that observations involving these dyes did not extend to this concentration.

at 25°[5] reveals an inverse relationship between temperature and extent of interaction for the uncharged dyes. However, this temperature dependence must not be identical in all cases since at 25° it was found that at most of the concentrations examined 3′-methyl and 4′-methyl-4-aminoazobenzene were not bound in significantly different quantities but both were bound in significantly larger amounts than 4-aminoazobenzene while at 0° 3′-methyl-4-aminoazobenzene was bound in significantly greater quantities at most concentrations examined than both 4′-methyl-4-aminoazobenzene and 4-aminoazobenzene and that these latter two dyes were not bound in significantly different quantities. If the natures of the interactions of 4-aminoazobenzene and 3′-methyl-4-aminoazobenzene with bovine serum albumin are such that the equilibrium constants associated with these two are more temperature dependent than that involving 4′-methyl-4-aminoazobenzene then one can qualitatively account for these observations. That this might be the case is suggested by the thermodynamic functions listed below.

In order to evaluate the thermodynamic functions for these interactions it was first thought desirable to calculate the correlation coefficients for the 25° data previously reported.[5] These coefficients were found to be 0.94, 0.96 and 0.94 for 4-aminoazobenzene, 3′-methyl-4-aminoazobenzene and 4′-methyl-4-aminoazobenzene, respectively. Thus from the previously and currently reported $1/nk$ values the thermodynamic functions associated with these interactions were calculated.

TABLE III

AMOUNTS OF DYE BOUND TO PROTEINS IN RAT LIVER EXTRACT AND THEIR COMPARISONS TO AMOUNTS BOUND TO BOVINE SERUM ALBUMIN (0°, *p*H 6.8)

Dye[a]	No. of detn.	Mean % of total dye bound per mg. N in RLE[a]	Stand. dev.	Binding expressed as moles of dye bound per mg. N $\times 10^5$ at total dye concn. of 5×10^{-6}, mole/l. RLE	BSA[a,b]
AB	19	18	6	1.1	2.98
3′-Me-AB	15	28	4	1.9	4.09
4′-Me-AB	18	26	8	1.8	3.35

[a] Abbreviations: same as Table I for the dyes; RLE (rat liver extract); BSA (bovine serum albumin). [b] These values were obtained from the data used to prepare Tables I and II.

It was stated previously that there was not a significant difference between the slopes of the lines derived from data involving the methylated uncharged dyes at 25°.[5] Further calculations involving 4-aminoazobenzene revealed, however, that the slope of this line was significantly different from that involving 3′-methyl-4-aminoazobenzene (t = 2.27, D.F. = 27) but not different from the slope of the line involving 4′-methyl-4-aminoazobenzene (t = 1.64, D.F. = 33).[12] Calculations involving the slopes obtained at 0° revealed that these relationships held also at the lower temperature. The slope of the line involving methyl orange was found to differ significantly only from that observed with 3′-methyl-4-aminoazobenzene (t = 4.24, D.F. = 17).

The thermodynamic functions associated with the binding of each first dye molecule or ion are shown in Table I. It should be noted that the free energy changes include values calculated from the 95% confidence limits of the various slopes while the enthalpy and entropy changes do not. Comparison of these values with previously reported ones shows favorable agreement.[4,17] They, however, do not allow one to evaluate with certainty the importance of the various factors which might be involved in the binding of such dyes to bovine serum albumin. Further experimentation is now in progress in this Laboratory in an attempt to correlate the structure of uncharged dyes with their ability to form complexes with proteins.

The correlation coefficients for the dependence of the percentage of total dye bound per milligram of nitrogen on total dye concentration in the case of the rat liver extracts were found to be 0.09 (D.F. = 17) for 4-aminoazobenzene, −0.22 (D.F. = 15) for 3′-methyl-4-aminoazobenzene, and 0.30 (D.F. = 18) for 4′-methyl-4-aminoazobenzene.[12] From these it was concluded that the percentage of total dye bound was independent of the total dye present and thus these percentages could be averaged for each system and the mean percentages reported. These values and the standard deviations are listed in Table III.

Analysis of variance revealed that these means were not all the same (F = 10, D.F.$_1$ = 2, D.F.$_2$ = 49). Further analysis revealed that there was not a significant difference between the means for the methylated compounds but that there were significant differences between the means for the methylated compounds and aminoazobenzene (for example, t = 3.31, D.F. = 35 for 4′-methyl-4-aminoazobenzene *vs.* 4-aminoazobenzene).[12] These results agree with those obtained earlier by Grossman[6] and also suggest that factors other than basicity are of major importance in determining the extents of interaction of these three uncharged dyes with the proteins in these rat liver extracts.

The amounts of these uncharged dyes bound to both bovine serum albumin and the proteins in the

rat liver extracts at a free dye concentration of 5×10^{-6} mole per liter are also listed in Table III. It will be noted that at this particular free dye concentration and in terms of the units used the amount of any one dye bound to the proteins in the rat liver extracts is approximately one third to one half of the amount bound to bovine serum albumin. This observation may be of some significance since it has been found by other investigators that neutral dye molecules do not bind to bovine γ-globulin or pepsin.[4] The composition of these rat liver extracts is currently unknown, but an attempt is being made in this laboratory to isolate and characterize the protein or proteins involved in the formation of these complexes with uncharged dyes.

Acknowledgment.—The authors are indebted to Dr. Holly C. Fryer, Statistical Laboratory, Kansas State College, for advice regarding the statistical analysis of the observed data.

Studies in Steroid Total Synthesis. V. Abnormal Cleavage of Some Tricyclic Ketone Epoxides

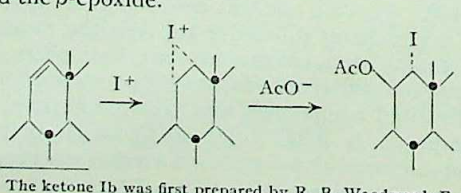
BY WILLIAM S. KNOWLES AND QUENTIN E. THOMPSON

RECEIVED JANUARY 17, 1957

Reductive cleavage of the 5β,6β-epoxide function of the tricyclic ketone IIIa does not give the axial 5β-ol (IIc) predicted by conformational theory but gives the equatorial 6β-ol (IId). Both IIIa and the isomeric 5α,6α-epoxide IIIb are opened abnormally by methoxide and thiophenoxide anions giving products to which we have assigned structure VIIIa,b,c and IXa,b.

In the course of work designed to prepare ring B,C,D-tricyclic intermediates containing a potential C-11 oxygen, the chemistry of the isomeric 5,6-oxides derived from *dl-anti-trans*-1,6a,7,7a,10a,-11,11a,11b - octahydro - 4,6a,9,9 - tetramethylphenanthro[2,3][1,3]dioxol-3(2H)-one (Ic) was investigated. The course of the reactions in most cases was found to be extremely unpredictable. Abnormal cleavage by methoxide and thiophenoxide anions and the abnormal reductive cleavage of the β-oxide form the subject of the present paper.

The readily available tricyclic ketone Ic[1] served as the starting point for the preparation of both oxides. Reaction of Ic with approximately one mole of silver acetate and iodine in glacial acetic acid gave the 5β-acetoxy-6α-iodoketone IIa which upon treatment with aqueous base gave the 5β,-6β-epoxide IIIa, m.p. 200–201°.[2] The isomeric 5α,6α-epoxide IIIb, m.p. 214–217°, readily was obtained by treatment of Ic with perbenzoic or monoperphthalic acids. Configurational assignments were made assuming backside attack by peracids would give the α-epoxide, whereas silver acetate–iodine treatment would result in an initial α-oriented attack by I^+ followed by opening with acetate ion to form the 5β-acetoxy-6α-iodo configuration assigned. Base treatment would then yield the β-epoxide.



(1) The ketone Ib was first prepared by R. B. Woodward, F. Sondheimer, D. Taub, K. Heusler and W. M. McLamore (THIS JOURNAL, **74**, 4223 (1952)) as the minor β-*cis*-glycol resulting from osmium tetroxide oxidation of the unsaturated ketone Ia. Subsequently, Woodward and Brutcher (private communication) prepared the same glycol (m.p. 181–182°) by silver acetate–iodine oxidation of Ia.

(2) Compounds IIa and IIIa were first prepared at Harvard by F. V. Brutcher and R. B. Woodward and were disclosed to us by private communication.

Catalytic reduction of the α-epoxide IIIb yielded the 6α-alcohol IIb. As expected for an axial hydroxyl located vinylogously beta to a carbonyl group, mild treatment with base caused elimination of water and formation of the dienone Ic. Several attempts to reduce the isomeric epoxide IIIa catalytically did not give clear results. Reduction with zinc and acetic acid proceeded smoothly to yield a new alcohol, m.p. 187–188°, λ_{max}^{alc} 250, ϵ 15,380. If the reduction had occurred in a normal manner, IIc would be the expected structure for the product. However, ready acetylation at room temperature with pyridine and acetic anhydride indicated the presence of an equatorial hydroxyl function.[3] Attempts to oxidize the alcohol with manganese dioxide[4a,b] or chromic anhydride in pyridine[5] yielded chiefly starting material, again indicative of a non-allylic equatorial hydroxy group.

The rearrangement of Δ^4-cholestenone-6-ol systems to the corresponding 3,6-diones under alkaline conditions has been well established.[6a,b,c] Moreover, it has been shown both in the Δ^4-3-one-6-ol[6b] system and the Δ^8-11-α-ol-7-one[7] system that it is significantly easier to effect rearrangement when the hydroxyl group is axial than when it is equatorial. The axial alcohol represented by

(3) The isomeric alcohol IIb acetylated incompletely under the same conditions. This somewhat slower acetylation would be expected for an axial hydroxyl at C-6. The analogous C-12 α- and β-alcohols in the bile acid series show similar behavior [B. Koechlin and T. Reichstein, *Helv. Chim. Acta*, **25**, 918 (1942)].

structure IIc thus would be expected to undergo facile conversion to the corresponding saturated diketone IV. All attempts to effect rearrangement failed. When the product was subjected to hot potassium *t*-butoxide treatment,[7] only dehydration occurred giving the dienone Ic. These facts indicated that in all probability the alcohol was not IIc but rather IId, the isomer obtained by abnormal epoxide opening. This result represents an exception to the general rule that in a polycyclic cyclohexane system an epoxide always opens to give the axial alcohol.[8]

Reduction of IIIa with lithium aluminum hydride to the epimeric diols V followed by oxidation with manganese dioxide likewise yielded IId indicating that abnormal epoxide cleavage was not peculiar to the method of reduction.[8a]

Sulfide anions have been shown to be excellent reagents[9] for opening epoxides, and thus it was of interest to see whether they would behave in a normal manner on IIIa. A base-catalyzed reaction of the β-epoxide IIIa with excess thiophenol in *t*-butyl alcohol at room temperature gave a high yield of crystalline adduct, m.p. 140–142°. Infrared and ultraviolet spectra (λ_{max}^{alc} 254, ϵ 15,000) and analyses showed clearly that the material was an α,β-unsaturated ketone containing one hydroxyl group and one phenylthioether group. Normal addition of thiophenol to IIIa would be expected to give a 5β-ol-6α-thiophenyl ether, *i.e.*, IIe. However, desulfurization of the adduct with Raney nickel gave the 6β-alcohol IId, m.p. 187–188°, thus indicating again an abnormal epoxide cleavage. Furthermore, treatment of the adduct for ten minutes with hot alcoholic alkali gave a new compound, $C_{25}H_{30}O_3S$, m.p. 128–129°, which arose from the loss of a mole of water and not a mole of thiophenol as would be expected for a structure IIe. These facts would seem to suggest the adduct had the 5-thiophenol-6β-ol structure IIf and the $C_{25}H_{30}O_2S$ dehydration product was VIa. However, examination of the ultraviolet spectrum of the latter product clearly indicated that it could not be VIa. The observed spectrum showed a single peak at 280 mμ, ϵ 17,500, a figure quite inconsistent with structure VIa since the unsubstituted dienone chromophore of Ic has a peak at 289 mμ, ϵ 25,400. An appreciable bathochromic shift would be expected for dienones substituted as in VIa with an electron-rich thiophenyl group. No specific example of a thioenol ether cross-conjugated with a dienone was found in the literature. However, $\Delta^{4,6}$-cholestadien-3-one absorbs at 284 mμ, ϵ 26,300,[10] while the corresponding 6-ethoxy-$\Delta^{4,6}$-cholestadien-3-one absorbs at 295 mμ, ϵ 16,800.[11] In this case, the ethoxyl group causes an 11 mμ bathochromic shift. The greater bathochromic effect of RS-groups as compared to RO-groups has been shown clearly.[12] Therefore, the hypsochromic shift observed in our dienone thioether, m.p. 128–129°, rules out structure VIa. These conclusions are supported by chemical evidence also. Enol thioethers like their oxygen analogs are acid labile.[13]

Solution of our unknown dienone in a small amount of trifluoroacetic acid followed by trituration with water resulted in the quantitative removal of the acetonide groups without affecting the phenyl thioether linkage.

Desulfurization of the dienone acetonide with Raney nickel in ethyl acetate gave the known ketone IIg thus indicating no rearrangement of the carbon skeleton. The dihydroketone IIg had been previously prepared by catalytic hydrogenation of Ic using palladium-on-strontium carbonate.[14] The reduction of the 5,6-double bond during desulfurization was not unexpected since other work in this Laboratory has shown it to be very easily reduced. Attempts to effect desulfurization while preserving the dienone were not completely successful. Use of deactivated nickel at low temperature in ethyl acetate gave what appeared to be a mixture of Ic and IIg since the ultraviolet spectra showed maxima at 289 and 250 mμ the correct positions for the dienone and its dihydro-derivative, respectively.

It can be concluded from the evidence cited that the dienonethioether has the intact carbon skeleton of Ic, and the point of substitution of the thioether linkage cannot be at positions 3, 4, 4a, 5 or 6.[12] However, other points of substitution which would be expected to satisfy the spectral requirements are positions 2 (VIIa), on the methyl group attached to the 4-position (VIIb) and position 11b (IXa). Reasonable mechanisms can be written for the formation of the sulfide linkage at each of these points. However, in work to be cited below, all but the last have been eliminated. Thus, structure VIIIa has been assigned to the adduct of IIIa with thiophenol and IXa for the dehydrated product.

Reaction of the isomeric epoxide IIIb with thiophenol gave an adduct VIIIb apparently differing from VIIIa only in the configuration of the hydroxyl group since dehydration with base yielded IXa.

Because of the unexpected course of base-catalyzed mercaptan opening, the nucleophilic cleavage with methoxide ion was investigated. Treatment of IIIa at reflux with excess sodium methoxide in methanol gave a complex mixture of methoxy tricyclic ketones. The major product, a methoxydienone, m.p. 108–110°, λ_{max}^{alc} 289 mμ, ϵ 25,200, was obtained in 60–70% yield. Treatment with acid removed the acetonide group without affecting the methoxyl or the ultraviolet spectrum, since the glycol could be converted back to the parent ketone with acetone and copper sulfate. On the basis of these data and the arguments presented below, the ketone and glycol resulting from acid treatment were assigned the structures IXb and Xb, respectively.

In addition to the major product Xb, three other pure compounds were isolated from the reaction mixture. The first minor product was merely the undehydrated precursor to IXb. Thus its structure was VIIIc, and further treatment with methoxide converted it to IXb. The other compounds, m.p. 142–143° and m.p. 152–153°, were isomeric with IXa. The ultraviolet spectrum of the higher melting compound had a single maximum at 304 mμ, ε 15,300, indicating that it was probably VIb, since the observed bathochromic shift of 15 mμ would be expected for this type of substitution on the dienone chromophore.[10] The lower melting isomer had an ultraviolet maximum at 294 mμ, ε 24,000. Because of the limited quantity, the structure of this compound remained unknown.

Cleavage of the α-epoxide IIIb with sodium methoxide gave an even more complex mixture of products from which could be isolated the methoxydienone IXb previously obtained from the β-epoxide. Thus, both the mercaptide and methoxide anions cleaved the α- and β-epoxides IIIa and IIIb in a closely analogous and abnormal manner.

The possibility still remained that the methoxyl and the thiophenyl groups could reside on the C-4 methyl group as far as could be deduced from spectral data. This position was ruled out by running Kuhn–Roth C-methyl determinations which conclusively showed the presence of two C-methyl groups in Xa and Xb. Obviously, only one could be present if the thioether or the methoxyl function were located as in VIIc or VIIb.

In addition, it can be argued that the alkoxyl or the thiophenyl group might occupy the 2-position. This alternative has been excluded by synthesis of VIIa. Treatment of the potassium salt of Ic with phenylsulfenyl chloride gave a low yield of an epimeric mixture of the two phenylthioethers VIIa. Extensive crystallization yielded an apparently pure isomer, m.p. 195–197°, λ_{max}^{alc} 293 mμ, ε 19,800. Alkali caused a shift of the maximum to 287 mμ, ε 22,400. The infrared spectra of the crude epimers VIIa or of the purified isomer in no way resembled IXa. Moreover, the ultraviolet spectrum of IXa was unaffected by base.

Though deduced from evidence of a negative nature, the structural assignments made appear to be the only ones consistent with the known facts. The mechanism of the reaction can be readily rationalized. Under the influence of base, the α,β-unsaturation in the epoxides III is isomerized to some extent to the β,γ-position. Attack by sulfide or methoxide anion then in essence becomes a 1,4-addition to an unsaturated system. Analogous addition to α,β-unsaturated ketones are of course well known. Subsequent abstraction of a proton from the solvent gives the primary adduct shown. Isomerization of the double bond to the α,β-position followed by loss of water would give IXa.

Acknowledgments.—We thank Dr. Bernart Katlafsky and Mr. O. E. Kinast for their help with the numerous spectra required in this work. We also are indebted to Dr. R. B. Woodward for valuable advice and discussion and to Drs. F. C. Meyer and O. J. Weinkauff whose interest and cooperation made this work possible.

Experimental[15]

dl-anti-trans-1,6a,7,7a,10a,11,11a,11b-Octahydro-4,6a,9,9-tetramethylphenanthro[2,3][1,3]dioxol-3(2H)-one (Ic).—To a slurry of 30.9 g. of silver acetate in 350 ml. of glacial acetic acid at 25° was added 18.3 g. of *dl-anti-trans*-4,4a,4b,5,8,8a-hexahydro-1,8a-dimethyl-2(3H)phenanthrone (Ia).[16] The mixture was stirred rapidly and 21.5 g. of iodine was added over a period of 15 minutes. When addition of iodine was complete, 3.0 ml. of water was added. The temperature was raised to 90–95° and held for 3 hr. The reaction mixture was then cooled, filtered and the filter cake washed thoroughly with 100 ml. of chloroform and discarded. The filtrate was dried *in vacuo* with the temperature kept below 85°. The thick residue remaining was dissolved in 500 ml. of methanol and filtered to remove a small amount of solid. Strong aqueous base was added dropwise to the methanol solution until just basic to litmus. A solution of 4.8 g. of potassium hydroxide in 100 ml. of methanol was added, and the dark solution was allowed to stand under nitrogen for 16 hr. at room temperature. Following this, the solution was acidified to test paper with a few ml. of acetic acid. Most of the solvents were then removed under reduced pressure at water-bath temperature. The residue was dissolved in 200 ml. of chloroform and washed with 200 ml. of water in two portions. The chloroform layer was then dried with calcium sulfate and the solvent removed under reduced pressure. When about 90% of the chloroform had been removed, the residue was triturated with 75 ml. of hot ethyl acetate. A copious precipitate of glycol Ib separated. The first crop amounted to 14.9 g., m.p. 180–182°. A second crop, 0.60 g., m.p. 170–180° (74%), was obtained from the mother liquors. The infrared spectrum of this glycol was identical with the minor osmium glycol obtained by Woodward.[1]

The glycol was converted to the acetonide (Ic) by dissolving (both crops) in 1 liter of dry acetone and stirred for 48 hr. with 90 g. of anhydrous copper sulfate. The latter was then removed by filtration and the solvent distilled out. The crude acetonide crystallized from the residue and amounted to 13.7 g., m.p. 152–154°. Second and third crops, 1.9 g., m.p. 147–151°, and 0.35 g., m.p. 138–148°, respectively, were obtained by further concentration of the mother liquors. Recrystallization of first crop acetonide once from acetone gave pure material, m.p. 153–154°, λ_{max}^{alc} 289 mμ, ε 25,400.

Anal. Calcd. for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67. Found: C, 75.18; H, 8.71.

dl-anti-trans-1,5,6,6a,7,7a,10a,11,11a,11b-Decahydro-4,6a,9,9-tetramethylphenanthro[2,3][1,3]dioxole-3(2H)-one (IIg).—One gram of dienone Ic, dissolved in 30 ml. of isopropyl alcohol and treated with 3 drops of 10% aqueous sodium hydroxide solution, was hydrogenated exactly as described for optically active Ia in a previous paper.[17] The yield of crystalline dihydro-ketone was 1.0 g., m.p. 155–158°. One recrystallization from ether gave pure material, m.p. 157–159°, λ_{max}^{alc} 250 mμ, ε 15,400.

Anal. Calcd. for $C_{19}H_{28}O_3$: C, 74.97; H, 9.31. Found: C, 74.51; H, 9.30.

dl-anti-trans-1,5,6,6a,7,7a,10a,11,11a,11b-Decahydro-5β-hydroxy-6α-iodo-4,6a,9,9-tetramethylphenanthro[2,3][1,3]dioxole-3(2H)-one Acetate (IIa).[2]—To a suspension of 15 g. of silver acetate in 270 ml. of glacial acetic acid and 90 ml. of chloroform was added 25 g. of crystalline acetonide Ic. The mixture was then stirred rapidly at 25–30° and 22.1 g. of iodine was added over a period of 15 minutes. Stirring was continued for 1.5 hr. after addition of the iodine. The suspension was filtered and the solid washed thoroughly with 300 ml. of chloroform. The filtrate was then quenched with about 400 ml. of ice-water and the chloroform layer was separated and washed twice with 200 ml. of water, once each with 200 ml. of 5% bicarbonate solution and finally once with water. The organic layer was dried with Drierite and the chloroform was removed under slightly reduced

(15) Melting points are uncorrected. Infrared spectra were run in chloroform on a Perkin–Elmer recording spectrophotometer, model 21. Ultraviolet spectra were run on a Cary recording spectrophotometer, model 11. Analyses were done by Mr. A. Bybell of this Laboratory and by Du Good Chemical Laboratory of St. Louis.

reaction had subsided. After the first 15 min., the temperature dropped and stirring was continued at around 30° for another 3.5 hr. before 120 ml. of chloroform was added and the zinc removed by filtration. The filtrate was washed successively with 100-ml. portions of water (twice), 5% bicarbonate solution and finally water. After drying with Drierite, the chloroform was removed and the residual glass triturated with 10 ml. of ether and 10 ml. of hexane. Crystallization occurred immediately. The first crop of IId amounted to 2.0 g. (70%), m.p. 187–188°. No second crop could be obtained. One recrystallization from ether–acetone gave the analytical sample, m.p. 187–188°, λ_{max}^{alc} 250 mμ, ε 15,400.

Anal. Calcd. for $C_{19}H_{28}O_4$: C, 71.22; H, 8.81. Found: C, 70.93; H, 8.58.

(b) By Reduction to the Epimeric Glycols V, Followed by Oxidation with Manganese Dioxide.—To a slurry of 2.0 g. of lithium aluminum hydride in 50 ml. of anhydrous ether was added 2.4 g. of IIIa dissolved in 15 ml. of dioxane and 50 ml. of ether. After stirring at 25° for 2 hr., the mixture was carefully quenched with 5 ml. of methanol. Approximately 100 ml. of an aqueous saturated sodium chloride solution was added and the heterogeneous mixture was filtered to remove solids. The organic layer in the filtrate was separated, washed once with 50 ml. of saturated salt solution, dried and the solvent removed. The residual oil was boiled with 10 ml. of ether causing crystallization. About 1.5 g. of V, m.p. 177–184°, was obtained as a white powder. The infrared spectrum of this material showed strong hydroxyl and no carbonyl absorption. Examination of the mother liquor from the glycol crystallization showed that it was primarily alcoholic but contained some saturated carbonyl.

Oxidation of V was effected by stirring 100 mg. dissolved in 40 ml. of benzene and acetone (about 25%) for 16 hr. with 1 g. of manganese dioxide. The oxidizing agent was separated by filtration and the solvent removed. Addition of a few drops of ether to the clear oily residue gave 85 mg. of crystals, m.p. 185–186°. One recrystallization from ether and acetone gave crystalline IId, m.p. 187–188°. No depression of melting point was observed when taken with the material obtained in part a.

dl-anti-trans-**1,5,6,6a,7,7a,10a,11,11a,11b-Decahydro-6α-hydroxy-4,6a,9,9-tetramethylphenanthro[2,3][1,3]dioxole-3(2H)-one (IIb).**—A slurry of 0.100 g. of 2% palladium-on-strontium carbonate catalyst in 50 cc. of isopropyl alcohol was prereduced with hydrogen, and then 0.300 g. of IIIb and 0.05 cc., of 10% aqueous NaOH was added. Hydrogenation was continued at 25° and atmospheric pressure until exactly one equivalent was absorbed. The catalyst was filtered and the solvent was evaporated *in vacuo*. The 300 mg. of crude gummy crystals were crystallized from isopropyl alcohol to give 0.152 g. (50%) of material melting at 205–210°. Further crystallization gave an analytical sample, m.p. 208–211°, λ_{max}^{alc} 250 mμ, ε 15,000.

Anal. Calcd. for $C_{19}H_{28}O_4$: C, 71.2; H, 8.81. Found: C, 71.7; H, 9.14.

Dehydration of IIb.—A solution of 0.050 g. of IIb in 1 cc. of *t*-butyl alcohol and 1 ml. of 0.95 *N* potassium *t*-butoxide was allowed to stand at 25° 1 hr. After neutralizing the base with acetic acid, the mixture was poured into water and was extracted with chloroform. The extract was washed with bicarbonate and water and dried. Removal of the solvent *in vacuo* followed by trituration with ether gave crystals, m.p. 153–154°, which showed no depression with authentic Ib.

Dehydration of IId.—An identical procedure with the β-alcohol IId at 25° gave back only starting material. However, at boiling temperatures, Ib was obtained in low yield.

dl-anti-trans-**1,5,6,6a,7,7a,10a,11,11a,11b-Decahydro-6β-hydroxy-4,6a,9,9-tetramethylphenanthro[2,3][1,3]dioxole-3(2H)-one Acetate (IIh).**—A mixture of 160 mg. of IId, 300 mg. of acetic anhydride and 3 ml. of pyridine was allowed to stand at room temperature for 16 hr. Water (5 ml.) was added and crystals began to separate. These were collected and when dry amounted to 100 mg., m.p. 173–175°. Recrystallization from ether–petroleum ether gave pure IIh, m.p. 174–175°, λ_{max}^{alc} 247 mμ, ε 15,350.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.58; H, 8.34. Found: C, 69.55; H, 8.31.

dl-**1,5,6,6a,7,7a,10a,11,11a,11b-Decahydro-6β-hydroxy-4,6a,9,9-tetramethyl-11b-phenylthiophenanthro[2,3][1,3]dioxole-3(2H)-one (VIIIa).**—To a suspension of 396 mg. of IIIa in 5 ml. of *t*-butyl alcohol and 3 ml. of thiophenol was added 1 ml. of 0.9 molar potassium *t*-butoxide solution. The mixture was stirred at room temperature under nitrogen for 4 hr. The difficultly soluble epoxide gradually went into solution during this period. Chloroform (50 ml.) was added and this solution was extracted three times with 50-ml. portions of 1 molar sodium hydroxide solution. The chloroform was then washed once with water and dried with Drierite. Removal of solvent left 535 mg. of oily residue which crystallized upon addition of a few drops of ether. Filtration gave 485 mg. of white crystals, m.p. 109–114°. Melting was accompanied by the evolution of a gas. Recrystallization from ether gave sharp melting prisms, m.p. 110–111°, again accompanied by gas evolution. The melts resolidified and melted again at 140–142°. The infrared spectra of the lower melting material and the 140–142° material indicated that the former was very probably an etherate. Loss of ether accompanied the melting process. The analytical sample was obtained by several recrystallizations from ether followed by a final melting under reduced pressure, m.p. 140–142° (pure), λ_{max}^{alc} 254 mμ, ε 15,000. The infrared spectrum indicated the presence of an hydroxyl group and an α,β-unsaturated ketone function.

Anal. Calcd. for $C_{25}H_{32}O_4S$: C, 70.06; H, 7.53; S, 7.48. Found: C, 69.94; H, 7.51; S, 7.53.

Desulfurization of VIIIa.—Approximately 500 mg. of alcohol-washed Raney nickel was refluxed for 10 minutes with 20 ml. of ethyl acetate and then cooled. To this suspension was added 74 mg. of VIIIa. After stirring for 6 hr. at room temperature, the nickel was removed by filtration and the solvent distilled off. A clear glass (51 mg.) remained which crystallized on addition of a few drops of ether. The crude material, m.p. 172–177°, was recrystallized from ether–acetone yielding white needles, m.p. 185–187°. The infrared spectrum of this material was found to be identical with that of IId. No depression was observed upon taking a mixed melting point.

dl-**1,5,6,6a,7,7a,10a,11,11a,11b-Decahydro-6α-hydroxy-4,6a,9,9-tetramethyl-11b-phenylthiophenanthro[2,3][1,3]dioxole-3(2H)-one (VIIIb).**—The α-epoxide IIIb (309 mg.) was treated with thiophenol exactly as described for the preparation of VIIIa. The yield of crystalline VIIIb, m.p. 215–217°, after trituration with ether was 400 mg. (96%). One recrystallization from ether–chloroform gave pure material, m.p. 216–217°, λ_{max}^{alc} 254 mμ, ε 14,200.

Anal. Calcd. for $C_{25}H_{32}O_4S$: C, 70.06; H, 7.53; S, 7.48. Found: C, 70.12; H, 7.48; S, 7.50.

dl-**1,6a,7,7a,10a,11,11a,11b-Octahydro-4,6a,9,9-tetramethyl-11b-phenylthiophenanthro[2,3][1,3]dioxole-3(2H)-one (IXa).**—A mixture of either VIIIa or VIIIb (1.41 g.) and 5 ml. of 95% ethanol was treated with 10 ml. of 1.2 molar ethanolic potassium hydroxide. After refluxing gently under nitrogen for 10 min., the reaction was cooled and quenched with 40 ml. each of saturated sodium chloride solution and chloroform. The chloroform layer was separated, washed again with salt solution, dried and the solvent removed. The residual oil was dissolved in a few ml. of ether and allowed to crystallize in an ice-bath. The yield of first crop crystalline IXa was 875 mg., m.p. 126–128°, second crop 200 mg., m.p. 118–124°. The analytical sample was prepared by recrystallizing first crop material from a small amount of ether, m.p. 128–129°, λ_{max}^{alc} 280 mμ, ε 17,500. Careful comparison of material obtained starting with either VIIIa or VIIIb failed to show any difference. Both yielded IXa as evidenced by comparison of ultraviolet and infrared spectra and mixed melting points.

Anal. Calcd. for $C_{25}H_{30}O_3S$: C, 73.14; H, 7.37; S, 7.81. Found: C, 72.87; H, 7.46; S, 7.94.

Desulfurization of IXa.—Approximately 1.0 g. of alcohol-washed Raney nickel was added to a solution of 98 mg. of IXa in 20 ml. of acetone. After the mixture had been stirred overnight at room temperature, the nickel was removed by filtration. After evaporation of solvent, the crystalline residue, m.p. 140–150°, amounting to 50 mg. was dissolved in 20 ml. of ether and filtered through a few grams of alumina to remove hydroxylic materials. The clear oil obtained upon removal of ether yielded 35 mg. of material, m.p. 156–158°. Infrared and mixed

m.p. showed this material to be identical with IIg, obtained by hydrogenation of Ic.

dl-4,4a,4b,5,6,7,8,8a-Octahydro-6β,7β-dihydroxy-1,8a-dimethyl-4a-phenylthio-2(3H)-phenanthrone (Xa).—Approximately 350 mg. of IXa was dissolved at room temperature in 2 ml. of glacial trifluoroacetic acid. As soon as the solid had dissolved (5 min.), the mixture was quenched with 15 ml. of saturated sodium chloride solution and 30 ml. of chloroform. The aqueous phase was extracted with another small portion of chloroform and discarded. The chloroform solutions were combined, washed once with salt solution, dried and the solvent removed. The good quality glycol remaining amounted to 271 mg. (86%), m.p. 178–180°. A single recrystallization from ethyl acetate gave pure Xa, m.p. 179–180°, λ_{max}^{alc} 282 mμ, ϵ 15,000, as colorless needles.

Anal. Calcd. for $C_{22}H_{26}O_3S$: C, 71.31; H, 7.07; S, 8.65. Found: C, 71.19; H, 7.05; S, 8.70.

dl-*anti*-*trans*-1,6a,7,7a,10a,11,11a,11b-Octahydro-4,6a,-9,9-tetramethyl-2-phenylthiophenanthro[2,3][1,3]dioxole-3(2H)-one (VIIa).—A suspension of 3.6 meq. of potassium *t*-butoxide in toluene was prepared by adding 3.8 ml. of 0.95 molar potassium *t*-butoxide in *t*-butyl alcohol to 80 ml. of boiling anhydrous toluene. All of the alcohol was fractionated out. The fine suspension of potassium *t*-butoxide at reflux temperature under nitrogen was treated with 1.0 g. of Ic dissolved in 15 ml. of anhydrous toluene. The suspension was then heated and the additional *t*-butyl alcohol formed was distilled out. The potassium salt of the ketone separated as a yellow-white powder. After the alcohol had been removed, the suspension was cooled to −5° and 570 mg. of benzenesulfenyl chloride[19] in 10 ml. of anhydrous toluene was added. A rapid reaction occurred and the heavy suspension was replaced by a fine precipitate of potassium chloride. Water (50 ml.) and ether (50 ml.) were added and the organic layer separated. After washing and drying, the organic solvents were removed under reduced pressure. The residual orange oil which partially crystallized on trituration with ether yielded 600 mg. of impure crystals, m.p. 150–165°. About 200 mg. of diphenyl disulfide was isolated from the mother liquors. Recrystallization of the crude crystalline product 5 times from ethyl acetate and acetone and finally from ethanol gave what appeared to be a pure compound, m.p. 192–194°. Infrared spectra on intermediate fractions had shown the presence of small amounts of saturated carbonyl-containing impurities. The spectrum of the 192–194° material showed only dienone absorption and bands characteristic of an aromatic ring. The ultraviolet spectrum in 95% ethanol showed λ_{max}^{alc} 293 mμ, ϵ 19,800. When this solution was treated with two drops of sodium hydroxide solution, a shift to λ_{max}^{alc} 287 mμ, ϵ 22,400, occurred.

Anal. Calcd. for $C_{25}H_{30}O_3S$: C, 73.14; H, 7.37; S, 7.81. Found: C, 73.18; H, 7.15; S, 7.65.

Reaction of IIIa with Sodium Methoxide.—Four grams of IIIa was refluxed under nitrogen for 4 hr. with 40 ml. of 1.2 molar sodium methoxide in methanol. The greenish-yellow solution was cooled and quenched with 150 ml. of aqueous saturated sodium chloride solution. The oil which separated was extracted with 200 ml. of ether in three portions. The ether extracts were washed with salt solution, dried with Drierite and the solvent removed. The yellow glass remaining amounted to 3.75 g. and partially crystallized on standing. The crude mass was boiled with 100 ml. of petroleum ether (b.p. 60–70°). The hot liquor was decanted from some insoluble residue, treated with a little carbon and concentrated. A yellow oil separated on cooling and slowly crystallized on standing. This crop of material amounted to 1.35 g., m.p. 105–108°. Three recrystallizations from petroleum ether gave a pure sample of the methoxy dienone IXb, m.p. 108–110°, λ_{max}^{alc} 289 mμ, ϵ 25,200. A comparison of the infrared spectrum of this pure ketone with that of the initial reaction product indicated that IXb was present in the crude material roughly to the extent of 70%.

Anal. Calcd. for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49; CH_3O–, 9.34. Found: C, 72.63; H, 8.75; CH_3O–, 9.35.

Mother liquors from preceding crystallizations were combined and concentrated to about 50 ml. This solution was then placed on a column of 100 g. of alumina and eluted with a mixture of hexane (80%) and ether; 23 fractions of 50 ml. each were collected. Fraction 1 contained 150 mg. of a new methoxy ketone, m.p. 149–151° (crude) and m.p. 152–154°, λ_{max}^{alc} 304 mμ, ϵ 15,300, shoulder at 256 mμ, after several recrystallizations from ether. On the basis of its spectra, this material was tentatively identified as VIb, since it was undoubtedly isomeric with IXb.

Anal. Calcd. for $C_{20}H_{28}O_3$: C, 72.26; H, 8.49; CH_3O–, 9.34. Found: C, 72.18; H, 8.46; CH_3O–, 9.49.

Fractions 2, 3 and 4 and the mother liquors from 1 appeared to contain, in addition to IXb and VIb, another unidentified methoxydienone which was indicated by the presence of several extremely distinct diamond-shaped crystals. These fractions, amounting to about 80 mg., were combined and chromatographed separately on 5 g. of alumina using the same ether–hexane eluent as in the previous chromatogram. Eight fractions were collected. The third fraction, 22 mg., appeared to be relatively pure, m.p. 141.5–143°. These crystals were recrystallized twice from ether and hexane giving 8 mg. of a new C_{20}-methoxy dienone, m.p. still 141.5–143°, λ_{max}^{alc} 294 mμ, ϵ 24,000. The infrared spectrum closely resembled that of IXb and VIb in the carbonyl region but showed distinct differences in the fingerprint region. The structure of this material is still unknown. Again, however, it is almost certainly isomeric with IXb and VIb. It was an extremely minor product in the methoxide cleavage reaction, however.

Anal. Calcd. for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49; CH_3O–, 9.34. Found: C, 72.33; H, 8.32; CH_3O–, 9.48.

Still a fourth compound was isolated from the original chromatogram. Fractions 5 to 23 consisted mostly of IXb. The eluent was changed to acetone for fractions 24 to 27. Fraction 24 contained 100 mg. of hard ether-insoluble crystals, m.p. 195–200°, recrystallized from acetone, m.p. 198–202°, λ_{max}^{alc} 250 mμ, ϵ 12,700. The infrared spectrum showed the presence of one hydroxyl group and an α,β-unsaturated ketone. This material was shown to be VIIIc, the undehydrated precursor to IXb, by its conversion to the latter. Seventy-seven milligrams of VIIIc, refluxed for 3 hr. under nitrogen with 5 ml. of 1.1 molar sodium methoxide solution, yielded upon workup (as previously described) 50 mg. of crude IXb. This was cleaned up by filtration through about 700 mg. of alumina and gave 22 mg. of pure IXb, m.p. 108–110°. Comparison of infrared spectra and a mixed m.p. established their identity.

Reaction of α-Epoxide IIIb with Sodium Methoxide.—To 5 ml. of 1.1 molar sodium methoxide–methanol solution was added 260 mg. of IIIb. The mixture was refluxed under nitrogen for 7 hr. and worked up as described for the reaction of IIIa. The oily product, amounting to 248 mg., was dissolved in 2 ml. of ether, cooled to 0° and seeded with a microcrystal of IXb. After standing at 0° for 60 hr., 77 mg. of crystals, m.p. 113–121°, had formed. These were collected, dissolved in benzene and chromatographed on 15 g. of alumina. In all, 45 fractions were collected. Fractions 22 to 31 contained 20 mg. of crystals, m.p. 105–108°. These were combined and recrystallized twice from petroleum ether giving 10 mg. of pure IXb, m.p. 108–110°. The infrared spectrum of this material was identical with IXb obtained by methoxide cleavage of the β-epoxide IIIa. A mixed m.p. showed no depression. Comparison of the infrared spectrum of the crude product obtained and pure IXb indicated that the latter was present in the crude to the extent of about 30–40%. No other pure material was isolated from the very complex reaction product, although infrared spectra on various fractions suggested that VIb also might be present.

dl-4,4a,4b,5,6,7,8,8a-Octahydro-6β,7β-dihydroxy-4a-methoxy-1,4a-dimethyl-2(3H)phenanthrone (Xb).—Treatment of 480 mg. of purified IXb, m.p. 108–110°, with 3 ml. of trifluoroacetic acid exactly as described previously for the preparation of Xa, gave 350 mg. of crude glycol Xb, m.p. 162–165°. Two melting points, m.p. 165–166° (metastable) and 177–178° (stable), were found for the pure glycol upon several recrystallizations from ethyl acetate. When the melt from the 165–166° material was allowed to resolidify, it remelted at the higher temperature. Furthermore, a solution of the lower melting material seeded with the higher melting form crystallized completely as the latter, λ_{max}^{alc} 289 mμ, ϵ 25,800.

The acetonide group was also removed with the same results using aqueous mineral acids and dioxane. A number

C-22 Isomeric Dihydrosapogenins from Kryptogenin

BY IRVING SCHEER, MALCOLM J. THOMPSON AND ERICH MOSETTIG

RECEIVED DECEMBER 29, 1956

In the reduction of kryptogenin in acidic media three compounds have been obtained: dihydrotigogenin and two new sapogenin derivatives. It is shown that the new compounds are isomeric at C-22 and are 22,26-epoxycholestane-3β,16ξ-diol and 22,26-epoxy-22-isocholestane-3β,16ξ-diol. The preparation of cholestane-3β,22,26-triol and cholestane-3β,26-diol-22-one is described. The latter was converted to 22,26-epoxycholestan-3β-ol and 22,26-epoxy-22-isocholestan-3β-ol.

The reduction of kryptogenin (I) yields a variety of products, depending on the experimental conditions employed. Thus, Marker, *et al.*,[1] obtained diosgenin when reducing I with sodium in ethanol, tigogenin (II) and dihydrotigogenin (III) when using platinum oxide in acid media, and dihydrokryptogenin with the same catalyst in a neutral medium. On the other hand, Kaufmann and Rosenkranz[2] obtained "16-dihydrokryptogenin" (XVII) by hydrogenating I in neutral solution with Raney nickel catalyst. In our hands the hydrogenation of kryptogenin (I) with platinum oxide in glacial acetic acid at 25° gave a mixture of at least three compounds which were separated by chromatography on alumina. The main product was dihydrotigogenin (III) and was obtained in a yield of about 80%. The two other products each being formed in an approximate yield of 10% were unknown derivatives.[3] We could show that these new compounds differ only in their configuration at C-22 and have the structures of a 22,26-epoxycholestane-3β,16ξ-diol (IV) and a 22,26-epoxy-22-isocholestane-3β,16ξ-diol (V).[4] The reduction of kryptogenin diacetate under similar conditions yielded only dihydrotigogenin diacetate as previously reported.[1] The infrared spectra of IV and V exhibited strong hydroxyl absorption at 3571 cm.$^{-1}$ (unassociated) and at 3401 cm.$^{-1}$ (associated), no carbonyl absorption, and differed decidedly in the fingerprint region. The bands characteristic for sapogenins were absent, and there was no resemblance to the infrared spectra of dihydrosapogenins. Elemental analysis established for IV and V the empirical formula $C_{27}H_{46}O_3$, *i.e.*, they are isomeric with dihydrotigogenin. Esterification readily gave diesters, indicating that each, IV and V, contained two hydroxyl groups and a third oxygen in an inert ether-like linkage. Oxidation of IV and V with chromic acid led to the diketo-compounds VI and VII, respectively. The strong bands at 1712 and at 1736 cm.$^{-1}$ suggested a 3-ketone and a 16-ketone. Reduction of VI and VII, either catalytic (with PtO_2 in acetic acid) or with sodium borohydride in methanol, gave nearly quantitatively the dialcohols IV and V, respectively, *i.e.*, in either instance only one isomer.

The deoxylation of 22,26-epoxycholestane-3β,16ξ-diol (IV) and 22,26-epoxy-22-isocholestane-3β,16ξ-diol (V) yielded 22,26-epoxycholestane (VIII) and 22,26-epoxy-22-isocholestane (IX), respectively. Compounds VIII and IX contain only two asymmetric centers (C_5 and C_{22}) not found in the original kryptogenin. The remote possibility that these isomers differ at C_5 was eliminated by showing that 5,6-dihydrokryptogenin (XII) was also reduced to III, IV and V.

In order to confirm the structures of VIII and IX, these compounds were also prepared by a different route. Treatment of 5,6-dihydrokryptogenin diacetate (XIII) with ethane dithiol gave a monoethylenethioketal derivative. Infrared analysis showed that it was not the C-22 carbonyl group that had reacted and that XIV was a C_{16}-ethylenethioketal. Desulfurization with freshly prepared Raney nickel in dioxane yielded a mixture from which after hydrolysis and chromatography on alumina cholestane-3β,22,26-triol (XV) and cholestane-3β,26-diol-22-one (XVI) were obtained in an approximate ratio of 6:1. For the routine preparation of XVI the crude mixture from the desulfurization of XIV was oxidized gently with chromic acid to give XVI as the sole product after saponification. Catalytic reduction (PtO_2, acetic acid) of XVI led to a mixture of the triol XV, 22,26-epoxycholestan-3β-ol (X) and 22,26-epoxy-22-isocholestan-3β-ol (XI). By chromatography and fractional crystallization compounds

(1) R. E. Marker, R. B. Wagner, P. R. Ulshafer, E. L. Wittbecker, D. J. P. Goldsmith and C. H. Ruof, THIS JOURNAL, **69**, 2167 (1947).

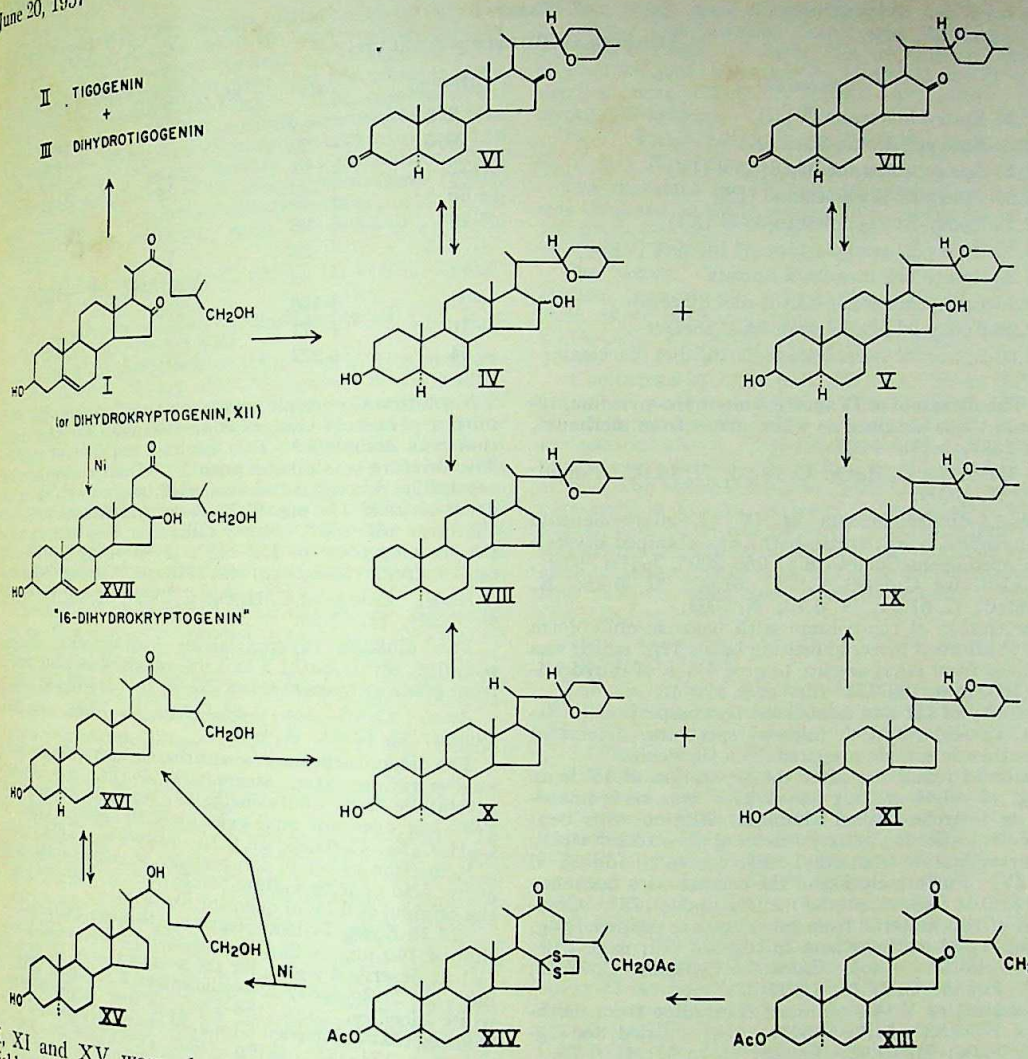
(2) S. Kaufmann and G. Rosenkranz, *ibid.*, **70**, 3502 (1948).

(3) In one instance when for some reason the reduction did not go to completion a small amount of tigogenin (II) could be isolated.

(4) The configuration at C-22 as shown in the structural formulas V and V is arbitrary. The naming of V as an iso compound is provisional.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri



X, XI and XV were obtained in the respective yields of 23, 43 and 15%. Deoxylation of X and XI gave VIII and IX showing that X and XI were the 16-deoxy analogs of IV and V. Reduction of XVI with sodium borohydride in methanol gave the triol XV in excellent yield. Deoxylation of XV gave cholestane.

It should be noted that no definite assignment of configuration at C-16 of IV and V can be made at this time. Hirschmann, *et al.*,[5] had postulated that reduction of a 16-ketosteroid leads to a 16β-hydroxy compound. Hence we were inclined to assign to IV and V the 16β-hydroxy configuration. The $\Delta M_{D^{16\text{-OH}-H}}$ values for IV and V, however, are -72 and $-70°$, respectively (Table I), agreeing fairly well with the average value $\Delta M_{D^{16\alpha\text{-OH}-H}} -60°$ in ethanol which Fukushima, *et al.*,[6] attributed to a 16α-hydroxyl group. Furthermore, these authors have shown that the contribution of a 16α-acetoxy group is about $-300°$ and of a 16β-acetoxy approximately $+100°$. The contribution of the 16-acetoxy group in our 22,26-epoxycholestane derivatives (see acetates of X and IV and of XI and V, respectively) is approximately $+200°$. Even though no configuration can be assigned to the 16-oxygen functions of IV and V on the basis of the anomalous rotational data, the indications are very strong that the configuration is the same in both series.

Experimental[7]

Reduction of Kryptogenin.—A mixture of 10.0 g. of rigorously purified kryptogenin (I, m.p. 192–193°, $[\alpha]^{20}D$ -198 to $-200°$), 1.0 g. of Adams catalyst and 350 ml. of glacial acetic acid was shaken with hydrogen at room temperature and atmospheric pressure for 24 hr. Three molecular equivalents of hydrogen was absorbed. The crystalline residue obtained from the mixture was chromatographed on benzene-washed alumina. The first few fractions eluted with benzene–chloroform 9:1 yielded 5.0 g. of a mixture melting above 175°. This material was fractionally crystallized from ethyl acetate to give 1.0 g. of **22,26-epoxycholestane-3β,16ξ-diol** (IV) as thin, white needles, melting at 265–268°, $[\alpha]^{20}D$ $-22°$.

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.46; H, 11.08. Found: C, 77.59; H, 11.22.

IV was obtained in several polymorphic forms melting at 240–240.5°, 265–268°, 276–277°. Their identity was established by infrared analysis, optical rotation and interconversion of one form to another by seeding and crystalli-

(5) R. Hirschmann, F. B. Hirschmann and M. A. Daub, THIS JOURNAL, **74**, 539 (1952); see also leading references in this paper.

(6) D. K. Fukushima and T. F. Gallagher, *ibid.*, **73**, 196 (1951).

(7) All melting points were determined on the Kofler block. Unless otherwise noted, rotations were determined in approximately 1% solutions in chloroform. Infrared spectra were obtained with a Perkin-Elmer double beam spectrophotometer with sodium chloride prism and cells.

TABLE I

MOLECULAR ROTATION ANALYSIS

Compound	$[\alpha]^{CHCl_3}D$	M_D	ΔM_D M_D 16-OH−H	M_D 22-"normal" − 22-"iso"
22,26-Epoxycholestane (VIII)	− 1.5°	− 6°		
22,26-Epoxycholestan-3β-ol (X)	− 5.5	− 22		−141°
22,26-Epoxycholestane-3β,16ξ-diol (IV)	−22	− 94	− 72°	−115
22,26-Epoxy-22-isocholestane (IX)	+35	+135		−117
22,26-Epoxy-22-isocholestan-3β-ol (XI)	+23	+ 93		
22,26-Epoxy-22-isocholestane-3β,16ξ-diol (V)	+ 5.5	+ 23	− 70	
22,26-Epoxycholestan-3β-ol acetate	−14	− 62	$M_{D16\text{-}OAc-H}$	−133
22,26-Epoxycholestane-3β,16ξ-diol diacetate	+31	+156	+218	
22,26-Epoxy-22-isocholestan-3β-ol acetate	+16	+ 71		−116
22,26-Epoxy-22-isocholestane-3β,16ξ-diol diacetate	+54	+272	+201	

zation. **The diacetate of IV** (acetic anhydride–pyridine, reflux, 30 min.) was obtained as white plates from methanol, m.p. 152–153°, $[\alpha]^{20}D$ +31°.

Anal. Calcd. for $C_{31}H_{50}O_6$: C, 74.06; H, 10.02. Found: C, 74.32; H, 10.09.

The di-3,5-dinitrobenzoate of IV (3,5-dinitrobenzoyl chloride–pyridine, 4 hr., steam-bath) was obtained crystalline from acetone–methanol, m.p. 268–269°, $[\alpha]^{20}D$ +19°. *Anal.* Calcd. for $C_{41}H_{50}O_{13}N_4$: C, 61.02; H, 6.25; N, 6.94. Found: C, 61.24; H, 6.13; N, 7.03.

Further elution of the column with benzene–chloroform 9:1 and 1:1 afforded material melting below 175° which was recrystallized from ethyl acetate to give 4.4 g. of **dihydrotigogenin (III)**, m.p. 169–171° (lit.[1] m.p. 170°).

The identity of III was established by comparison (melting point, optical rotation, infrared spectrum, diacetate) with an authentic sample prepared from tigogenin.

The material remaining after the separation of IV from the 5.0 g. of solids melting above 175° was rechromatographed on benzene-washed alumina. Elution with benzene–ether 3:1 afforded material melting above 230° which upon recrystallization from ethyl acetate gave an additional 0.2 g. of **IV**. Further elution of the column with benzene–ether 3:1 and 1:1 gave material melting above 175°. Crystallization of this material from ethyl acetate yielded 1.0 g. of **22,26-epoxy-22-isocholestane-3β,16ξ-diol (V)**, m.p. 212–215°, $[\alpha]^{20}D$ +5.5°. *Anal.* Calcd. for $C_{27}H_{46}O_3$: C, 77.46; H, 11.08. Found: C, 77.18; H, 11.37.

The diacetate of V was obtained crystalline from methanol, m.p. 179–182°, $[\alpha]^{20}D$ +54°. *Anal.* Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.02. Found: C, 74.07; H, 9.75.

The di-3,5-dinitrobenzoate of V was crystallized from acetone–methanol, m.p. 235–237, $[\alpha]^{20}D$ +36°. *Anal.* Calcd. for $C_{41}H_{50}O_{13}N_4$: C, 61.02; H, 6.25; N, 6.94. Found: C, 60.87; H, 6.37; N, 6.93.

Elution of the column with chloroform yielded an additional 2.2 g. of **III**.

Thus from 10.0 g. of kryptogenin (I) was obtained 1.2 g. (12.4%) of 22,26-epoxycholestane-3β,16ξ-diol (IV), 1.0 g. (10.3%) of 22,26-epoxy-22-isocholestane-3β,16ξ-diol (V) and 6.6 g. (68%) of dihydrotigogenin III.

The infrared spectra of IV and V in chloroform solution (3%) were distinctly different. IV showed a weak band at 1129 cm.$^{-1}$ and twin bands at 907 and 871 cm.$^{-1}$, while V showed a strong absorption maximum at 1129 cm.$^{-1}$ and twin bands at 905 and 895 cm.$^{-1}$, other differences useful for distinguishing the two isomers were medium bands at 978, 967 and 957 cm.$^{-1}$ in IV which appeared at 983, 969 and 954 cm.$^{-1}$ in V.

In another reduction experiment under these same conditions, 0.4 g. of **tigogenin (II)** was isolated from 12.0 g. of kryptogenin in addition to III, IV and V which were obtained in their usual proportions. The tigogenin was identified by direct comparison with an authentic sample.

Reduction of 5,6-Dihydrokryptogenin.—A mixture of 1.0 g. of 5,6-dihydrokryptogenin (XII), 0.1 g. of Adams catalyst and 50 ml. of glacial acetic acid was shaken with hydrogen at room temperature and atm. pressure for 24 hr. Two molecular equivalents of hydrogen were absorbed. Separation of the reduction mixture as described above yielded 0.1 g. of IV, 0.09 g. of V and 0.6 g. of III.

22,26-Epoxycholestane-3,16-dione (VI).—To a stirred solution of 160 mg. of 22,26-epoxycholestane-3β,16ξ-diol (IV) in 200 ml. of acetone at 20° was added, dropwise, 0.8 ml. of 8 *N* solution of chromic acid in dilute sulfuric acid (*ca.* 40%) until a persistent orange-brown coloration indicated oxidation was complete.[8] This addition required 45 minutes. The mixture was diluted with 2 l. of water and the white crystalline precipitate was collected, washed with water and dried to yield 140 mg. of **22,26-epoxycholestane-3,16-dione VI**, m.p. 167–169°. Recrystallization from ethanol raised the melting point to 172–173°, $[\alpha]^{20}D$ − 107°, ν^{CHCl_3} 1736 cm.$^{-1}$ strong (16-ketone) and 1716 cm.$^{-1}$ strong (3-ketone).

Anal. Calcd. for $C_{27}H_{42}O_3$: C, 78.21; H, 10.21. Found: C, 78.28; H, 10.26.

The dioxime (hydroxylamine hydrochloride, ethanol-pyridine, steam-bath, 2 hr.) was obtained as white needles from ether–petroleum ether (30–60°), m.p. 246–248° dec.

Anal. Calcd. for $C_{27}H_{44}O_3N_2$: C, 72.93; H, 9.97. Found: C, 72.60; H, 9.75.

The disemicarbazone (semicarbazide hydrochloride, methanol–pyridine–water, steam-bath, 16 hr.) was obtained crystalline from dilute methanol, begins to decompose at 278° but does not melt even at 320°. *Anal.* Calcd. for $C_{29}H_{48}O_3N_6$: C, 65.87; H, 9.15. Found: C, 65.65; H, 9.01.

Reduction of VI in the presence of Adams catalyst and acetic acid or with sodium borohydride in methanol yielded the original diol IV in quantitative yield.

22,26-Epoxy-22-isocholestane-3,16-dione (VII).—Oxidation of 140 mg. of 22,26-epoxy-22-isocholestane-3β,16ξ-diol (V) as described above for the preparation of VI gave 130 mg. of **22,26-epoxy-22-isocholestane-3,16-dione (VII)** as white needles, m.p. 138–175°. Three recrystallizations from methanol afforded 65 mg. of constantly melting material, m.p. 171–175°, $[\alpha]^{20}D$ −104°. ν^{CHCl_3} 1736 cm.$^{-1}$ strong (16-ketone) and 1716 cm.$^{-1}$ strong (3-ketone). A polymorphic form was also obtained which melts at 133–135°.

Anal. Calcd. for $C_{27}H_{42}O_3$: C, 78.21; H, 10.21. Found: C, 77.97; H, 10.19.

Treatment of VII under the conditions which yielded a disemicarbazone from VI afforded a monosemicarbazone, **22,26-epoxy-22-isocholestane-3,16-dione 3-semicarbazone**, m.p. 236–243° dec. The infrared spectrum of this derivative exhibits the typical bands of a semicarbazone[9] and in addition retains the strong absorption band at 1736 cm.$^{-1}$ attributed to the 16-ketone.

Anal. Calcd. for $C_{28}H_{45}O_3N_3$: C, 71.30; H, 9.61. Found: C, 71.60; H, 9.80.

Reduction of VII in the presence of Adams catalyst and acetic acid yielded the original diol V.

22,26-Epoxycholestane (VIII).—To a solution of 0.3 g. of 22,26-epoxycholestane-3β,16ξ-diol (IV) in 12 ml. of dry pyridine at 0° was added an ice-cold solution of 0.6 ml. of methanesulfonyl chloride in 3 ml. of pyridine, and the mixture was kept at 3° overnight. The orange solution was poured into ice and water, and the oily precipitate was extracted with ether. The ethereal solution was washed with cold 5% hydrochloric acid, water, 2% sodium bicarbonate solution, water and dried over sodium sulfate. The solution was evaporated *in vacuo* to an oil which was dissolved in 30 ml. of benzene, distilled to a volume of 18 ml., and 18 ml. of dry ether and 4 ml. of a 1.6 *M* solution of lithium aluminum hydride in ether were added and the mixture was

refluxed overnight. The reaction mixture was cooled and after the addition of a few drops of ethyl acetate, treated with 10 ml. of 6 *N* hydrochloric acid. The aqueous layer was separated, extracted with ether and the extracts combined with the benzene–ether layer. The combined extracts were washed with 10% sodium bicarbonate solution and with water, dried over sodium sulfate and evaporated to dryness *in vacuo*. The oily residue was crystallized from methanol to yield 0.2 g. of **22,26-epoxycholestane (VIII)**, m.p. 149–152°. One recrystallization gave 0.18 g. of analytically pure material, m.p. 151.5–152.5°, $[\alpha]^{20}D$ −1.5°.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.87; H, 11.99. Found: C, 83.71; H, 11.97.

The reduction of 22,26-epoxycholestan-3β-ol (X) in a similar manner also yielded VIII.

22,26-Epoxy-22-isocholestane (IX).—As in the preparation of VIII above, 150 mg. of 22,26-epoxy-22-isocholestane-3β,16ξ-diol (V) in 5 ml. of dry pyridine was treated with 0.3 ml. of methanesulfonyl chloride in 1.5 ml. of dry pyridine at 3°. The oil thus obtained was dissolved in 15 ml. of benzene and distilled to a volume of 9 ml. To the solution was added 9 ml. of dry ether and 2 ml. of a 1.6 *M* solution of lithium aluminum hydride in ether, and the mixture was refluxed overnight. The oil obtained from the reduction mixture gave a slight positive test with tetranitromethane and was dissolved in 10 ml. of dioxane and shaken under hydrogen in a stainless steel bomb for 24 hr. at 150° and 1500 p.s.i. in the presence of 2 ml. of Raney nickel in ethanol. The mixture was filtered and concentrated *in vacuo* to a colorless oil which gave a negative test with tetranitromethane. Crystallization from methanol yielded 70 mg. of **22,26-epoxy-22-isocholestane (IX)**, m.p. 159–163°, $[\alpha]^{20}D$ + 35°. Recrystallization did not alter the melting point.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.87; H, 11.99. Found: C, 83.70; H, 11.87.

The reduction of 22,26-epoxy-22-isocholestan-3β-ol (XI) in a similar manner, also yielded IX.

Cholestane-3β,26-diol-16,22-dione 3,26-Diacetate 16-Ethylenethioketal (XIV).—To a solution of 3.0 g. of 5,6-dihydrokryptogenin diacetate (XIII) in 2 ml. of ethanedithiol was added 1.5 ml. of a solution of boron fluoride in ether (Eastman Kodak Co. practical 45% BF_3 in ether). The mixture was hand stirred and set to a stiff paste in about one minute. The paste was thinned with methanol and the white solid collected and washed with methanol. Recrystallization from ethanol gave 3.1 g. of **cholestane-3β,26-diol-16,22-dione 3,26-diacetate 16-ethylenethioketal (XIV)** as white needles, m.p. 193–194°, $[\alpha]^{20}D$ −37°, ν^{CS_2} 1739 cm.$^{-1}$ strong (acetate) and 1706 cm.$^{-1}$ strong (22-ketone).

Anal. Calcd. for $C_{33}H_{52}O_6S_2$: C, 66.85; H, 8.84; S, 10.82. Found: C, 67.00; H, 8.91; S, 11.10.

Saponification of XIV with 2% potassium hydroxide in methanol for 2 hr. at reflux temperature afforded **cholestane-3β,26-diol-16,22-dione-16-ethylenethioketal (kryptogenin 16-ethylenethioketal)** in quantitative yield as white needles from methanol, m.p. 194–195°, $[\alpha]^{20}D$ −28°. For analysis a sample was recrystallized from ethyl acetate, m.p. 195–197°.

Anal. Calcd. for $C_{29}H_{48}O_3S_2$: C, 68.45; H, 9.51; S, 12.60. Found: C, 68.30; H, 9.39; S, 12.30.

Cholestane-3β,26-diol-22-one (XVI).—A mixture of 1.0 g. of cholestane-3β,26-diol-16,22-dione 3,26-diacetate 16-ethylenethioketal (XIV), 4 teaspoons of Raney nickel and 150 ml. of dioxane was refluxed for 16 hr. The Raney nickel was filtered and washed several times with hot dioxane. The combined filtrate and washings were concentrated to dryness *in vacuo* to yield a solid residue. The residue was dissolved in 300 ml. of acetone at 20° and oxidized by dropwise addition of an 8 *N* solution of chromic acid in sulfuric acid and water until a persistent orange color remained. The solution was poured into 3 l. of water and extracted with ether. The ethereal solution was washed with water, 2% aqueous sodium bicarbonate, water, dried over sodium sulfate and concentrated to dryness *in vacuo*. The resultant residue was dissolved in 120 ml. of ethanol and saponified by refluxing for 5 hr. with 6.0 g. of potassium bicarbonate in 100 ml. of water. The solution was concentrated *in vacuo* to one-half its volume and extracted with ether. The ethereal solution was washed with water, dried over sodium sulfate and concentrated to dryness *in vacuo* to yield a crystalline residue which was chromatographed on benzene-washed alumina. The fractions eluted with benzene–chloroform 9:1 and 6:1 were combined and crystallized from benzene to yield 0.6 g. of **cholestane-3β,26-diol-22-one (XVI)** as white needles, m.p. 173–175°, $[\alpha]^{20}D$ +6°, ν^{CHCl_3} 1706 cm.$^{-1}$ strong (22-ketone).

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.46; H, 11.08. Found: C, 77.54; H, 11.05.

The diacetate (acetic anhydride–pyridine, 18 hr., 25°) was obtained as white needles from methanol, m.p. 102.5–103.5°, $[\alpha]^{20}D$ −8.5°. *Anal.* Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.02. Found: C, 74.35; H, 10.08.

The oxime (hydroxylamine hydrochloride, pyridine–ethanol, steam-bath, 4 hr.) was obtained as thin plates from dilute methanol, m.p. 192–194°. *Anal.* Calcd. for $C_{27}H_{47}O_3N$: C, 74.78; H, 10.92. Found: C, 74.62; H, 10.89.

Cholestane-3β,22,26-triol (XV). a. From XIV.—Three grams of cholestane-3β,26-diol-16,22-dione 3,26-diacetate 16-ethylenethioketal (XIV) was reduced with Raney nickel as described above. The dioxane solution was concentrated to dryness *in vacuo*. The residue was dissolved in 200 ml. of ethanol and refluxed for 5 hr. with 12.0 g. of potassium bicarbonate in 140 ml. of water. The solution was cooled, diluted with water and filtered. The crystalline precipitate was triturated with benzene and recrystallized from methanol–benzene to yield 1.2 g. (47.5%) of **cholestane-3β,22,26-triol (XV)** as white needles, m.p. 229–232°, $[\alpha]^{20}D$ +15° (EtOH).

Anal. Calcd. for $C_{27}H_{48}O_3$: C, 77.09; H, 11.50. Found: C, 76.91; H, 11.53.

The triacetate of XV (acetic anhydride–pyridine, 18 hr., 25°) was obtained as needles from methanol, m.p. 98–100°. *Anal.* Calcd. for $C_{33}H_{54}O_6$: C, 72.49; H, 9.96. Found: C, 72.68; H, 9.72.

The benzene solution which was recovered after the trituration of the crystalline precipitate from the Raney nickel was chromatographed on benzene-washed alumina. Elution with benzene yielded 0.20 g. (8%) of **XVI**, m.p. 172–175°. One hundred milligrams of another crystalline material was obtained from a fraction eluted with benzene–chloroform 9:1. This compound melted at 163–171°, exhibited strong absorption in chloroform at 1678 cm.$^{-1}$ (—C═C—?) and gave a positive tetranitromethane test. Reduction of this material (PtO_2, acetic acid) yielded **22,26-epoxy-22-isocholestan-3β-ol (XI)** from methanol, m.p. 150–153°. Concentration of the mother liquor gave an unsharply melting compound which is very likely the impure C-22-isomer of XI. The unsaturated parent compound is probably a 22,26-epoxide with a double bond at C-20,22 or at C-22,23, but no further work has been done with this compound.

b. From XVI.—A mixture of 0.050 g. of XVI, 0.150 g. of sodium borohydride, 5 ml. of methanol and 0.5 ml. of water was allowed to stand overnight at room temperature. Three drops of acetic acid were added, and the mixture was diluted with water and filtered to yield 0.045 g. (90%) of **cholestane-3β,22,26-triol (XV)**, m.p. 210–220°. Crystallization from methanol–benzene afforded 0.040 g. of **XV** as white needles, m.p. 227–230°, identical with the material obtained from procedure a above.

Cholestane from Cholestane-3β,22,26-triol.—Reduction of 0.150 g. of cholestane-3β,22,26-triol as previously described[10] for the reduction of tetrahydrotigogenin afforded 0.080 g. (60%) of cholestane, identical with an authentic sample.

22,26-Epoxy-22-isocholestan-3β-ol (XI).—A mixture of 1.0 g. of cholestane-3β,26-diol-22-one (XVI), 0.2 g. of Adams catalyst and 100 ml. of glacial acetic acid was shaken with hydrogen at room temperature and atm. pressure for 3 hr. until hydrogenation was complete. The crystalline residue obtained from the reaction was triturated with 50 ml. of benzene. The benzene-insoluble material yielded 0.10 g. of **cholestane-3β,22,26-triol (XV)**. The benzene-soluble material was chromatographed on benzene-washed alumina and a mixture was obtained from the fraction eluted with benzene–chloroform 98:2. From the fraction eluted with ethanol an additional 0.05 g. of XV was obtained. Repeated recrystallization of the mixture from the benzene–chloroform eluate yielded 0.42 g. of **22,26-epoxy-22-isocho-**

lestan-3β-ol (XI), m.p. 152–158°. Another recrystallization from methanol yielded constant melting material, 0.33 g., m.p. 155–158°, but still not pure. From the combined recrystallization mother liquors was obtained 0.10 g. of pure XI, m.p. 161–163°, $[\alpha]^{20}D$ +23°.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.54; H, 11.52. Found: C, 80.42; H, 11.64.

The acetate was obtained as white crystals from dilute methanol, m.p. 131–133.5°, $[\alpha]^{20}D$ +16°. *Anal.* Calcd. for $C_{29}H_{48}O_3$: C, 78.33; H, 10.88. Found: C, 78.02; H, 10.92.

22,26-Epoxycholestan-3β-ol (X).—The mother liquors from the above reduction and subsequent purification procedures were combined and concentrated to dryness *in vacuo*. The residue was crystallized from ethyl acetate to yield thick plates of X, m.p. 215–219°. Recrystallization from methanol yielded 0.23 g. of 22,26-epoxycholestan-3β-ol (X) as needles, m.p. 211–214°, $[\alpha]^{20}D$ −5.5°.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.54; H, 11.52. Found: C, 80.51; H, 11.78.

The acetate was obtained as needles from methanol, m.p. 188.5–190°, $[\alpha]^{20}D$ −14°. *Anal.* Calcd. for $C_{29}H_{48}O_3$: C, 78.33; H, 10.88. Found: C, 78.46; H, 10.73.

Acknowledgment.—We are indebted to Dr. G. Rosenkranz, Syntex, S. A., Mexico, for a generous supply of kryptogenin. Microanalyses are by the Analytical Service Laboratory of this Institute under the direction of Dr. William C. Alford. Infrared spectra were determined by Mr. H. K. Miller and Mr. W. Jones of this Laboratory.

Steroidal Sapogenins. XXXVI. Side Chain Bromination Isomers of Diosgenin and Tigogenin[2]

BY MONROE E. WALL AND HOWARD W. JONES

RECEIVED NOVEMBER 30, 1956

Bromination of diosgenin acetate with 3 moles of bromine in acetic acid solution for 2 to 3 hr. gave a mixture of 5α,6β,23a-tribromodiosgenin acetate (I) and the corresponding 23b isomer II which could be separated by fractional crystallization. Treatment of I with sodium iodide in ethanol gave 23a-bromodiosgenin acetate (III). Similar treatment of II yielded 23b-bromodiosgenin acetate (IV). Catalytic hydrogenation of III and IV gave, respectively, 23a-bromotigogenin acetate (V) and 23b-bromotigogenin acetate (VI). V and VI were also obtained by monobromination of tigogenin acetate. Prolonged treatment of diosgenin with $3^1/_3$ to $3^1/_2$ moles of bromine gave two isomeric tetrabromide isomers, arbitrarily designated tetrabromodiosgenin acetates A (VII) and B (VIII). Treatment of VII and VIII with sodium iodide gave the same dibromodiosgenin acetate (IX) which on catalytic hydrogenation gave dibromotigogenin acetate (X). Bromination of tigogenin acetate gave two dibromotigogenin acetate isomers, A (X) and B (XI). Dibromotigogenin acetate A was identical with the product obtained by hydrogenation of dibromodiosgenin acetate IX. Treatment of X and XI with sodium iodide in ethanol resulted in conversion of XI to X.

Bromination of the steroidal sapogenin side chain has received sporadic attention in the past 15 years. Marker and Rohrmann,[3] who first investigated the problem, stated that only one bromine atom could be introduced in the side chain of 25D ("iso") or 25L ("normal") sapogenins. Later Djerassi[4] and co-workers found that two atoms of bromine could be introduced in the side chain of sarsasapogenin (25L series). More recently Ziegler, Rosen and Shabica[5] have found that smilagenin (25D) series) can also be dibrominated in the side chain. In addition there have been several reports of the existence of bromine side chain isomers.[6] Recently Barton, Page and Shoppee[7] have on the basis of infrared spectra in the 700–500 $cm.^{-1}$ region assigned the equatorial position to the 23a compounds of the type described by Mueller and Norton[6a] and Dickson and Page.[6b] The 23b isomers were accordingly designated axial. The location of the bromine in the various side-chain brominated sapogenins has been placed at C_{23}[8] and accepted by subsequent workers. Although this assignment is logical, since the bromine atoms are located on a carbon atom adjacent to a potential carbonyl, it must be emphasized that the C_{23} assignment is not based on a rigid structure proof.

The experiments to be reported in this paper were the outgrowth of our interest in the stereochemistry of the spiroketal side chain.[9] On bromination of diosgenin acetate with 3 moles of bromine in acetic acid at 15–20°, a precipitate was noted. After filtration, the products in both the precipitate and filtrate fractions were isolated. It was apparent from the properties of the two fractions that they were isomeric. Since the infrared spectra of the soluble and insoluble fractions resembled, respectively, those of the 23a and 23b series described by Dickson and Page,[6b] we designated the acetic acid soluble fraction as 5α,6β,23a-tribromodiosgenin acetate (I) and the insoluble, precipitate fraction as 5α,6β,23b-tribromodiosgenin acetate (II). The structural assignments of I and II were on the following evidence. Bromine analysis showed that three bromine atoms were present. The infrared absorption bands between 800–840 $cm.^{-1}$ characteristic of the Δ^5-ethylenic moiety in diosgenin[10] and

other steroids[11] were absent. It is reasonable to conclude therefore that two bromine atoms were located at carbons 5 and 6. By analogy with the bromination of cholesterol, the structure should be 5α,6β.[12] The assignment of two bromine atoms in the 5α,6β location was further strengthened by the finding that I and II on refluxing with sodium iodide in ethanol were smoothly converted to 23a-bromodiosgenin acetate (III) and 23b-bromodiosgenin acetate (IV). Compounds III and IV on analysis showed only one bromine atom. The infrared spectra showed that the Δ^5-moiety had been regenerated. Since only the bromine atoms in the diaxial 5α,6β grouping are smoothly eliminated by sodium iodide,[12a] the structural assignments of I and II at carbons 5 and 6 seem justified. Treatment of I, II, III and IV with zinc–acetic acid removed the bromine and in all cases gave the original diosgenin acetate. Bromination of tigogenin acetate with 1.5 moles of bromine under the previously described conditions gave a mixture of 23a-bromotigogenin acetate (V) and 23b-bromotigogenin acetate (VI). The mixture could be separated partially by chromatography, and final purification was achieved by fractional crystallization. Compounds V and VI analyzed for one bromine atom. The infrared spectra showed the typical 23a and 23b-bromosapogenin bands. Catalytic hydrogenation of III and IV with platinum oxide (Adams catalyst) in ether containing 5% acetic gave the corresponding 23a- (V) and 23b-bromotigogenin acetate (VI). Treatment of V and VI with zinc–acetic acid gave tigogenin acetate.

Introduction of one bromine atom into the sapogenin side chain proceeded smoothly with both diosgenin and tigogenin acetates, yields averaging about 65–75%. The 23a bromo isomers were always the predominant by a large factor, although the ratio of 23a to 23b could not be determined exactly because of losses incurred during the separation of the isomers.

The problem of the stereochemistry of the 23a- and 23b-bromosapogenins is of interest. The partial formulation shown below represents a conception of the 25D type of bromosteroids. The configuration of ring F has been accepted by a number of groups.[9] It is assumed that the bromine atoms are located at C-23. Inspection of Fisher–Hirschfelder models constructed as formulated above would indicate little stereochemical preference for either the 23a- or 23b-isomers. If the mechanism of bromination of the sapogenin side chain bears any relationship or analogy to that of α-brominated ketones, then the axial epimer should be the product of kinetic control and formed first. The most stable epimer (which in this case could be either axial or equatorial) would be the product of thermodynamic control.[13] We attempted to determine which isomer was the most stable by equilibrating 23a-bromodiosgenin and -tigogenin acetates and the corresponding 23b-epimers with hydrogen bromide in ether or glacial acetic acid. In all cases the starting materials were recovered *unchanged*. In another experiment the two isomeric 23-bromodiosgenin acetates III and IV were treated with 2 moles of bromine for 5 hr. Only the corresponding 23a- and 23b-tribromides I and II could be isolated. Thus the methodology applicable to the prediction of the stereochemistry of α-bromoketones is not applicable to the bromosapogenin side chain. Another attempt to determine the stereochemistry of the 23a- and 23b-epimers involved the use of deuterium. Corey, *et al.*,[14] had shown that there was a difference in the C–D stretching absorption between equatorial and axial

deuterium epimers. We treated 23a- and 23b-bromodiosgenin acetates with zinc dust and *o*-deuteroacetic acid. However, we obtained the same deuterated compound in both instances. Callow, James and Massy–Beresford[15] have shown that the same reaction takes place with tigogenin bromide isomers and that deuterium will also replace two hydrogen atoms in tigogenin acetate (presumably at C_{23}) when the latter is refluxed with deuterium actate.[16] It seems likely that the replaceable hydrogen atoms are located at C_{23} adjacent to a potential carbonyl at C_{22}. We found that treatment of diosgenin acetate with deuterium acetate or refluxing 23a- and 23b-bromodiosgenin acetates with zinc–deuterium acetate all gave the same deuterated diosgenin acetate. This indicates that the replaced hydrogen atoms must be labile. The corresponding deuterium atoms are also labile. Bromination of the deuterated diosgenin acetate gave a tribromo compound in which deuterium was absent. Similarly treatment of the former with acetic anhydride–pyridine hydrochloride gave a pseudodiosgenin acetate with no deuterium. It is apparent therefore that the deuteration procedure of Corey[14] cannot be applied to determination of the conformation of the bromine atoms at C_{23} in the sapogenin side chain.

Recently Barton, Page and Shoppee studied the infrared spectra of epimeric pairs of halogenated steroids of known conformation. They found that steroids with an equatorial carbon–halogen linkage invariably had C–halogen bands absorbing at a higher frequency than the corresponding axial epimer. Similar differences were noted between epimeric 23a- and 23b-bromosapogenins in the 25D series. We have confirmed these findings with 23a-bromodiosgenin acetate and its 23b-epimer. Barton, *et al.*,[7] concluded that if the bromine atoms were in fact attached to C_{23}, the 23a- type was equatorial and the 23b- axial. We feel that this hypothesis is attractive but would prefer to have more conclusive chemical evidence on this subject.

Turning next to the subject of dibromination of the spiroketal side chain, it will be recalled that conducting the bromination in acetic acid with a large excess of bromine for time periods up to 2 hr. did not lead to the introduction of a second atom of bromine.[17] Changing the solvent to chloroform, benzene, carbon tetrachloride or methylene chloride had no effect, nor did use of anhydrous glacial acetic acid. However, when diosgenin acetate was treated with $3^1/_3$–$3^1/_2$ moles of bromine in acetic acid at room temperature and allowed to stand for 72 hr., a poor yield of tetrabromodiosgenin acetate was obtained. Most of the material was resinous. Chromatography of the tetrabromodiosgenin acetate gave a major fraction (VII) which was eluted in hexane and a minor product (VIII), eluted with benzene. Bromine analysis showed that both VII and VIII had four bromine atoms. The infrared spectra of the two isomers were markedly different. On refluxing VII and VIII with sodium iodide–ethanol, the same dibromodiosgenin acetate (IX) was obtained. Catalytic hydrogenation of IX gave dibromotigogenin acetate (X).

Bromination of tigogenin acetate under similar conditions gave a low yield of crystalline dibromotigogenin acetate. Chromatography gave a major fraction identical to X above and a minor isomer XI. The infrared spectra of X and XI differed characteristically and were similar to the spectra of VII and VIII, respectively. Compound X was not affected by sodium iodide–ethanol whereas XI was converted to X. Neither X nor XI was affected by treatment with hydrogen bromide in glacial acetic acid. From the data it is apparent that VII, IX and X have bromine atoms in the same location in the side chain. We have tentatively assigned the 23,23-dibromo- configuration to these compounds. The unstable compounds VIII and XI obviously must have one bromine atom located in some position other than C_{23}. Attempts to

(15) R. K. Callow, V. H. T. James and P. N. Massy–Beresford, *Chem. and Ind.*, R26 (1956).

(16) We conducted the deuteration experiments on the isomeric diosgenin bromides prior to the publication of reference 15. Shortly after we carried out this experiment we had the pleasure of an interesting discussion with Dr. Callow at which time he was kind enough to give us information in advance of the publication of reference 15.

(17) The replacement of the first hydrogen atom by bromine proceeds rapidly, the rate being comparable to the addition of bromine to the Δ^5-ethylenic bond. This is indicated by the fact that addition of one mole of bromine to diosgenin acetate invariably gave mixtures of unbrominated, monobrominated, dibrominated, tribrominated and tetrabrominated.

[a] All compounds were 3-acetates: V, 23a-bromotigogenin; III, 23a-bromodiosgenin; I, 5α,6β,23a-tribromodiosgenin; VI, 23b-bromotigogenin; IV, 23b-bromodiosgenin; II, 5α,6β,23b-tribromodiosgenin; IX, 23,23-dibromodiosgenin; X, 23,?-dibromotigogenin; XI, 23,?-dibromotigogenin; VII, 5α,6β,23,23-tetrabromodiosgenin; VIII, 5α,6β,23,?-tetrabromodiosgenin. [b] The relative intensities of the various bands at a concentration of 10 g./liter, 1 mm. cell length are indicated by s (strong), m (medium) and w (weak).

further brominate the monobrominated tigogenin acetate isomers V and VI gave resinous products. Treatment of the various sapogenins dibrominated in the side chain with zinc–acetic acid regenerated the original tigogenin acetate indicating that no major structural changes took place during dibromination.

The infrared spectra of the various brominated sapogenins were invaluable in detecting mixtures and determining the effectiveness of the various procedures used to resolve these mixtures. Table I gives the characteristic frequencies of the diosgenin and tigogenin isomers; Figures 1, 2 give the infrared curves for the various tigogenin isomers. Some general observations on the subject are pertinent. Bromination of the side chain completely changes the typical spiroketal band system.[18] Addition of bromine in the nucleus such as at carbons 5 and 6 had little effect on the infrared spectra as shown by the fact that the spectra of compounds with nuclear and side-chain bromination were similar to those with only side-chain substitution. In addition we noted that the infrared spectra of 5α,6β-dibromodiosgenin acetate closely resembled that of diosgenin acetate. As shown in Table I, the monobrominated 23a- and 23b-isomers readily could be distinguished, the former being characterized by bands absent in the latter (near 1015 and 950 cm.$^{-1}$) and the latter having bands absent in the former (near 985 and 975 cm.$^{-1}$).

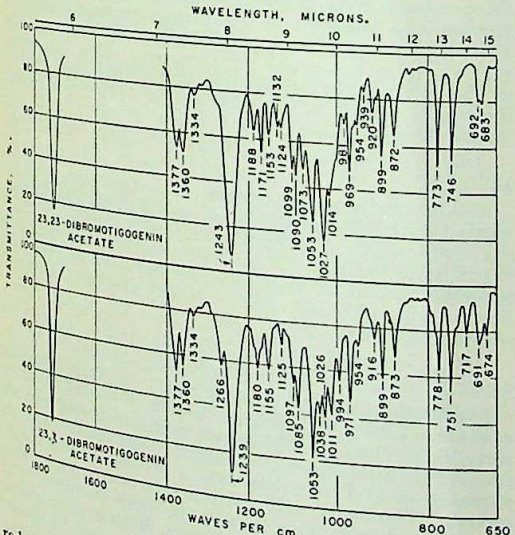

Fig. 1.

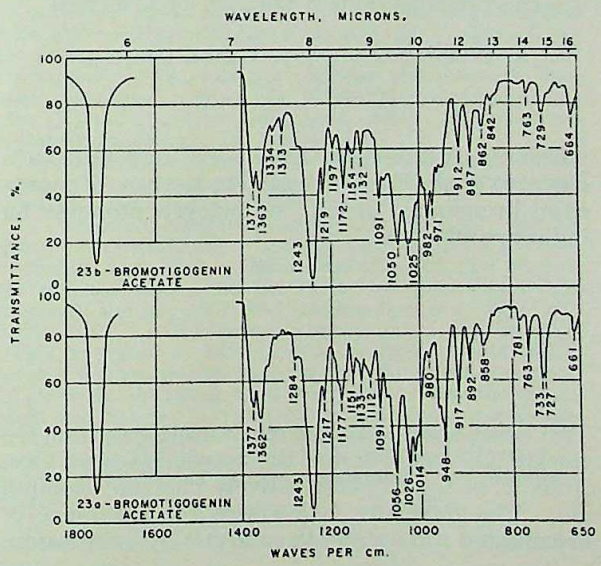

Fig. 2.

The sapogenin isomers containing two bromine atoms in the side chain could be easily differentiated from each other and from the monobrominated compounds. As shown in Table I, this group was characterized by a doublet (probably C–Br) in the region of 745 and 775 cm.$^{-1}$. In the case of the 23,23,-dibromo- group the band near 775 cm.$^{-1}$ was invariably slightly stronger than that at 750 cm.$^{-1}$, whereas the reverse was true in the group designated as 23,?-dibromo. In addition, this latter group had a band absent in the 23,23-dibromo- series near 1040 cm.$^{-1}$.

During the course of these investigations, it was noted that the presence of bromine in the side

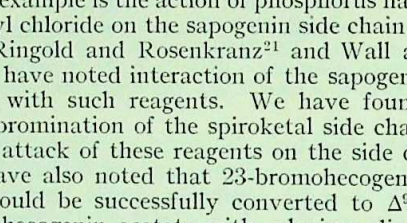
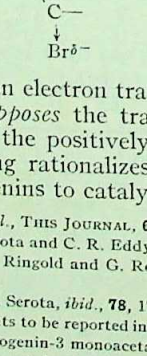
chain markedly stabilized the spiroketal moiety against attack by acidic reagents. For example, it is well known that catalytic hydrogenation of sapogenins in acidic media opens ring F with the formation of dihydrosapogenins.[19] A rationalization of this attack on the spiroketal side chain has been given in previous papers of this series[9,20] Under our experimental conditions using acetic acid as a solvent, diosgenin and tigogenin were rapidly hydrogenated in 1–2 hr. Under the same conditions, the side chains of the corresponding 23a- and 23b-bromo analogs were not appreciably affected up to 8 hr., after which time disappearance of bromine and formation of dihydrosapogenins occurred. Another example is the action of phosphorus halides or thionyl chloride on the sapogenin side chain. Djerassi, Ringold and Rosenkranz[21] and Wall and Serota[22] have noted interaction of the sapogenin side chain with such reagents. We have found that monobromination of the spiroketal side chain prevents attack of these reagents on the side chain.[23] We have also noted that 23-bromohecogenin acetate could be successfully converted to $\Delta^{9(11)}$-23-bromohecogenin acetate with selenium dioxide in acetic acid whereas this reagent attacks the side chain of hecogenin acetate.[24] The stabilizing effect of the bromine atom on the spiroketal side chain may be explained as follows. When unbrominated sapogenins are subjected to a proton attack, it seems probable that an oxonium ion is formed



which under favorable conditions may lead to a cleavage of the C_{22}–O– bond. In the case of sapogenins brominated at C_{23}, the halogen produces an inductive effect as



This bring about an electron transmission from C_{22} toward C_{23} and *opposes* the transmission of electrons from C_{22} to the positively charged oxonium ion. The foregoing rationalizes the resistance of brominated sapogenins to catalytic hydrogenation, no reaction occurring until the bromine atom is removed, and the increased stability of brominated sapogenins in general toward attack by Lewis acids.

Experimental[25]

5α,6β,23a-Tribromodiosgenin Acetate (I).—18.24 g. of diosgenin acetate (0.04 mole) was dissolved in 2.0 liters of glacial acetic acid. To the solution were added 8 drops of acetic acid saturated with hydrogen bromide. The solution was cooled to 15–20°. A solution of 0.12 mole of bromine in 160 ml. of acetic acid was added dropwise over a period of 30 minutes to the above solution with constant stirring. About 2 hr. after the addition of the bromine, a precipitate was noted in the orange solution. The precipitate was filtered. The filtrate, containing I, was mixed with two volumes of water and the solids filtered. Crystallization from acetone gave 13.5 g. of crude I. Purification was carried out by triturating the product in warm acetic acid and discarding insoluble material. The analytical sample after several crystallizations from acetone was obtained as rods, m.p. 158–162°, $[\alpha]^{25}D$ −108°, infrared spectrum shown in Table I.

Anal. Calcd. for $C_{29}H_{43}O_4Br_3$: Br, 34.53. Found: Br, 34.30.

5α,6β,23b-Tribromodiosgenin Acetate (II).—The precipitate obtained during the bromination described in the preceding section was crystallized from acetone to give 4.9 g. of II. Purification was carried out by trituration with warm acetic acid and discarding *soluble* material. The insoluble fraction was crystallized from acetone to give plates, m.p. 174–176°, $[\alpha]^{25}D$ −112°, principal infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{43}O_4Br_3$: Br, 34.53. Found: Br, 34.29.

23a-Bromodiosgenin Acetate (III).—One gram of I was refluxed for 2 hr. with 200 ml. of ethanol containing 0.2 g. of sodium iodide. The solvent was removed *in vacuo* and the residue taken up in ether. The ethereal solution was washed with a dilute sodium thiosulfate solution, then with water, dried over sodium sulfate and the solvent removed. The residue was dissolved in hexane and chromatographed on Florisil. A small fraction was eluted with hexane. The major portion was eluted with benzene. After evaporation of the solvent, the residue was crystallized from acetone–methanol, rods, m.p. 171–175°, $[\alpha]^{25}D$ −111°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{43}O_4Br$: Br, 14.95. Found: Br, 14.72.

23b-Bromodiosgenin Acetate (IV).—One gram of II was treated with sodium iodide as described above and the product chromatographed on Florisil. The main fraction was eluted with hexane. The hexane was evaporated and the residue crystallized from acetone–methanol to give thick plates, m.p. 195–198°, $[\alpha]^{25}D$ −138°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{43}O_4Br$: Br, 14.95. Found: Br, 14.62.

23a-Bromotigogenin Acetate (V). (a) From Tigogenin Acetate.—9.16 g. of tigogenin acetate (0.02 mole) was dissolved in 1.0 liter of glacial acetic acid and treated with 0.03 mole of bromine exactly as described previously under the preparation of I. In this case a precipitate was not observed. The acetic acid solution was poured with stirring into two volumes of water and the solids recovered by filtration. Repeated fractional crystallization from acetone separated two isomers. The separation could be followed by infrared (see Table I, Compounds V and VI) microscopic observation and melting point differences. In this manner pure V, 1.5 g., was obtained in the fractions relatively less soluble in acetone as thick hexagonal plates, m.p. 205–210°, $[\alpha]^{25}D$ −60°.

(22) M. E. Wall and S. Serota, *ibid.*, **78**, 1747 (1956).

(23) Thus in experiments to be reported in a separate paper we have noted that 23 bromo-rockogenin-3 monoacetate and 23 bromo-11 keto rockogenin-3 monoacetate retained the sapogenin side chain on reaction with reagents such as phosphorus tribromide or thionyl chloride. Unfortunately, the desired replacement of the equatorial 12β-hydroxyl group by halogen (*cf.* E. Borgstrom and T. F. Gallagher, *J. Biol. Chem.*, **177**, 951 (1949)) did not occur. Instead under mild conditions no reaction took place, under more drastic conditions ester formation or ring C/D contraction–expansion took place (*cf.* R. Hirschmann, C. S. Snoddy, Jr., C. F. Hiskey and N. L. Wendler, THIS JOURNAL, **76**, 4013 (1954)).

(24) Selenium dioxide was first used on bromosapogenins by Marker and co-workers[19] and later by Hirschmann, *et al.*, *ibid.*, **75**, 3252 (1953). The former group noted the increased stability of bromosapogenins toward attack by selenium dioxide.

(25) All melting points were obtained with a Köfler micro melting point apparatus. Optical rotations were determined in chloroform solution, concentration *ca.* 8.0 mg./ml. The infrared spectra were obtained on a Perkin–Elmer Model 21 spectrophotometer using a sodium chloride prism, in carbon bisulfide solution, concentration 10.0 grams per liter. We wish to thank S. Serota for the optical rotation determinations, C. R. Eddy and C. S. Fenske for infrared and Ruth B. [illegible] for the analyses.

Anal. Calcd. for $C_{29}H_{45}O_4Br$: Br, 14.87. Found: Br, 14.50.

(b) **From Bromodiosgenin Acetate (III).**—0.1 g. of III was dissolved in glacial acetic acid and hydrogenated for five hours at room temperature and three atmospheres in the presence of 0.1 g. of platinum oxide (Adams catalyst). After filtering the catalyst and evaporating the solvent, the residue on crystallization from acetone gave V, m.p. 204–208°. Similar results were obtained by hydrogenating III in the same manner in ether containing 5% acetic acid or ethanol acidified with a few drops of hydrochloric acid. Similar hydrogenation in acetic acid for 15 hr. gave a product free from bromine identified as dihydrotigogenin-3 monoacetate. Tigogenin acetate was converted to the same product in 2 hr. under the above conditions.

23b-Bromotigogenin Acetate (VI). (a) From Tigogenin Acetate.—The *more soluble* acetone fractions, described under V above, contained VI, 1.2 g., rods, m.p. 220–230°, $[\alpha]^{25}D$ −81°.

Anal. Calcd. for $C_{29}H_{45}O_4Br$: Br, 14.87. Found: Br, 14.80.

(b) **From 23b-Bromodiosgenin Acetate (IV).**—Catalytic hydrogenation of IV in the manner described under V, part (b), gave VI, m.p. 222–229°.

5α,6β,23,23-Tetrabromodiosgenin Acetate (VII).—Diosgenin acetate (9.12 g., 0.02 mole) was dissolved in one liter of glacial acetic acid. To this solution 0.08 mole of bromine in 100 ml. of acetic acid was added in the usual manner. No precipitation occurred. After standing 3 hr. at 15–20°, the solution was allowed to come to room temperature and then to stand for 72 hr. The acetic acid solution was poured into excess water precipitating the brominated sapogenin and the solids collected by filtration. They were taken up in hexane, acetic acid neutralized with sodium bicarbonate solution and the hexane dried over anhydrous sodium sulfate. Chromatography on Florisil gave 0.75 g. of crystalline product on hexane elution and 1.0 g. of product on benzene elution. Elution with chloroform and alcohol accounted for the bulk of the weight. These products were dark resins. Acetone crystallization of the solids from the hexane elution gave VII, 0.3 g. prisms, m.p. 177–180°, $[\alpha]^{25}D$ −105°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{42}O_4Br_4$: Br, 41.34. Found: Br, 41.92.

5α,6β,23,?-Tetrabromodiosgenin Acetate (VIII).—Acetone crystallization of the *benzene* eluate described above gave VIII, 0.2 g., rods, m.p. 188–191°, $[\alpha]^{25}D$ −43°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{42}O_4Br_4$: Br, 41.34. Found: Br, 40.92.

23,23-Dibromodiosgenin Acetate (IX).—One-tenth gram of VII or VIII was refluxed with sodium iodide in ethanol as described previously. After acetone crystallization only IX was obtained in each case, m.p. 193–198°, $[\alpha]^{25}D$ −94°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{42}O_4Br_2$: Br, 25.97. Found: Br, 25.77.

23,23-Dibromotigogenin Acetate (X).—Tigogenin acetate (9.16 g., 0.02 mole) in one liter of glacial acetic acid was brominated with 0.06 mole of bromine as described under the preparation of VII with the exception that the product was held at room temperature for 24 hr. The brominated sapogenin was transferred to hexane as under VII and then chromatographed on silica gel. Elution with hexane–benzene, 1:1, gave 6.0 g. of semicrystalline product; elution with benzene gave 1.0 g. of crystals mixed with resin, further elution with more polar solvents yielded only dark resins. Methanol crystallization of the residue from the hexane–benzene eluates gave X, 0.5 g., m.p. 199–200°, $[\alpha]^{25}D$ −68°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{44}O_4Br_2$: Br, 25.89. Found: Br, 25.60.

X was also obtained by catalytic hydrogenation of IX using platinum oxide catalyst and ether containing 5% acetic acid as the solvent.

23,?-Dibromotigogenin Acetate (XI).—The *benzene* eluate obtained in preparation of X above was evaporated and the residue crystallized from methanol repeatedly to yield XI, 0.06 g., m.p. 178–182°, $[\alpha]^{25}D$ −40°, chief infrared bands shown in Table I.

Anal. Calcd. for $C_{29}H_{44}O_4Br_2$: Br, 25.89. Found: Br, 25.42.

23,23-Dibromotigogenin acetate (X), 0.025 g., and 23,?-dibromotigogenin acetate (XI), 0.015 g., were refluxed with sodium iodide as described under III. The infrared spectra of the crystalline residues showed that X was unchanged and that XI was completely converted to X.

Compounds X and XI were dissolved in acetic acid and heated in the presence of zinc dust. Infrared examination of the crystalline reaction products indicated that each compound had been converted to tigogenin acetate.

Equilibration Experiments.—(a) 23a-Bromodiosgenin acetate (III) (0.2 g.), in 100 ml. of ethanol containing 1 ml. of 48% hydrobromic acid was refluxed 12 hr. The product obtained by ethereal extraction in the usual manner was acetylated and found to be unchanged III. Similar treatment of 23b-bromodiosgenin acetate (IV), yielded unchanged starting material.

(b) 23a-Bromotigogenin acetate (V) (0.1 g.), in 30 ml. of anhydrous ether containing 3 ml. of acetic acid saturated with hydrogen bromide (approximately 38% solution) was allowed to stand overnight. After the usual work-up, only unchanged V was isolated. Similar treatment of 23b-bromotigogenin acetate (VI), 23,23-dibromotigogenin acetate (X) and 23,?-dibromotigogenin acetate (XI) gave, respectively, unchanged VI, X and XI.

Deuteration of Sapogenins.—Deuterium acetate was prepared by mixing acetic anhydride with the appropriate quantity of deuterium oxide (98%).

(a) 23a-Bromodiosgenin acetate (III) (0.5 g.), was refluxed 5 hr. with 75 ml. of deuterium acetate in the presence of 10.0 g. of zinc dust. The residue obtained after filtering the zinc and evaporating the solvent was crystallized from methanol and gave 0.3 g. of long needles, m.p. 196–199°, $[\alpha]^{25}D$ −117°. The infrared spectrum of the product, which we regard as 23,23-deutero-diosgenin acetate (XII), showed marked deviations from that of diosgenin acetate. In particular the strong band near 900 cm.$^{-1}$ and the weaker band near 865 cm.$^{-1}$, typical of the 25D series, were absent.

Similar treatment of 23b-bromodiosgenin acetate (IV) gave a compound identical to XII, the identity being verified by comparison of infrared spectra and X-ray diffraction patterns.

(b) Diosgenin acetate (0.1 g.), was refluxed 2 hr. with deuterium acetate.[15,16] The product isolated in the usual manner was XII.

Steroidal Sapogenins. XLII. Partial Synthesis of 11-Ketodiosgenin[2]

BY EDWARD S. ROTHMAN AND MONROE E. WALL

RECEIVED DECEMBER 13, 1956

The steroidal sapogenin gentrogenin (3β-hydroxy-22a,25D-spirost-5-en-12-one, I), considered as a suitable cortisone precursor substance, was transformed to 11-ketodiosgenin (3β-hydroxy-22a,25D-spirost-5-en-11-one, VIa) and to 11α-hydroxydiosgenin (22a,25D-spirost-5-en-3β,11α-diol, Va). The route employed involved the tetrabromination of I to 3β-acetoxy-5α,6β,11α,23-tetrabromo-22a,25D-spirostan-12-one (II). This tetrabromide was selectively debrominated to restore the olefinic bond by means of iodide ion to form 3β-acetoxy-11α,23-dibromo-22a,25D-spirost-5-en-12-one (III). Hydrolysis of III formed, after acetylation, 23-bromo-3β,12β-diacetoxy-22a,25D-spirost-5-en-11-one (IVb) which was debrominated with zinc dust in acetic acid to form 3β,12β-diacetoxy-22a,25D-spirost-5-en-11-one (IVc). Selective deacetoxylation of IVc with calcium, sodium or lithium in liquid ammonia gave rise to 11-ketodiosgenin (VIa) or to 11α-hydroxydiosgenin, depending on reaction conditions utilized. Small amounts of 3-desoxy sapogenins also were detected as by-products.

In the course of examination of natural steroidal materials of botanic origin as possible source materials for steroid hormones, we have been studying the 12-ketosteroids hecogenin, gentrogenin[3] and correllogenin.[3] When we read of the discovery by Chapman, Elks and Wyman[4] of the conversion of hecogenin to 11-ketotigogenin by the route of selective deacetoxylation of 3β,12β-diacetoxy-5α,22a,25D-spirostan-11-one by means of calcium in liquid ammonia, it seemed that such a method might be advantageously applied to gentrogenin to prepare the unknown C-11 oxygenated derivatives of diosgenin. Since 11-ketotigogenin is a commercially utilized intermediate for cortisone production, it was reasonable to expect that its 5,6-dehydro derivative, 11-ketodiosgenin, might be similarly used. The present communication describes the preparation of 11-ketodiosgenin and 11α-hydroxydiosgenin.

For this work we had available a ketonic sapogenin fraction obtained from *Dioscorea spiculiflora*[5] containing a mixture of the 25D- and 25L-diastereoisomeric sapogenins gentrogenin and correllogenin, the 25D-isomer greatly predominating in the mixture. Fortunately, separation of isomers is unnecessary for practical work since conversion to derivatives in the C-21 series expels the single differing asymmetric center and leads to a single series of compounds. The constants reported in this paper are for sterically pure 25D-gentrogenin derivatives, although we have carried out the same transformations on the natural mixtures as well.

Bromination of I[6] gave a 90–94% yield of crystalline 3β-acetoxy-5α,6β,11α,23-tetrabromo-22a,25D-spirostan-12-one (II). This crystalline tetrabromide on treatment with zinc in refluxing acetic acid for 1.5 hr. regenerated starting material I essentially completely (95%). However, selective regeneration of the 5,6-olefinic bond with iodide gave only a 48–63% yield of the desired dibromide 3β-acetoxy-11a,23-dibromo-22a,25D-spirost-5-en-12-one (III).[7] The mother liquors were not useful for reconversion to starting material. The speed of the debromination was surprisingly rapid. The reaction in acetone solution was complete in less than six minutes at room temperature.

The hydrolysis of 11α,23-dibromohecogenin acetate had been studied by Mueller, *et al.*,[6] and by Rosenfeld and Gallagher.[8] We applied the conditions of the latter authors to 11α,23-dibromogentrogenin acetate (III) and obtained, after reacetylation and debromination, the desired product 3β,12β-diacetoxy-22a,25D-spirost-5-en-11-one (IV c).[9] The 12β-hydroxyl group adjacent to the 11-ketone group does not reliably acetylate with pyridine and acetic anhydride on the steam-bath so that we used perchloric acid catalysis.[10] When we attempted to carry out the hydrolysis reactions in smaller volumes by using refluxing ethanol in 2-hr. reactions or when we used water-miscible co-solvents (*e.g.*, tetrahydrofuran), the yields were sharply reduced.

A carboxylic acid by-product was obtained in low yields from the hydrolysis reactions. Wendler, Hirschmann, Slates and Walker,[11] working with 11,12-dimesylates, obtained by alkaline treatment a C-ring carboxylic norsteroid.[12] We suspect a

(2) Paper XLI, H. E. Kenney and M. E. Wall, *J. Org. Chem.*, **22**, 468 (1957).

(3) For a preliminary description of these new sapogenins see H. A. Walens, S. Serota and M. E. Wall, THIS JOURNAL, **77**, 5196 (1955). A more complete description has been submitted to *J. Org. Chem.*

(4) J. H. Chapman, J. Elks and L. J. Wyman, *Chemistry & Industry*, 603 (1955).

(5) This material was collected in Chiapas, Mexico, by Drs. H. S. Gentry and D. S. Correll, Horticultural Crops Research Branch, Agricultural Research Service, Beltsville, Md.

(6) The conditions of the bromination were essentially those used by J. W. Cornforth, J. M. Osbond and G. H. Phillips, *J. Chem. Soc.*, 907 (1954), but several differences from results with hecogenin acetate are worth mentioning. We obtained a 37% yield of crystalline 11α,23-dibromohecogenin acetate, melting point 188–190°, rather than the 54% yield reported by Cornforth, *et al.* (See also G. P. Mueller, L. L. Norton, R. E. Stobaugh, L. Tsai and R. S. Winniford, THIS JOURNAL, **75**, 4892 (1953), for yield and melting point data.) The mother liquors from the crystallization were deep green, viscid residues which could be freed of bromine by treatment with zinc and refluxing acetic acid but which yielded only half the calculated content of crystallizable hecogenin acetate.

(7) Attempts to improve the yield of III by treating II with zinc dust in benzene or tetrahydrofuran were not successful since the 11α-bromine atom was more susceptible to reductive attack than the 5,6-bromine atom pair. The direction of attack could be indirectly observed by infrared spectral means since the 11α-bromo ketone absorbs at 1735 cm.$^{-1}$, while the free 11-ketone absorbs in the usual region near 1709 cm.$^{-1}$.

(8) R. S. Rosenfeld and T. F. Gallagher, THIS JOURNAL, **77**, 4367 (1955).

(9) We confirm the 92% yield for 20-hour, room temperature hydrolysis of 11α,23-dibromo hecogenin acetate reported by Rosenfeld and Gallagher; however, identical reaction conditions applied to the closely related III gave IVc in somewhat lower yields averaging 50 to 65%.

relationship between these two products but have as yet no experimental verification.

We carried out our preliminary C-12 deacetoxylation experiments of conversion of IVc to 11-ketodiosgenin and to 11α-hydroxydiosgenin on the basis of the communication of Chapman, Elks and Wyman.[4] These authors described the parallel experiments in the hecogenin series but in their preliminary disclosure gave no experimental details. In view of the fact that even closely related sapogenins often have inherent peculiarities that affect direction of reaction and yield it may not be amiss to note here some observations on the metal–ammonia reduction systems as applied to the compound IVc.

The selective deacetoxylations were carried out in liquid ammonia using calcium or *sodium* or *lithium* as the reducing element. The primary product of the reduction was 11-ketodiosgenin, 3β-hydroxy-22a,25D-spirost-5-en-11-one (VIa), which may further react with protonic materials (*e.g.*, water, alcohol) to form 11α-hydroxydiosgenin, 22a,25D-spirost-5-en-3β,11α-diol (Va), in a secondary reaction.[13] When water is used to quench the reaction and decompose excess metal reagent, a greater or lesser amount of 11α-ol is formed. Henry A. Walens of this Laboratory devised an experiment avoiding this quenching operation. The immiscible toluene layer could be separated from the liquid ammonia metal solution phase in a separatory funnel provided with a fritted glass disk. We have also used bromobenzene to quench the reaction as suggested by Chapman, Elks and Wyman.[14] Reduction of IVc gave a 90% yield of products consisting chiefly of 11-ketone VIa but containing about 10–20% of 11α-diol Va. The conversion of gentrogenin to 11-ketodiosgenin is effected in about 35% over-all yield. A further observation in the calcium deacetoxylation experiments is the formation by the reduction system of small amounts of 3-desoxysapogenins by apparently non-specific deacetoxylation. Isolated and identified were 3-desoxy-11-ketodiosgenin (22a,25D-spirost-5-en-11-one, VII) and 3-desoxy-12β-hydroxydiosgenin (22a,25D-spirost-5-en-12β-ol, VIII). The latter compound was characterized by oxidation to the 12-ketone, 3-desoxygentrogenin (22a,25D-spirost-5-en-12-one). The 12β-configuration is tentatively suggested since the 12β-configuration is the equatorial one usually favored by metal reduction systems. The C-11 ketones can be distinguished from the C-12 ketones not only by reduced chemical reactivity of the former but also by infrared differences. Thus, the 11-ketones show a band at 1704–1710 cm.$^{-1}$ (VIb at 1706 cm.$^{-1}$)[15] while the 12-ketones show the band at 1706–1712 cm.$^{-1}$ (I at 1713 cm.$^{-1}$).[15] In addition the 11-ketones show a band[16] at 970 cm.$^{-1}$ not given by the 12-ketones. Such a band occurs also for ex-

(13) F. Sondheimer, O. Mancera, G. Rosenkranz and C. Djerassi, THIS JOURNAL, **75**, 1282 (1953), using calcium, sodium or lithium in liquid ammonia to reduce 3β-propionoxy-5α,22a,25D-spirost-8(9)-en-11-one reported formation of the saturated ketone in the absence of ethanol and the 11α-ol in the presence of ethanol. S. Bernstein, R. Littell and J. H. Williams, *ibid.*, p. 1481, used lithium–ammonia–ethanol to reduce a saturated 11-ketone to an 11α-ol in a similar manner.

ample in the spectrum of tigogenin, diosgenin and 3,5-cyclo-22a,25D-spirostane, but compounds of these types are easily distinguished by other criteria. The relative intensities of the ketone and acetate bands also vary erratically. In hecogenin acetate the acetate band is slightly stronger than the ketone band.[16,17] In gentrogenin and correllogenin, the ketone band[18] is the stronger, while the 11-ketones have a ketone band definitely weaker than the acetate band.

In the course of the identification and structure assignments of the C-11 ketonic products, we observed a substantial deviation of the sapogenin 11-ketone molecular rotation contribution from the mean value of +79° calculated by Barton and Klyne.[19] A check of literature values of 11-ketone molecular rotation contributions in the sterol series gave a value[20] of about +72° in good agreement with Barton and Klyne's value. However, the 11-ketone contribution in 11-ketotigogenin[21] is +150° and in 11-ketotigogenin acetate[16] is +169°. The +207° molecular rotation contribution in 11-ketodiosgenin is even more positive. Similar deviation in a positive direction from the calculated[19] molecular rotation contribution of the 11α-ol also occurs. The calculated value is −29°; the observed value[13] is +35°.

Experimental

Rotations were measured in chloroform in a 2 dm. tube, c = 25 mg./1.5 ml. Melting points were determined on the Kofler block but are otherwise uncorrected.

3β-Acetoxy-5α,6β,11α,23-tetrabromo-22a,25D-spirostan-12-one (II).—Gentrogenin acetate (I), 7.0 g. (0.01486 mole), in 76 ml. of ordinary C.P. chloroform was treated at room temperature with a solution of 0.01486 mole of bromine in 59 ml. of carbon tetrachloride in the course of 5 minutes time. The initial uptake was slow, but the rate of uptake accelerated with time. The bromine was added in batches rather than dropwise. The colorless solution was further treated with 1.9 ml. of liquid bromine dissolved in 15 ml. of chloroform. Various colorations, sometimes yellow-orange, pink or green developed during this second bromination, again carried out in only 5 minutes time despite difficulties in visual observation of the bromine uptake. The solution was stirred, still at room temperature, for an additional 10 minutes, and then all solvents were removed at 30° using water aspiration. The residue was a pale green, glassy froth which on dissolution in 25 ml. of methylene chloride[22] gave a dark green solution. Addition of ethanol incrementally caused color change to a pale pink. Absolute ethanol was then added as rapidly as possible without causing flocculation until a volume of 250 ml. of clear, nearly colorless solution was obtained. Stirring with scratching caused sudden crystallization of 11.1 g. of snow-white product (decomposing at 193° with effervescence and reddening).

Recrystallization was effected by dissolution in a minimal volume of hot methylene chloride, dilution with ether and boiling off the methylene chloride azeotropically. The product formed a mass of felted micro-needles melting suddenly at 199° with browning and effervescence. The analytical sample was recrystallized from methanol to give silky filaments, m.p. 199°, $[\alpha]^{25}D$ −84.5°.

Anal. Calcd. for $C_{29}H_{38}O_5Br_4$: C, 44.30; H, 4.87; Br, 40.66. Found: C, 44.16; H, 5.04; Br, 40.65.

Selective Debromination of II to 3β-Acetoxy-11α,23-dibromo-22a,25D-spirost-5-en-12-one (III).—A sample of II, 11 g., in 250 ml. of ethanol was refluxed for 2 hr. with 14 g. of sodium iodide. The solids went into solution during the course of the reaction. The mixture was cooled, diluted with water and ether was added. A dilute solution of sodium thiosulfate was added in portions to just decolorize molecular iodine, avoiding excess reagent. The ether layer was washed with 1% sodium hydroxide (to remove traces of carboxylic material), with water, with saturated saline solution and after drying with sodium sulfate, was evaporated under reduced pressure at 30° to a pale-orange froth. Stirring with 35 ml. of absolute ethanol caused solution of the froth followed by precipitation of white crystalline III, 63%.[23] The analytical sample was recrystallized from ethanol–methylene chloride to fine hexagonal blades blackening at 152° and melting with effervescence from 160–170°, $[\alpha]^{25}D$ −81.9°.

Anal. Calcd. for $C_{29}H_{38}O_5Br_2$: C, 55.60; H, 6.11; Br, 25.51. Found: C, 54.14; H, 6.18; Br, 24.99.

The compound is not stable in chloroform or methylene chloride solutions for prolonged periods of time. Analytically pure samples let stand overnight in chloroform solution developed deep pink coloration.

23-Bromo-3β,12β-diacetoxy-22a,25D-spirost-5-en-11-one (IVb).—A sample of III, 5 g., suspended in 4.5 l. of 0.3 *N* 80% ethanolic potassium hydroxide was stirred at room temperature for 20 hr. The mixture was treated with 250 ml. of 6 *N* hydrochloric acid and was evaporated to 400 ml. under reduced pressure. The residue was diluted with water and extracted with ether. The ether was washed with 2% sodium hydroxide to remove a solid carboxylic acid[11] and was dried with saturated brine and with sodium sulfate. The solid froth obtained by reduced pressure evaporation of the dried ether extract was acetylated in 50 ml. of acetic acid and 15 ml. of acetic anhydride in the presence of 1 ml. of 2.5 *N* perchloric acid in acetic acid during 1.5 hr. at room temperature. The product was obtained by pouring the acetylation mixture into an excess of cold water and filtering off the flocculent precipitate. Crystallization of the air-dried product from ether gave 3.5 g. of IVb, m.p. 212–215°. The analytical sample, $[\alpha]^{25}D$ −88.7°, crystallized from ether, melted from 214–216° without decomposition, although the colorless melt turned slightly brown soon after melting was completed.

Anal. Calcd. for $C_{31}H_{43}O_7Br$: C, 61.28; H, 7.13; Br, 13.15. Found: C, 61.30; H, 7.02; Br, 13.25.

3β,12β-Diacetoxy-22a,25D-spirost-5-en-11-one (IVc).—The product from the preceding preparation, diminished by the removal of 121 mg. for analytical and reference purposes, was refluxed 6 hr. with zinc dust in acetic acid and the product isolated by dilution with water and extraction with ether and washing in the usual manner. A sample (after removal of zinc halide) gave a positive Beilstein flame test even after multiple crystallizations. The materials were recombined and retreated for an additional 4 hr. without change. Apparently the residual halogen content was vanishingly small since the infrared spectrum of the product was typical of 25D-sapogenins and showed no band at 739 cm.$^{-1}$. The product, 2.13 g., obtained by crystallizing the evaporated ether extract from ethanol, formed feathery, branched masses, m.p. 195–218°. The analytical sample, $[\alpha]^{25}D$ −106°, recrystallized from ethanol, began to undergo transition over 202° to elongated needles, but melting occurred at 221–225° before the transition was completed.

Anal. Calcd. for $C_{31}H_{44}O_7$: C, 70.43; H, 8.39. Found: C, 70.71; H, 8.53.

A. Reduction of 3β,12β-Diacetoxy-22a,25D-spirost-5-en-11-one (IVc) with Calcium and Ammonia to Give a Mixture of Products.—A sample of IVc, 0.85 g., in 9 ml. of tetrahydrofuran was added to a solution of 0.67 g. of calcium in 200 ml. of liquid ammonia. The reactants were stirred 2 hr.

(22) If isolation of the tetrabromide is not required, the methylene chloride should not be added, but the product should be triturated with ethanol to loosen any crystalline residues from the walls of the flask to pervent scorching during subsequent heating. Debrominative regeneration of the Δ^5-bond with sodium iodide does not require that the tetrabromide be in solution initially.

(23) The yield was about 50–55% when the reaction was carried out with the natural mixture of C-25 diastereoisomers.

during which time the solvent boiled away. The residue was sifted into water to form a flocculent precipitate. The mixture was acidified, extracted with ether and evaporated. The residue was saponified with 5% methanolic sodium hydroxide. The resulting product was dissolved in 50 ml. of ethanol and 5 ml. of acetic acid. Girard reagent T, 2 g., was added and the mixture was refluxed for 1 hr., poured into dilute aqueous sodium carbonate and extracted with ether. The aqueous layer and aqueous washings of the ether on acidification and isolation with ether yielded a negligible quantity of steroid, *i.e.*, the metal–ammonia reduction product was non-reactive with the Girard reagent.[24] The infrared spectrum of the reduction product was similar to that of 11α-hydroxydiosgenin but showed, in addition, the presence of some 11-ketonic material by a weak to medium strength band at 1707 cm.$^{-1}$.

The reduction mixture was resolved in the following manner by chromatography. Seven hundred milligrams of the reduction product was chromatographed on a column of Florisil 20 by ¾ inches. Benzene, 900 ml., eluted no material. Chloroform–benzene (1:20) eluted 30 mg. of **3-desoxy-11-ketodiosgenin (VII) (22a,25D-spirost-5-en-11-one)**, m.p. 178–184°, $\nu_{max}^{CS_2}$ 1705 and 970 cm.$^{-1}$. Chloroform–benzene (1:10), 600 ml., eluted traces of material not examined. Chloroform–benzene (1:5), 500 ml. eluted 30 mg. of **22a,25D-spirost-5-en-12β-ol (VIII)**.—The infrared spectrum showed the absence of ketone and ester bands and showed absorption bands in the hydroxyl region and olefinic absorption band between 800 and 850 cm.$^{-1}$. Oxidation of VIII with pyridine–chromium trioxide produced **3-desoxygentrogenin (22a,25D-spirost-5-en-12-one IX)**, a monoketone forming a water-soluble Girard T complex. The ketone, m.p. 209–213°, $[\alpha]^{25}D$ −65°, formed prisms from ethanol and underwent sequential transition on the Kofler block to rectangular scales and then to elongated blades. The infrared spectrum of IX, $\nu_{max}^{CS_2}$ 1713 cm.$^{-1}$, was different from that of VII and showed Δ^5-unsaturation. Chloroform, 100%, eluted 110 mg. of **11-ketodiosgenin (3β-hydroxy-22a,25D-spirost-5-en-11-one, VIa)** which was unreactive to Girard T complex formation (11-ketone). The infrared spectrum showed bands at 1707 cm.$^{-1}$ (11-ketone) and at 970 and 984 cm.$^{-1}$. The analytical sample recrystallized from hexane melted from 180 to 183°, $[\alpha]^{25}D$ −76.4°. *Anal.* Calcd. for $C_{27}H_{40}O_4$: C, 75.66; H, 9.41. Found: C, 75.92; H, 9.60. The acetylated substance **11-ketodiosgenin acetate (3β-acetoxy-22a,25D-spirost-5-en-11-one, VIb)**, prepared using pyridine–acetic anhydride at room temperature, formed transparent pearly scales from aqueous methanol, $[\alpha]^{25}D$ −85°, m.p. 221–222° after incomplete transition to rhombic scales. *Anal.* Calcd. for $C_{29}H_{42}O_5$: C, 74.01; H, 9.00. Found: C, 73.69; H, 9.28. Further elution[25] with chloroform yielded 184 mg. of **11α-hydroxydiosgenin (22a,25D-spirost-5-en-3β,11α-diol, Va)**. Crystallization from hexane and from ether of the unusually soluble material gave thick, hexagonal, bladed or prism-like forms, $[\alpha]^{25}D$ −116°, m.p. 233–235° after incomplete transition over 228° to whips. *Anal.* Calcd. for $C_{27}H_{42}O_4$: C, 75.31; H, 9.83. Found: C, 75.37; H, 10.00. Acetylation of Va in pyridine–acetic anhydride on the steam-bath for 0.75 hr. gave **11α-acetoxydiosgenin acetate (3β,11α-diacetoxy-22a,25D-spirost-5-ene, Vb)**. Crystallization from methanol gave the analytical sample, m.p. 195–198°,[26] $[\alpha]^{25}D$ −116°. *Anal.* Calcd. for $C_{31}H_{46}O_6$: C, 72.34; H, 9.01. Found: C, 72.41; H, 9.33. Elution with 5% ethanol in benzene gave 160 mg. of amorphous, colorless material that did not crystallize even after acetylation and chromatography of the acetylated product.

B. Reduction of IVc with Calcium–Ammonia to Give Essentially VI.—Liquid ammonia, 1000 ml., was dried by treating with portions of calcium metal until a persisting blue color developed (1.7 g.) after which point reagent calcium, 4.2 g., was added. The steroid IVc, 14.3 g., was dissolved in 250 ml. of toluene, the volume was reduced somewhat by distillation to remove traces of water and addition was carried out during 8 minutes time. After stirring an additional 5 minutes a solution of 12 ml. of bromobenzene in 50 ml. of toluene was added to decolorize the solution after which 50 ml. of water was added cautiously. The ammonia was allowed to evaporate, the residue was taken up in ether and the ether was evaporated *in vacuo* to dryness. The residue was saponified with 10% sodium hydroxide at reflux for 0.5 hr. and isolated with ether to give a crystalline residue, 10.7 g. (92%), consisting essentially of VIa but containing a small proportion of diol Va. The ketone was eluted from a Florisil column with benzene–hexane 1:1, while chloroform was required to elute the diol. The overall yield of 11-ketodiosgenin from gentrogenin is approximately 35%.

C. Reduction of IVc with Sodium in Ammonia and with Lithium in Ammonia.—Treatment of IVc with sodium or with lithium in ammonia under reaction conditions as in procedure B gave the same products. If instead of decomposing the excess calcium metal the reaction flask is opened to the air with access to atmospheric moisture, an essentially quantitative yield of diol Va is obtained after the usual saponification.

Acknowledgment.—The authors wish to express their thanks to H. A. Walens who carried out certain experiments in ketol–acetate reductions with metal–ammonia systems, to R. B. Kelly, D. McClelland and C. L. Ogg for microanalyses, to C. Fenske for infrared spectra and to S. Serota for optical rotation measurements.

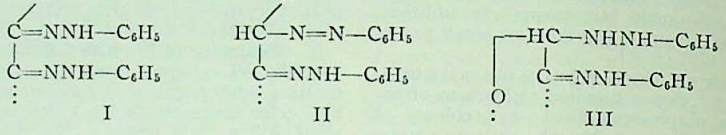
A New Interpretation of the Mutarotation of Sugar Osazones

BY LÁSZLÓ MESTER AND ADAM MAJOR

RECEIVED AUGUST 6, 1956

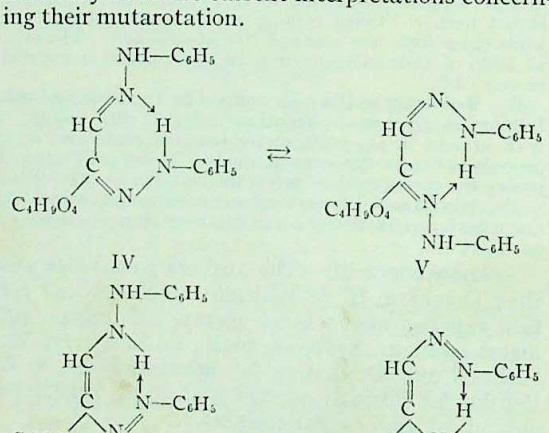
Mutarotation of a sugar osazone was first observed by Levene and Jacobs,[1] but they did not attempt to explain the phenomenon. Zerner and Waltuch[2] suggested that it should be ascribed to the tautomeric change of the bishydrazone form I into the azohydrazone form II. Haworth[3] favored the production of an equilibrium with the cyclic form III.



I II III

Discarding all earlier views, Engel,[4] in studying glucosazone, endeavored to show that mutarotation is due to hydrolysis, with phenylhydrazine splitting off.

Since evidence has lately been provided for the acyclic structure of sugar osazones[5,6,7] and since the previously postulated presence of a chelate ring (Fig. 1) has been confirmed,[5,6] it now appears necessary to revise current interpretations concerning their mutarotation.



IV V IV′ V′

Fig. 1.

Experimental

Mutarotation of D-glucose phenylosazone[9] and D-glucose-1-methylphenyl-2-phenylosazone[10] was measured (c = 0.5) in a 1:1 mixture of pyridine and ethanol at 20 ± 2°; for D-glucose phenylosazone: $[\alpha]^{20}D$ −67.3° (10 min.), −45.5° (1 hr., 10 min.), −27.7° (5 hr., 10 min.), −23.8° (8 hr.), −23.8° (11 hr., 15 min.), −23.8° (24 hr.); for D-glucose-1-methylphenyl-2-phenylosazone: $[\alpha]^{20}D$ −52.2° (10 min.), −42.1° (1 hr., 15 min.), −36.1° (2 hr.), −26.1° (5 hr., 40 min.), −24.1° (7 hr., 10 min.), −20.1° (24 hr., 5 min.). The solutions were evaporated to dryness, and mutarotation was repeated with the substances recovered without purifying them; the same mutarotations were observed.

Ultraviolet spectra were determined with a Beckman DU-type spectrophotometer in samples taken from time to time from the above solutions and diluted with ethanol to 0.0001 mole (Fig. 2 for D-glucose phenylosazone).

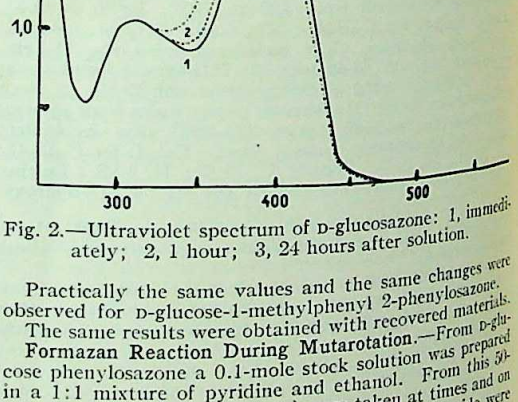


Fig. 2.—Ultraviolet spectrum of D-glucosazone: 1, immediately; 2, 1 hour; 3, 24 hours after solution.

Practically the same values and the same changes were observed for D-glucose-1-methylphenyl 2-phenylosazone.

The same results were obtained with recovered materials.

Formazan Reaction During Mutarotation.—From D-glucose phenylosazone a 0.1-mole stock solution was prepared in a 1:1 mixture of pyridine and ethanol. From this 50-ml. samples (1.8 g. of osazone) were taken at times and on adding 50 ml. of 2 N alcoholic potassium hydroxide were coupled to formazan with diazo solution prepared from 0.75 g. of aniline.[5] The crude formazans obtained were twice recrystallized from a mixture of four times the volume of pyridine and ten times the volume of ethanol; m.p. 198°.

Simultaneously, samples taken from the stock solution were diluted with a 1:1 mixture of pyridine and ethanol (c = 0.5), and the rotational changes observed. On completion of the mutarotation the stock solution was evaporated to dryness *in vacuo* and the above experiment repeated with the substances obtained without purifying them (Fig. 3).

Mutarotation of tetra-O-acetyl-D-galactose phenylosazone[11] was measured in dioxane (c = 0.5): $[\alpha]^{20}D$ +56° (10 min.), +80° (1 hr., 35 min.), +80° (38 hr., 40 min.). The solution on concentration to dryness, yielded the osazone unchanged; dissolving the recovered material in dioxane gave the same rotational values.

The ultraviolet spectra were determined in samples taken from time to time from the mutarotational solution and diluted with dioxane to 0.0001 mole. They showed the same changes for both the original and the recovered material, and these changes were identical with those for D-glucose phenylosazone.

4-Desoxy-L-glycerotetrose phenylosazone dissolved in pyridine was subjected to mutarotation and evaporated to dryness; the osazone recovered was again dissolved in pyridine, and once more the mutarotation as described by Fried, *et al.*,[12] was observed.

Result and Discussion

Since mutarotation, spectral displacement and formazan formation after distillation of the solvent in the redissolved substance are reiterating processes, Engel's[4] view that mutarotation depends on the hydrolysis of osazones seems to be excluded.

The reaction of the glucosazone with the diazo solution in samples taken from the mutarotating solution yields less and less osazone formazan (Fig. 2). This is due obviously to the same structural change which is optically perceivable during mutarotation. Since Haworth's cyclic formula III is unable to yield formazan, the transformation of the two anomers into each other cannot possibly be regarded as the cause of mutarotation. It now remains to be ascertained whether the open-chain compound I changes into Haworth's cyclic form III during mutarotation. Were it so, owing to the disappearance of one chromophoric group, the maximum of the ultraviolet spectrum would have to show a substantial alteration of the characteristics.[5]

The observations of Weygand, *et al.*,[13] on the mutarotation of 5,6-di-O-methyl-D-glucose *p*-bromophenylosazone, and those of Gorin, *et al.*,[14] on the mutarotation of L-*glycero*tetrulose phenylosazone and its derivatives, leave no room for a concept which holds that mutarotation might be caused by cyclization departing from the second carbon.

Finally, the mutarotation in tetra-O-acetyl-D-glucose phenylosazone,[11] in tetra-O-acetyl-D-galactose phenylosazone and in 4-desoxy-L-glycero-D-tetrose phenylosazone,[12] can in no way be explained by cyclization, since in these cases there is definitely no possibility for ring formation to take place.[15]

It also seems impossible that a stable conjugated system I of double bonds should change into an unstable compound II of isolated double bonds, as has been suggested by Zerner and Waltuch.[2] Nevertheless, on the evidence of our findings above it would appear that the real cause of the mutarotation is to be sought in the electron displacement which takes place in the chelate structure of the osazones upon the action of the solvent,[17-19] and which amongst others reveals itself in a displacement of the ultraviolet spectra and in a decrease of the coupling capacity.

The two latter observations suggest the conclusion that in the course of mutarotation there is a structural shift from somewhere near the IV state toward the IV′ state, since while the former is suitable, the latter is definitely unsuited for coupling and for the change in the ultraviolet spectra, the above structural shift seem to be responsible.[24,26]

(17) Reference is made to Burawoy, *et al.*,[18] concerning 1-phenylazo-2-naphthol and 1,2-naphthoquinon-2-phenylhydrazone, the chelate structure of which can be influenced by the solvent.

(18) A. Burawoy, A. G. Salem and A. R. Thompson, *J. Chem. Soc.*, 4793 (1952).

(19) There are several references in the literature pointing out that an α,β-unsaturated azo-structure forms in the *p*-nitrophenylhydrazones of unsaturated ketones[20-22] and that the rearrangement of hydrazone of the compound of azo-structure takes place upon the action of a solvent, finally that this is a somewhat slow process causing changes in the optical rotation.[23]

(23) W. F. McGuckin and E. C. Kendall, THIS JOURNAL, **74**, 5812 (1952).

(24) As regards D-glucose 1-methylphenyl-2-phenylosazone, of the chelate structures proposed by Fieser and Fieser[25] the V and V′ structures must be discarded because of the presence of the methyl group, and only the IV and IV′ structures can be taken into consideration. In our view, the extraordinary resemblance of the mutarotation, the ultraviolet spectrum and the polarographic behavior of glucosazon

Experiments to disclose the mechanism of this structural displacement are in progress.

to those of glucose-1-methylphenyl-2-phenylosazone justifies discarding the V and V′ formulas of glucosazone as well. All the more so, as the methylation of glucosazone, as has already been pointed out,[5] invariably leads to D-glucose-1-methylphenyl 2-phenylosazone derivable from the IV and IV′ forms, and so, so far, it has proved impossible to prepare methylated D-glucosazone from the chelate structures V and V′ neither by direct methylation nor in some roundabout way. The so-called mixed osazone B, which could be supposed to possess this structure, has been proved to be D-glucosazone contaminated with mixed osazone A.[5]

Acknowledgment.—We wish to express our indebtedness to Professor G. Zemplén for valuable advice given and to thank Dr. W. Cieleszky for the determination of the ultraviolet spectra, finally, Miss Ilona Batta for the microanalyses.

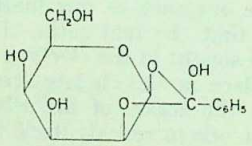
1-*O*-Benzoyl-α-D-talopyranose

BY HARRY B. WOOD, JR., AND HEWITT G. FLETCHER, JR.

RECEIVED JANUARY 26, 1957

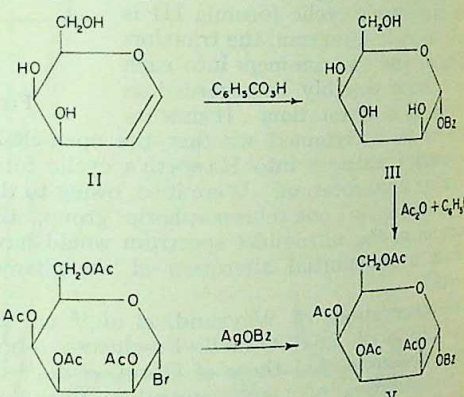
Oxidation of D-galactal with perbenzoic acid has given a new D-talose monobenzoate. Acetylation of this ester afforded an amorphous ester which is identical with 2,3,4,6-tetra-*O*-acetyl-1-*O*-benzoyl-α-D-talose synthesized from 2,3,4,6-tetra-*O*-acetyl-α-D-talopyranosyl bromide. The new substance is, therefore, 1-*O*-benzoyl-α-D-talopyranose. The possible structure of another D-talose monobenzoate, described earlier in the literature, is discussed.

In 1937, Pigman and Isbell[1] described a mono-*O*-benzoyl-D-talose which they had obtained as a by-product in the preparation of D-talose *via* the oxidation of D-galactal (II) with perbenzoic acid. Owing to the fact that the substance was stable in dilute acid solution but mutarotated in water, methanol, dilute alkali and pyridine, a cyclic orthoacid structure (I) was assigned to it.



I

The lability of this substance compared with the stability of the well-characterized 1-*O*-benzoyl-β-D-glucopyranose prepared somewhat earlier by Zervas[2] and the widespread currency of the cyclic orthoacid concept which had first been suggested by Emil Fischer,[3] combined to make such a tentative assignment of structure a reasonable one at that period.[4] However, subsequent advances in the chemistry of the sugar esters have shown (a) that acyl groups are very prone to migrate from C_1 to C_2 of an aldose when the hydroxyl at C_2 is free and spatially accessible to C_1[5,6] and (b) that cyclic orthoacid structures such as I are not likely to be sufficiently stable for isolation.[6] Furthermore, Isbell and his co-workers[7] have shown recently that the sample of D-talose monobenzoate prepared in 1937 had undergone no change in physical properties during the intervening years and was indeed a normal ester as shown by its characteristic ester carbonyl absorption in the infrared.



II III IV V

In all known additions to the double bond of glycals[8] the anionic portion of the adding molecule has been found attached to C_1 of the sugar and it seems reasonably certain, therefore, that the substance reported by Pigman and Isbell is a 1-*O*-benzoyl-D-talopyranose. Its failure to mutarotate in acid solution[1] and to give a phenylhydrazone[7] appear to support this assumption. The mutarotations in water, methanol, dilute alkali and pyridine reported by Pigman and Isbell[1,7] may then represent acyl migration from C_1 to C_2 or some other position. Indeed these mutarotations, which start in a *levo* direction and then turn in the *dextro* direction, suggest that an initial acyl migration frees a β-hydroxyl at C_1 and that normal equilibration of the anomeric forms then ensues. If the instability of the ester is due to a $C_1 \rightarrow C_2$ migration we must expect it to be the β- rather than the α-1-*O*-benzoyl-D-talopyranose, for such a *cis* isomer would resemble the easily rearranged 1-*O*-mesitoyl-α-D-glucose[5] and 1,3,5-tri-*O*-benzoyl-α-D-ribose[6] while the

α-(*trans*) isomer should be similar in stability to the well-known 1-*O*-benzoyl-β-D-glucopyranose.

On the other hand, the mechanism postulated for the oxidation of double bonds by per-acids[9,7] is such as to lead to *trans* products and this generalization has been made specifically for perbenzoic acid by Posternak and Friedli.[10] Levene and Tipson,[11] for instance, obtained 3,4,6-tri-*O*-acetyl-1-*O*-benzoyl-β-D-galactopyranose through the action of this reagent on D-galactal triacetate.[12] In the hope of throwing some light on these apparently contradictory indications[13] we have now re-examined the reaction of D-galactal with perbenzoic acid.

Preliminary experiments, following the directions which Pigman and Isbell[1] described for the aqueous oxidation of D-galactal, failed to yield us a crystalline, water-soluble product having ester carbonyl absorption. However, the second, non-aqueous oxidation procedure of these authors readily afforded a crystalline monobenzoylhexose; minor changes in the work-up procedure raised the yield to 13%. However, the physical constants of this monobenzoylhexose as shown in Table I clearly distinguish our substance from that described by the earlier authors. Not only does the new substance have an infrared absorption spectrum which distinguishes it from that reported earlier[1] but its stability is markedly greater, no mutarotation being detected in water, methanol or pyridine. All our attempts to obtain a product similar to Pigman and Isbell's have thus far failed although the oxidation produced, in addition to the new crystalline product, a large quantity of amorphous material which, upon acid hydrolysis, afforded D-talose and benzoic acid.

TABLE I

PROPERTIES OF D-TALOSE MONOBENZOATES

	Compound of Pigman and Isbell[1,7]	1-*O*-Benzoyl-α-D-talopyranose
$[\alpha]^{25}D$ in water	+21.2 (0.08 hr.) → + 5.1° (54 hr.) → 24.2° (648 hr.)	+72.4°
$[\alpha]^{25}D$ in 0.01 *N* HCl	+22.6°	+72.5°
$[\alpha]^{25}D$ in methanol	+15.4° (2.96 min.) → −33.3° (60.1 min.) → +11° (2550 min.)	+74°
$[\alpha]^{25}D$ in pyridine	+16.5° (0.1 hr.) → −12.5° (191.3 hr.) → + 4.8° (430.5 hr.)	+53°

The nature of the new monobenzoyl hexose was investigated in the following fashion. Infrared absorption measurements showed the presence of a normal ester carbonyl group. Hydrolysis with barium methoxide afforded crystalline D-talose in good yield.[14] In glacial acetic acid solution the compound consumed two moles of lead tetraacetate. Since the substance showed no mutarotation in pyridine, a sample was acetylated in this solvent. Unfortunately the product could be obtained only as a sirup, but chromatography readily gave a homogeneous fraction which had the composition of a tetra-*O*-acetyl-*O*-benzoylhexose and showed $[\alpha]^{20}D$ +84° in chloroform.

The known, crystalline 2,3,4,6-tetra-*O*-acetyl-D-talosyl bromide (IV)[1] was treated with silver benzoate under anhydrous conditions to give a sirup which, after chromatography, rotated $[\alpha]^{20}D$ +83° in chloroform. The infrared spectra of the sirups from the two sources (III and IV) were identical in all respects. Since such reactions of acylated glycosyl halides normally lead to products with groups on C_1 and C_2 in the *trans* relationship[15] we conclude that the product is 2,3,4,6-tetra-*O*-acetyl-1-*O*-benzoyl-α-D-talose (V) and that our monobenzoate is 1-*O*-benzoyl-α-D-talopyranose (III).

In the light of our knowledge of the behavior of 1-acyl aldoses, the relative stability of 1-*O*-benzoyl-α-D-talopyranose (III) is wholly normal; in a negative sense the evidence here adduced lends support to the supposition that the compound made by Pigman and Isbell may be, despite its origin, the β-anomer, 1-*O*-benzoyl-β-D-talopyranose.[16]

Experimental[17]

1-*O*-Benzoyl-α-D-talopyranose (III).—The procedure followed for the oxidation was modeled after that of Isbell and Pigman[1]; repeated trials led, however, to a modified method of isolation, giving higher yields of crystalline product. D-Galactal[18] (10 g.) and benzoic acid (10 g.) were dissolved in a mixture of 300 ml. of dioxane and 200 ml. of acetone. The solution was cooled to +5° and a methylene chloride solution (167 ml.) containing perbenzoic acid (18 g.)[19] added. After stirring, the solution was held at 0° for 24 hr. and then at 5° for 24 hr. Solvent was then removed *in vacuo* at less than 30° and the resulting semi-crystalline

(9) Cf. W. A. Waters in "Organic Chemistry," ed. by H. Gilman, John Wiley & Sons, Inc, New York, N. Y., 1953, p. 1165.

(10) T. Posternak and R. S. Tipson, *J. Biol. Chem.*, **93**, 631 (1931). These authors found that further acetylation of their tri-*O*-acetyl-α-D-galactosyl bromide with silver benzoate. As will be mentioned later, such a condensation produces *trans* products.

(11) P. A. Levene and R. S. Tipson, *Helv. Chim. Acta*, **36**, 251 (1953). acetyl-1-*O*-benzoyl-D-galactopyranose afforded a product identical with that which they obtained through condensation of 2,3,4,6-tetra-*O*-

(12) Naturally, the identification of the parent sugar as D-talose, rather than D-galactose, is vital here. While Pigman and Isbell's evidence in this regard seemed unequivocal we have hydrolyzed a minute sample of their material and, by paper partition chromatography in a suitable solvent system, confirmed the fact that talose and only talose is present.

(14) To ensure the absence of alkali-induced rearrangements here, the reaction mixture was chromatographed on paper using a system known to separate talose and galactose. Only one spot was observed; chromatography of an acid hydrolyzed mixture gave identical results.

(15) As far as the present authors are aware, this generalization was first made by R. S. Tipson [*J. Biol. Chem.*, **130**, 55 (1939)] and first received theoretical interpretation by H. S. Isbell, *Ann. Revs. Biochem.*, **9**, 65 (1940); *J. Research Natl. Bur. Standards*, **26**, 35 (1941). It should be noted that while the high dextrorotation of tetra-*O*-acetyl-D-talopyranosyl bromide ($[\alpha]^{20}D$ +165.6° in $CHCl_3$; see ref. 1) indicates that the substance is almost certainly the α-anomer, the validity of the evidence presented here is independent of the anomeric configuration of this halide.

(16) It may be noted here that lead tetraacetate oxidation of 1-*O*-benzoyl-β-D-talopyranose and of 1-*O*-benzoyl-β-D-glucopyranose should produce the same dialdehyde and thus possibly provide a simple proof of the anomeric configuration of the D-talose monobenzoate reported by the earlier authors. Unfortunately the quantity of material available to us precluded such a test.

(17) Melting points are corrected for stem exposure.

(18) 3,4,6-Tri-*O*-acetyl-D-galactal was prepared by the method of C. Tamm and T. Reichstein [*Helv. Chim. Acta*, **31**, 1630 (1948)]; deacetylation with anhydrous, methanolic ammonia [R. Kuhn and H. H. Baer, *Chem. Ber.*, **88**, 1537 (1955)] gave D-galactal which showed $[\alpha]^{20}D$ −21.3° (MeOH, *c* 1.2) and gave satisfactory analyses for carbon and hydrogen.

(19) Perbenzoic acid was prepared by the method of G. Braun ["Organic Syntheses," Coll. Vol. I, 2nd ed., John Wiley and Sons, Inc., New York, N. Y., 1941, p. 431], the final extraction being made with methylene chloride and the extract, dried over sodium sulfate, used directly after titration of an aliquot to determine the perbenzoic acid content.

mass extracted with benzene–pentane (3 × 100 ml. of 1:2 v./v.). The mixture was dissolved in 100 ml. of water and the resulting solution extracted thrice with 1:2 benzene–pentane to remove remaining traces of acid. The aqueous solution was then extracted continuously with warm ether until no further material was removed. On concentration, the ethereal extract afforded crude crystalline product (2.6 g., 13%). Recrystallization from either ethyl acetate, acetone or 1,2-dimethoxyethane gave, with little loss, pure material melting at 165–166° and rotating $[\alpha]^{20}D$ +72.4° (H_2O, *c* 0.5), no mutarotation being observed within 1 hr. Rotations in other solvents were observed as follows: 0.01 *N* HCl, $[\alpha]^{20}D$ +72.5° (*c* 0.5); methanol, $[\alpha]^{20}D$ +74° (*c* 0.49); pyridine, $[\alpha]^{20}D$ +53° (*c* 1.1).

Anal. Calcd. for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67. Found: C, 54.84; H, 5.78.

A sample (36.5 mg.) of the substance was treated with lead tetraacetate in glacial acetic acid as described by Hockett and McClenahan.[20] After 355, 1340 and 1867 minutes, analyses indicated the consumption of 1.98, 2.09 and 2.07 molar equivalents of oxidant.

D-Talose from 1-*O*-Benzoyl-α-D-talopyranose (III).—A sample (0.1616 g.) of the ester was dissolved in absolute methanol to make a total volume of 10 ml. and the rotations observed in a 1.5-dm. tube. Over a period of 8 min. at 20° no change was observed, the rotation corresponding to $[\alpha]^{20}D$ +72.8°. Four drops of 1.3 *N* barium methoxide was then added. After 43 min. the rotation had become constant at a value of +0.34°, corresponding to $[\alpha]^{20}D$ +22.7°, based on the theoretical yield of hexose. Barium ions were removed with Amberlite IR-120 and the solution concentrated *in vacuo* to a sirup. From ethanol the handsome prisms characteristic of D-talose were deposited: 0.065 g. (64%), m.p. 130–131°, $[\alpha]^{20}D$ +20.1° (H_2O, *c* 1.2). Isbell and Pigman[21] recorded m.p. 133–134° and $[\alpha]^{20}D$ +20.8° (H_2O, *c* 4) for pure D-Talose.

2,3,4,6-Tetra-*O*-acetyl-1-*O*-benzoyl-α-D-talose (V). (a) From 1-*O*-Benzoyl-α-D-talopyranose (III).—To a mixture of 2 ml. of pyridine and 10 ml. of acetic anhydride cooled to 0° was added 1.0 g. of 1-*O*-benzoyl-α-D-talopyranose. After 3 days at 0° the reaction mixture was poured into cold water and worked up in the usual fashion. The sirup (1.41 g., 89%) which resisted all attempts at crystallization was dissolved in 4:1 hexane–benzene and adsorbed on a column of 56 g. of alumina.[22] Successive elution with 4:1 hexane–benzene, benzene and 1:1 benzene–ether eluted no material from the adsorbent. With ether a well-defined "peak" was eluted; several of the amorphous fractions before and at the top of the peak showed $[\alpha]^{20}D$ +84° in chloroform (*c* 0.3).

Anal. Calcd. for $C_{21}H_{24}O_{11}$: C, 55.75; H, 5.35. Found: C, 56.18; H, 5.51.

(b) From 2,3,4,6-Tetra-*O*-acetyl-α-D-talosyl Bromide (IV).—A mixture of 2,3,4,6-tetra-*O*-acetyl-α-D-talosyl bromide (6.5 g., m.p. 83–84°[23]), silver benzoate (10 g.) and benzene (50 ml.) was stirred at room temperature for 1 hr. and then filtered. Removal of solvent from the filtrate gave a sirup (6.5 g.) which could not be induced to crystallize. The sirupy product was, therefore, chromatographed on alumina as described in part (a) above. Elution with ether afforded a number of fractions showing $[\alpha]^{20}D$ +83° in chloroform; these were combined and rechromatographed to give a clear, colorless sirup showing $[\alpha]^{20}D$ +83° in chloroform (*c* 0.66).

Anal. Calcd. for $C_{21}H_{24}O_{11}$: C, 55.75; H, 5.35. Found: C, 55.96; H, 5.54.

Infrared absorption spectra of solutions of the products from (a) and (b) above appeared to be identical in all respects.

Acknowledgments.—We wish to express our indebtedness to Dr. H. S. Isbell for his helpful cooperation and interest in this research. We also wish to thank Mr. H. W. Diehl for the preparation of a quantity of D-galactal. Analytical determinations and absorption spectra measurements were carried out in the Institutes' microanalytical laboratory under the direction of Dr. W. C. Alford.

(22) "Alcoa" alumina, Grade F-20, mesh 80–200 manufactured by the Aluminum Company of America, Pittsburgh, Pa., was washed thoroughly with 5% hydrochloric acid and then with water until neutral. After activation at 200° the material was deliberately exposed to atmospheric humidity before use. The adsorptive capacity of alumina thus treated is inferior to that which has been kept under rigorously anhydrous conditions but its reproducibility is superior and the use of such partially hydrated alumina has the marked advantage of obviating the use of specially dried eluents.

(23) Pigman and Isbell (ref. 1) reported m.p. 84–84.5° for this substance.

Synthesis of Cycloserine and a Methyl Analog

BY CHARLES H. STAMMER, ANDREW N. WILSON, CLAUDE F. SPENCER, FRANK W. BACHELOR, FREDERICK W. HOLLY AND KARL FOLKERS

RECEIVED DECEMBER 29, 1956

DL-4-Carbomethoxy-2-phenyl-2-oxazoline (V) was converted into the corresponding hydroxamic acid VI. Dry hydrogen chloride in dioxane opened the oxazoline ring to a β-chloropropionohydroxamic acid which in aqueous alkali formed DL-4-benzamido-3-isoxazolidone (VIII). Treatment of VIII with ethanolic hydrogen chloride gave the aminoxy ester IX which cyclized in potassium hydroxide solution to DL-4-amino-3-isoxazolidone (X) (DL-cycloserine). The L-form of VIII was synthesized by the same series of reactions from L-serine. Both the benzamido (VIII) compound and DL-cycloserine were resolved. DL-4-Amino-5-methyl-3-isoxazolidone (XII) was synthesized from DL-threonine by the same series of reactions.

Cycloserine,[1] a broad-spectrum antibiotic, has been shown to be D-4-amino-3-isoxazolidone.[2,3] Preliminary reports of syntheses[3,4] of the racemate DL-4-amino-3-isoxazolidone (X) and a resolution[4] of the racemate have been published. The details of our synthesis and resolution together with the synthesis of an analog, DL-4-amino-5-methyl-3-isoxazolidone (XII), are described in this paper.

Since 3-isoxazolidone (I) had been synthesized[5]

(1) Cycloserine has been accepted as the generic name for this antibiotic. Oxamycin is now the trademark of Merck & Co., Inc., for cycloserine.

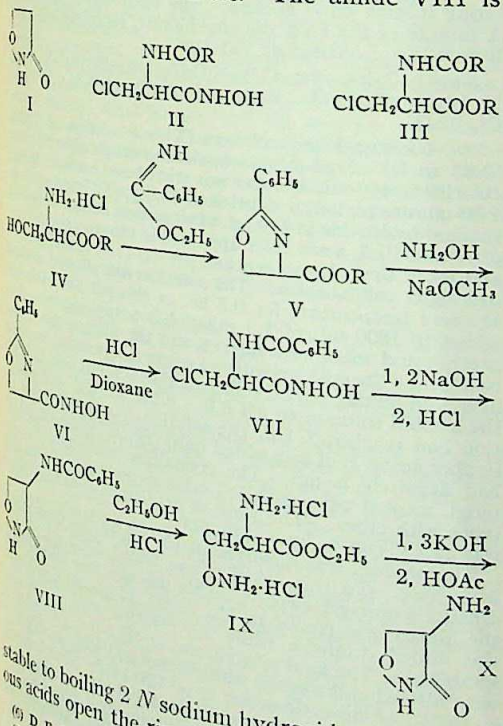
by cyclization of β-chloropropionohydroxamic acid, a key intermediate for synthesis of cycloserine appeared to be a β-chloro-α-acylaminopropionohydroxamic acid (II). The preparation of such a hydroxamic acid from the corresponding ester III was complicated by side reactions occurring in the necessarily alkaline reaction medium. Consequently, a structure was needed which was stable to alkali and convertible to the β-chloro-α-acylaminopropionohydroxamic acid. An oxazoline fulfils both of these requirements and was used in this synthesis.

DL-Serine methyl ester hydrochloride (IV, R = CH_3) was converted into DL-4-carbomethoxy-2-phenyl-2-oxazoline (V, R = CH_3) by the procedure of Elliott.[6] This ester yielded 4-carbohydroxamido-2-phenyl-2-oxazoline (VI) when treated with one equivalent each of hydroxylamine and sodium methoxide in methanol at room temperature. When the hydroxamic acid VI was heated on a steam-bath for 15 minutes in dioxane containing one equivalent of hydrogen chloride, α-benzamido-β-chloropropionohydroxamic acid (VII) was formed.[7] The β-chloropropionohydroxamic acid (VII) was cyclized to 4-benzamido-3-isoxazolidone (VIII) by aqueous alkali.[8]

Removal of the benzoyl group from the benzamidoisoxazolidone VIII by either acid or alkaline hydrolysis was not feasible. The amide VIII is

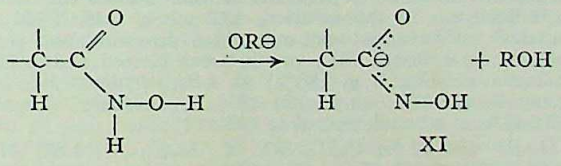


stable to boiling 2 *N* sodium hydroxide, while aqueous acids open the ring in addition to cleaving the amide. However, boiling ethanol saturated with hydrogen chloride removed the benzoyl group and also opened the isoxazolidone ring giving the hydrochloride of DL-β-aminoxyalanine ethyl ester (IX).[2] When this ester was treated with potassium hydroxide in aqueous solution, it cyclized rapidly to DL-cycloserine (X).

The resolution of DL-4-amino-3-isoxazolidone was accomplished with tartaric acid. Treatment of DL-cycloserine with D-tartaric acid gave D-4-amino-3-isoxazolidone-D-tartrate. This salt was converted by Amberlite IR-120 resin into D-4-amino-3-isoxazolidone, which was identical in all respects to cycloserine. Thus, the structure of cycloserine, deduced from degradation studies,[2,3] has been confirmed by synthesis. Using L-tartaric acid as resolving agent, we were able to prepare the unnatural L-cycloserine by the same procedure.

DL-4-Benzamido-3-isoxazolidone (VIII) was also resolved. This compound formed a crystalline cinchonidine metho-salt which on treatment with acid gave D-4-benzamido-3-isoxazolidone.

L-Serine ethyl ester hydrochloride (IV, R = C_2H_5) was prepared and converted into the optically active oxazoline ester (V, R = C_2H_5). When this ester was converted into the oxazoline hydroxamic acid VI by the procedure used on the racemic ester, about 50% racemization occurred. Variation of the reaction time, temperature or order of addition of the reactants to each other did not decrease the amount of racemization. It was interesting to note that the optically active hydroxamic acid VI did not racemize on standing in 0.1 *N* methanolic sodium methoxide overnight, but that the optically active ester V racemized so rapidly that its rotation in 0.1 *N* methanolic sodium methoxide when taken immediately was zero.[9] It is well known[10]



that optically active carboxylic acids racemize only with difficulty in alkali, whereas the corresponding esters racemize readily. Thus, the optical stability of the oxazoline hydroxamic acid in alkali may indicate that in the salt the negative charge resides next to the α-carbon (XI) just as the charge on a carboxylic acid salt does. This interpretation conflicts with the view[11] that hydroxamic acid salts have the charge on the hydroxyl oxygen.

The L-oxazoline hydroxamic acid VI was separated from its racemate by fractional crystallization. The 4-benzamido-3-isoxazolidone (VIII) formed from the L-hydroxamic acid VI by the reactions shown in the flow sheet was the optically pure L-4-benzamido-3-isoxazolidone. The conversion of this compound to L-cycloserine was not carried out,

(6) D. P. Elliott, *J. Chem. Soc.*, 589 (1949).

(7) Rearrangements of oxazoline hydrochlorides to β-haloalkylamides have been discussed by E. M. Fry, *J. Org. Chem.*, **14**, 887 (1949); **15**, 438, 802 (1950).

(8) There is a surprisingly large effect of temperature on the direction of the reaction between the β-chloropropionohydroxamic acid (VII) and aqueous alkali. At room temperature these reactants gave the oxazoline hydroxamic acid VI in 79% yield, but at 60–65° the isoxazolidone VIII was isolated in 82% yield. The oxazoline VI was not converted into VIII by aqueous alkali at 60–65°.

(9) In the light of our work, a report by Fry, *J. Org. Chem.*, **15**, 438 (1950), that the oxazoline ester (V, R = CH_3) is hydrolyzed in aqueous alkali to the corresponding acid *without racemization* was surprising. We confirmed this result. Apparently, in this case the rate of saponification is much greater than that of racemization.

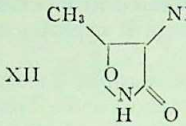
because the resolution of DL-cycloserine had been accomplished previously.

DL-4-Amino-5-methyl-3-isoxazolidone (XII), an analog of cycloserine, was synthesized from DL-



XII

threonine by the reaction series already described. This compound has two asymmetric centers and thus may exist as two DL-pairs. Our synthesis gave only one DL-pair since DL-threonine was used as starting material.[12]

Acknowledgment.—We are indebted to Dr. N. R. Trenner and Mr. R. W. Walker for infrared analyses and to Mr. R. N. Boos and associates for microanalyses.

Experimental

All melting points were taken on a Kofler micro hot-stage.

DL-4-Carbomethoxy-2-phenyl-2-oxazoline (V).—This compound was prepared by allowing ethyl benzimidate[13] and serine methyl ester hydrochloride[6] to react according to the procedure of Elliott.[6] A 45% yield of the oxazoline ester, b.p. 118–122° (0.15 mm.), $n^{24}D$ 1.5480, was obtained.

DL-4-Carbohydroxamido-2-phenyl-2-oxazoline (VI).—To a cooled solution of 4 g. (0.06 mole) of hydroxylamine hydrochloride in 100 ml. of absolute ethanol was added 35 ml. of 1.82 *N* (0.06 mole) sodium methoxide in methanol. The mixture was cooled to 0°, the sodium chloride was filtered and a solution of 10 g. (0.05 mole) of 4-carbomethoxy-2-phenyl-2-oxazoline in 20 ml. of ethanol was added to the filtrate. This solution was cooled to 0°, and 25 ml. of 1.82 *N* (0.05 mole) sodium methoxide was added slowly. The reaction mixture was allowed to stand overnight. The solution was concentrated *in vacuo* at room temperature to about 75 ml. When about 100 ml. of water was added to the solution, rapid and exothermic crystallization of what was probably the sodium salt of the oxazoline hydroxamic acid occurred. Further addition of water caused the solid to redissolve. To this solution, 43.3 ml. of 1.16 *N* (51.5 mmoles) hydrochloric acid was added dropwise, and the product crystallized. The product was filtered and dried *in vacuo* yielding 8 g. (80%) of 4-carbohydroxamido-2-phenyl-2-oxazoline, m.p. 174–176°. A sample, recrystallized from ethanol, melted at 176–179° dec.

Anal. Calcd. for $C_{10}H_{10}N_2O_3$: C, 58.20; H, 4.88; N, 13.60. Found: C, 58.38; H, 5.05; N, 13.41.

Our subsequent work indicated that the reaction of the oxazoline ester V with hydroxylamine and sodium methoxide is complete after 15 minutes at 0°.

DL-α-Benzamido-β-chloropropionohydroxamic Acid (VII).—To a mixture of 4 g. (0.02 mole) of 4-carbohydroxamido-2-phenyl-2-oxazoline and 50 ml. of dry dioxane, was added 44 ml. of 0.46 *N* hydrogen chloride (0.02 mole) in dry dioxane, and the resulting mixture was heated on a steam-bath for 15 minutes. During the heating period, the solution became pink and then colorless, and the solid dissolved. The hot solution was filtered and evaporated *in vacuo* to a thick mass of crystals. These crystals were dissolved in approximately 25 ml. of hot isopropyl alcohol, and 175 ml. of low-boiling petroleum ether was added slowly to the solution. Crystallization occurred and, after two days at 5°, the DL-α-benzamido-β-chloropropionohydroxamic acid, 4.4 g., m.p. 148–152°, was filtered. A second crop, weighing 0.2 g., brought the total yield to 94%. A small sample, recrystallized from isopropyl alcohol–petroleum ether, melted at 153–155°.

Anal. Calcd. for $C_{10}H_{11}N_2O_3Cl$: C, 49.40; H, 4.56; N, 11.54; Cl, 14.60. Found: C, 48.94; H, 4.49; N, 11.77; Cl, 14.31.

DL-4-Benzamido-3-isoxazolidone (VIII).—To a solution of 4.0 g. (0.017 mole) of α-benzamido-β-chloropropionohydroxamic acid in about 30 ml. of hot methanol was added dropwise 31.5 ml. of 1.0 *N* sodium hydroxide (0.032 mole, 1.9 equivalents). When 16 ml. of the sodium hydroxide solution had been added, a phenolphthalein end-point was reached; the solution was heated to 60°, the remaining alkali was added and the end-point became permanent. To the cold basic solution, 4.2 ml. of 1.16 *N* hydrochloric acid (0.017 mole) was added, and the solution was immediately extracted with one 100-ml. portion and five 50-ml. portions of chloroform. The combined chloroform extracts were concentrated to about a 225-ml. volume, filtered and further concentrated to a 200-ml. volume. Crystallization began and, after the mixture was cooled, 2.1 g. of DL-4-benzamido-3-isoxazolidone, m.p. 167–170°, was filtered. A second crop weighed 0.5 g., m.p. 158–168° (total yield 75%). An analytical sample melting at 165–168° was obtained by recrystallization of the crude product from ethyl acetate.

Anal. Calcd. for $C_{10}H_{10}N_2O_3$: C, 58.24; H, 4.89; N, 13.59. Found: C, 58.45; H, 4.70; N, 13.37.

DL-β-Aminoxyalanine Ethyl Ester Dihydrochloride (IX).—A rapid stream of hydrogen chloride was passed for 3 hr. into 2500 ml. of absolute ethanol cooled in an ice-bath. To this solution was added 100 g. (0.48 mole) of DL-4-benzamido-3-isoxazolidone, and this solution was refluxed for 3 hr. After standing at 3–5° overnight, the solution was concentrated at reduced pressure giving 83 g. of DL-β-aminoxyalanine ethyl ester dihydrochloride, m.p. 128–135°. An additional 3.6 g. of product was obtained by concentrating the mother liquor to about a 300-ml. volume and diluting it with ethyl acetate. The yield was 87 g. (81%). A sample of the ester dihydrochloride, recrystallized twice from ethanol, melted at 123–130°.

Anal. Calcd. for $C_5H_{14}N_2O_3Cl_2$: C, 27.16; H, 6.38; N, 12.67; Cl, 32.07. Found: C, 28.09; H, 6.35; N, 12.63; Cl, 32.00.

DL-4-Amino-3-isoxazolidone (X).—A solution of 73.3 g. (0.33 mole) of DL-β-aminoxyalanine ethyl ester dihydrochloride in 100 ml. of water was stirred and cooled. During a 30-minute period, a solution of 65.6 g. (1.17 moles) of potassium hydroxide in 100 ml. of water was added. Between *p*H 7 and 10.5, a red color appeared in the reaction mixture; and when the solution reached *p*H 11–11.5, it had changed to a light yellow color. The solution was allowed to stand at room temperature for 0.5 hr. at this *p*H and then was added to 1800 ml. of 1:1 ethanol–isopropyl alcohol. The precipitated salts were filtered and the filtrate was cooled to 5°. To the cold well-stirred solution was added dropwise over a 35-minute period sufficient glacial acetic acid to bring the alcohol solution to *p*H 6.0. When the *p*H of the solution had reached 7–7.5, the solution was seeded; and no further acetic acid was added until crystallization of the oil had definitely begun. The crystalline precipitate was filtered, washed twice with 1:1 ethanol–isopropyl alcohol and twice with ether. The yield of DL-4-amino-3-isoxazolidone was 22.7 g. (65%), m.p. 140–143°.

The product was dissolved in 152 ml. of 7% ammonium hydroxide. To this solution was added 1215 ml. of 1:1 ethanol–isopropyl alcohol. This mixture was filtered and the filtrate was cooled to 5°; 21 ml. of glacial acetic acid was added dropwise while the solution was seeded and scratched. The final solution was at *p*H 6.0. The crystals were filtered and washed with ethanol and ether giving 17.7 g. (52%) of DL-cycloserine, m.p. 137–140°. The infrared spectrum showed absorption in the 6.1–6.6 μ region characteristic of the zwitterion form of cycloserine. The spectra of the racemic and natural compounds differed in the 10–12 μ region.

Anal. Calcd. for $C_3H_6N_2O_2$: C, 35.29; H, 5.90; N, 27.45. Found: C, 35.11; H, 5.70; N, 27.14.

Resolution of DL-4-Amino-3-isoxazolidone.—A solution of 7.5 g. of D-tartaric acid in 25 ml. of water was cooled to 3°. To this solution was added rapidly 5.0 g. (0.05 mole) of DL-cycloserine and the mixture was stirred vigorously. Crystallization began almost immediately. After ten minutes, the crystals were filtered and washed with 5 ml. of cold water and three 20-ml. portions of acetone yielding

(12) The oxazoline ring opening and isoxazolidone ring closure are most probably S_N2 reactions, each of which inverts the β-carbon atom. Since the starting amino acid had the *threo* configuration, the aminoisoxazolidone XII should also have the *threo* configuration. The methyl and amino groups of XII will thus be *cis*.

cycloserine-D-tartrate, 5.2 g. (84%), m.p. 166–168° dec., $[\alpha]^{25}D$ +35.7° (*c* 0.7 in H_2O).

The D-cycloserine-D-tartrate was passed through a column of 200 g. of Amberlite IR-120 (Na^+ cycle). The column was washed free of sodium tartrate (eluate tested with lead acetate) with water, and D-cycloserine was eluted from the column with 2% ammonium hydroxide. The eluate was collected and lyophilized. The residue, 2.1 g., was dissolved in 14 ml. of 7% ammonium hydroxide, and 112 ml. of 1:1 ethanol–isopropyl alcohol was added. Super-Cel and Darco were added to the cloudy solution and the mixture was filtered. The clear filtrate was cooled to 5° and acetic acid was added dropwise to *p*H 6.0. The crystalline precipitate (1.1 g.) was filtered, washed with ethanol and ether and dried, m.p. 151–153° dec., $[\alpha]^{29}D$ +112° (*c* 1.0 in H_2O).

Recrystallization from 7 ml. of 7% ammonium hydroxide and 28 ml. of 1:1 ethanol–isopropyl alcohol in the manner described above gave 0.9 g. (39%) of D-cycloserine, m.p. 153–154° dec., $[\alpha]^{29}D$ +109° (*c* 1.0 in H_2O).

Anal. Calcd. for $C_3H_6N_2O_2$: C, 35.29; H, 5.92; N, 27.45. Found: C, 35.65; H, 5.78; N, 27.30.

The infrared spectrum of the synthetic D-cycloserine was identical with that of the natural compound.

L-Cycloserine-L-tartrate, $[\alpha]^{30}D$ −36.6° (*c* 0.79 in H_2O), was prepared as described above for the D-isomer. This tartrate was converted into L-cycloserine, $[\alpha]^{33}D$ −110° (*c* 0.83 in H_2O), as described above for the D-isomer.

Resolution of DL-4-Benzamido-3-isoxazolidone.—A solution of cinchonidine methohydroxide was prepared by dissolving 8.0 g. (18.4 mmoles) of cinchonidine methiodide in a few milliliters of water and shaking the solution for 4 hr. with 2.3 g. (10 mmoles) of silver oxide. Titration of an aliquot with 0.01 *N* hydrochloric acid showed that the solution contained 12.3 mmoles of the methohydroxide. To this solution was added 5.0 g. (24.3 mmoles) of DL-4-benzamido-3-isoxazolidone. The solution was kept overnight at room temperature. A small amount of undissolved isoxazolidone was filtered and the filtrate was evaporated *in vacuo* to a syrupy residue. The residue was dissolved in 500 ml. of hot methyl ethyl ketone, and the solution was cooled slowly to room temperature. The cinchonidine metho-salt of D-4-benzamido-3-isoxazolidone separated as small white needles. After two days at room temperature, the crystals were filtered, washed with ice-cold methyl ethyl ketone and dried *in vacuo* over phosphorus pentoxide yielding 2.0 g. of product, m.p. 192–195° dec., $[\alpha]^{25}D$ −80° (*c* 1.0 in H_2O).

A sample of this salt was recrystallized from water and dried at 100° (0.5 mm.).

Anal. Calcd. for $C_{20}H_{24}N_4O_4$: C, 70.01; H, 6.66; N, 16.89. Found: C, 69.82; H, 7.25; N, 10.81.

A sample of the cinchonidine metho-salt of D-4-benzamido-3-isoxazolidone, prepared from natural D-cycloserine, melted at 192–195° dec., $[\alpha]^{25}D$ −78° (*c* 0.9 in H_2O).

D-4-Benzamido-3-isoxazolidone.—A solution of 1.90 g. of the cinchonidine metho-salt of D-4-benzamido-3-isoxazolidone in 25 ml. of ice-water was acidified to *p*H 2 with concentrated hydrochloric acid. The solution was extracted with four 20-ml. portions of ether. The combined ether extracts were dried and evaporated *in vacuo*, giving a residue weighing 0.62 g. (86%). Crystallization from chloroform–petroleum ether gave 0.37 g. of D-4-benzamido-3-isoxazolidone, m.p. 172–175° dec., $[\alpha]^{25}D$ +16° (*c* 2.5 in pyridine). A sample, after recrystallization from water, melted at 173–175° dec.

Anal. Calcd. for $C_{10}H_{10}N_2O_3$: C, 58.24; H, 4.89; N, 13.59. Found: C, 58.42; H, 5.11; N, 13.09.

D-4-Benzamido-3-isoxazolidone, prepared from natural D-cycloserine, melted at 174–176° dec., $[\alpha]^{25}D$ +17° (*c* 2.6 in pyridine). The infrared absorption spectrum of this compound was identical with that of the resolved product.

L-Serine Ethyl Ester Hydrochloride.—Dry hydrogen chloride was passed into a suspension of 95 g. of L-serine in 950 ml. of ethanol until the amino acid dissolved. About 200 ml. of ethanol was distilled from the solution and the residue was concentrated *in vacuo* to a thick sirup. When triturated with ether the product crystallized. It was filtered, washed with ether and dried, yielding 148 g. (97%) of L-serine ethyl ester hydrochloride, m.p. 126–127°, $[\alpha]^{25}D$ −5.5° (*c* 9.9 in 95% ethanol). After three recrystallizations from ethanol–ether, the product showed m.p. 130–131°, and $[\alpha]^{25}D$ −5.7° (*c* 10.2 in 95% ethanol).

Anal. Calcd. for $C_5H_{12}NO_3Cl$: C, 35.40; H, 7.13; N, 8.26. Found: C, 35.00; H, 6.96; N, 7.82.

L-4-Carbethoxy-2-phenyl-2-oxazoline.—This compound was prepared from L-serine ethyl ester hydrochloride and ethyl benzimidate in 68% yield by the procedure described for synthesis of the racemate. After distillation at 100–130° (1 mm.), the product crystallized, m.p. 42–47°. A small sample, recrystallized from ether–petroleum ether, melted at 47–48°, $[\alpha]^{25}D$ +134.5° (*c* 10.0 in 95% ethanol).

Anal. Calcd. for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39. Found: C, 66.34; H, 5.14; N, 6.05.

A 2.5% solution of this ester in 0.2 *N* sodium methoxide showed no optical rotation when examined immediately.

L-4-Carboxy-2-phenyl-2-oxazoline.—To 5 ml. of 2 *N* sodium hydroxide was added 2.2 g. (0.01 mole) of L-4-carbethoxy-2-phenyl-2-oxazoline. The mixture became warm and was stirred intermittently for 3 hr. After dilution with about 20 ml. of water, 200 ml. of acetone was added slowly and the mixture was cooled in an ice-bath. The product was filtered and dried, giving 2.0 g. of L-4-carboxy-2-phenyl-2-oxazoline sodium salt, $[\alpha]^{27}D$ +82.4° (*c* 5.0 in H_2O).

A suspension of 1 g. of the sodium salt in 5 ml. of water was cooled and 4.4 ml. of 1 *N* hydrochloric acid was added. The precipitated acid was filtered and washed with cold water, giving 0.5 g. of L-4-carboxy-2-phenyl-2-oxazoline, m.p. 131–135°, $[\alpha]^{27}D$ +219° (*c* 1.0 in pyridine). Insoluble products were formed and the melting point was lowered when the acid was recrystallized from benzene. Recrystallization from a 1:2 mixture of ether–petroleum ether gave the acid, m.p. 135–138°, $[\alpha]^{27}D$ +200° (*c* 1.0 in pyridine).

Anal. Calcd. for $C_{10}H_9NO_3$: C, 62.81; H, 4.75; N, 7.33. Found: C, 62.68; H, 4.75; N, 7.29.

L-4-Carbohydroxamido-2-phenyl-2-oxazoline.—This compound was prepared in 81% yield from L-4-carbethoxy-2-phenyl-2-oxazoline essentially by the procedure used for the preparation of the racemic compound. However, the reaction mixture was allowed to stand at 0° overnight in order to lessen the amount of racemization. The product, m.p. 167–168°, had $[\alpha]^{25}D$ +65° (*c* 2.0 in 0.2 *N* sodium hydroxide).

One gram of this partially racemized hydroxamic acid was crystallized from 350 ml. of boiling 6:1 methyl isobutyl ketone–ethanol giving 0.3 g. of material, m.p. 180–181°, $[\alpha]^{27}D$ +2.4° (*c* 2.0 in 0.2 *N* sodium hydroxide). When the filtrate was cooled, 0.4 g. of a second crop was obtained, m.p. 179–180°, $[\alpha]^{29}D$ +97° (*c* 2.0 in 0.2 *N* sodium hydroxide). The filtrate from the second crop, when concentrated to 50 ml., yielded 0.15 g. of a third crop, m.p. 170–171°, $[\alpha]^{28}D$ +94.3° (*c* 2.0 in 0.2 *N* sodium hydroxide). The combined second and third crops were again recrystallized from 117 ml. of 6:1 methyl isobutyl ketone–ethanol giving 0.2 g. of product, m.p. 179–180°, $[\alpha]^{27}D$ +119.5° (*c* 2.0 in 0.2 *N* sodium hydroxide). Further recrystallization gave no increase in rotation.

L-4-Benzamido-3-isoxazolidone.—To a solution of 0.57 (2.8 mmoles) of L-4-carbohydroxamido-2-phenyl-2-oxazoline, $[\alpha]^{26}D$ +113° (*c* 2.0 in 0.2 *N* sodium hydroxide), in 20 ml. of dry dioxane was added 1.4 ml. of 2.2 *N* hydrogen chloride in dioxane. The solution was heated for 15 minutes on a steam-bath and was evaporated *in vacuo*. The residue was dissolved in 20 ml. of water, and the solution was heated at 55–65°, while 51.5 ml. of 0.1 *N* sodium hydroxide was added dropwise to a permanent phenolphthalein end-point. The solution was cooled to 10° and, after addition of 2.8 ml. of 1 *N* hydrochloric acid, was extracted with four 50-ml. portions of ethyl acetate. The extracts were dried and evaporated to 10 ml. This solution was cooled giving 0.24 g. of L-benzamido-3-isoxazolidone, m.p. 163–171°, $[\alpha]^{27}D$ −17.6° (*c* 2.5 in pyridine). The filtrate gave an additional 0.12 g., $[\alpha]^{27}D$ −17.5° (*c* 2.5 in pyridine), which brought the yield to 0.36 g. (63%).

DL-4-Carbohydroxamido-5-methyl-2-phenyl-2-oxazoline.—The procedure for the preparation of 4-carbohydroxamido-5-methyl-2-phenyl-2-oxazoline is similar to that described for the 4-carbohydroxamido-2-phenyl-2-oxazoline. From 187 g. of the oxazoline ester,[14] 149 g. (79%) of the oxazoline

hydroxamic acid, m.p. 152–154°, was obtained. A sample, recrystallized from isopropyl alcohol, melted at 148–150°.

Anal. Calcd. for $C_{11}H_{12}N_2O_3$: C, 59.99; H, 5.49; N, 12.73. Found: C, 59.98; H, 5.31; N, 12.91.

DL-α-Benzamido-β-chlorobutyrohydroxamic Acid.—To a stirred refluxing solution of 9.6 g. (0.044 mole) of 4-carbohydroxamido-5-methyl-2-phenyl-2-oxazoline in approximately 500 ml. of dry dioxane (distilled from sodium three times) was added dropwise over a period of 1 hr. 120 ml. of dioxane containing 1.8 g. (0.05 mole) of hydrogen chloride. During the addition of the hydrogen chloride solution, the reaction mixture became pink and a small quantity of a flocculent precipitate appeared. The solution was cooled, treated with Darco G-60 and filtered. The residue obtained from lyophilization of the filtrate was extracted with one 400-ml. and three 50-ml. portions of boiling ethyl acetate, and the combined extracts were diluted with an equal volume of chloroform. This solution was cooled and 6.6 g. (59%) of α-benzamido-β-chlorobutyrohydroxamic acid, m.p. 139–143°, was obtained. A sample, recrystallized from chloroform, melted at 141–142.5°. The ethyl acetate-insoluble portion of the residue was apparently unrearranged oxazoline hydrochloride and was not further investigated.

Anal. Calcd. for $C_{11}H_{13}N_2O_3Cl$: C, 51.47; H, 5.10; N, 10.89; Cl, 13.81. Found: C, 51.72; H, 5.40; N, 10.94; Cl, 13.72.

DL-4-Benzamido-5-methyl-3-isoxazolidone.—To a stirred slurry of 6.4 g. (0.025 mole) of α-benzamido-β-chlorobutyrohydroxamic acid in 100 ml. of water at 65–75°, 46 ml. (1.83 equivalents) of 1 *N* sodium hydroxide was added over a period of 1 hr. A permanent phenolphthalein end-point was obtained. The solution was cooled in an ice-bath and 21.4 ml. of 1.16 *N* (0.025 mole) hydrochloric acid was added. The acidic solution was extracted with three 250-ml. portions of chloroform, and the combined dried extracts were concentrated to approximately 225 ml. The DL-4-benzamido-5-methyl-3-isoxazolidone, 3.3 g., m.p. 188–194°, was filtered. The filtrate was concentrated and yielded another 1.0 g., m.p. 187–192°, bringing the total yield to 4.3 g. (79%). A small sample, recrystallized from chloroform, melted at 187–190°.

Anal. Calcd. for $C_{11}H_{12}N_2O_3$: C, 59.99; H, 5.49; N, 12.72. Found: C, 59.62; H, 5.14; N, 12.56.

Methyl DL-α-Amino-β-aminoxybutyrate Dihydrochloride.—A rapid stream of hydrogen chloride was passed into 250 ml. of dry methanol for approximately 40 minutes. To this solution was added 5 g. (0.02 mole) of 4-benzamido-5-methyl-3-isoxazolidone, and the solution was refluxed for 2 hr. The solvent was removed *in vacuo*. The crystalline residue was extracted with 150 ml. of boiling isopropyl alcohol leaving 2.1 g. (42%) of crystalline methyl α-amino-β-aminoxybutyrate dihydrochloride, m.p. 139–145°. A small sample, triturated with boiling isopropyl alcohol, melted at 136–138°.

Anal. Calcd. for $C_5H_{14}N_2O_3Cl_2$: C, 27.16; H, 6.38; N, 12.67; Cl, 32.07. Found: C, 27.44; H, 6.46; N, 12.46; Cl, 31.27.

In some runs only amorphous ester dihydrochloride was obtained. The amorphous product was used successfully in the next step.

DL-4-Amino-5-methyl-3-isoxazolidone (XII).—To a cold solution of 2.0 g. (9.1 mmoles) of methyl α-amino-β-aminoxybutyrate dihydrochloride in 2 ml. of water was added dropwise a cold solution of 1.8 g. (>3 equivalents) of potassium hydroxide in 2 ml. of water. During the addition of the alkali, the reaction mixture became pink and then colorless as the solution reached *p*H 11. The precipitate, after removal of the supernatant solution, was washed twice with 0.5 ml. of water. The washings and supernatant solution were combined and then diluted with 40 ml. of 1:1 ethanol-isopropyl alcohol. The resulting precipitate was filtered and was washed with a small volume of the 1:1 alcohol solution. The filtrate was cooled to 0–5° and was acidified to *p*H 6 by the dropwise addition of glacial acetic acid. The crystalline precipitate, 923 mg. (88%), was recrystallized in the same manner as DL-4-amino-3-isoxazolidone giving 761 mg. of DL-4-amino-5-methyl-3-isoxazolidone, m.p. 170–173°.

Anal. Calcd. for $C_4H_8N_2O_2$: C, 41.36; H, 6.94; N, 24.13. Found: C, 41.31; H, 6.68; N, 23.88.

Some Reactions of *erythro*- and *threo*-β-*p*-Nitrophenylserine

BY ARTHUR F. WAGNER

RECEIVED DECEMBER 29, 1956

Ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) was converted to the corresponding 2-oxazoline, 4-carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (II), by an SNi displacement using *p*-toluenesulfonyl chloride in pyridine solution. The 4-carbethoxy-2-oxazoline II was converted to the 4-carbohydroxamido-2-oxazoline IV which was opened to the *erythro*-β-chlorohydroxamic acid V. Among the products resulting from the alkaline cyclization of the *erythro*-β-chlorohydroxamic acid V was the 4-carbohydroxamido-2-oxazoline IV. Ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) reacted with thionyl chloride to yield the corresponding β-chloro compound III with retention of configuration. The corresponding *threo* isomer VI in the same reaction underwent nitrogen-to-oxygen acyl migration and inversion at the β-carbon to yield ethyl *erythro*-α-amino-β-benzoyloxy-β-*p*-nitrophenylpropionate hydrochloride (VII).

The characterization and synthesis of chloramphenicol[1] did much to stimulate interest in the stereochemistry and reactivity of the β-*p*-nitrophenylserines. More recently publications from these laboratories[2] described the synthesis of the antibiotic cycloserine[3] using serine as the precursor for the 3-isoxazolidone nucleus. This synthesis used a 4-carbethoxy-2-oxazoline intermediate to protect the α- and β-positions of the original serine molecule while the carbethoxy group was converted to a carbohydroxamido group. In contrast to the alternative of converting a β-chloroester to a β-chlorohydroxamic acid directly, the alkaline stability of the 2-oxazoline ring effectively protected the α- and β-positions of serine from undergoing any reaction during the conversion of the ester to a hydroxamic acid. The carbohydroxamido-2-oxazoline was opened to a β-chlorohydroxamic acid which was then cyclized to a 3-isoxazolidone.

This paper describes the behavior of *erythro*- and *threo*-β-*p*-nitrophenylserine in a similar sequence of reactions designed to synthesize 2-oxazolines and

2-isoxazolidones with a *p*-nitrophenyl substituent. Striking differences were observed in the behavior of *erythro*- and *threo*-β-*p*-nitrophenylserine derivatives at two steps of the reaction sequence. For the preparation of 2-oxazolines it was noted that "*cis* effects" of the substituents dictate the choice of reaction for the cyclization of either isomer. In reactions with thionyl chloride, ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) gave a different type of product from that isolated from the corresponding *threo* isomer II in the same reaction. A difference in reaction mechanism is clearly indicated here. All of these observations are presented below and some of the reactions are discussed in the light of recently confirmed configurations of the two diastereomers.[4]

As noted earlier, the key intermediate of the 3-isoxazolidone synthesis is a 2-oxazoline. Two courses were open for the synthesis of 4-carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (II). The first involves reaction of ethyl α-amino-β-hydroxy-β-*p*-nitrophenylpropionate hydrochloride with ethyl iminobenzoate[5,6] and the second consists of an SNi displacement[7] at the β-carbon in ethyl α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate. In the former case the participating groups should be *cis* oriented, while in the latter case they should be in a *trans* orientation. In the reaction of ethyl *erythro*-α-amino-β-hydroxy-β-*p*-nitrophenylpropionate hydrochloride with ethyl iminobenzoate at room temperature, no 2-oxazoline could be isolated.[8] When ethyl *erythro*-α-amino-β-hydroxy-β-*p*-nitrophenylpropionate hydrochloride was first benzoylated on nitrogen and the resulting amide I then allowed to react with *p*-toluenesulfonyl chloride in pyridine,[7] the 2-oxazoline II was isolated in yields up to 70%.

Considering the *cis* orientation requirements for cyclization with ethyl iminobenzoate and the *trans* orientation necessary for SNi cyclization, it can be seen that a "*cis* effect"[9] will play an important role in the transition state of each of these diastereomers

(4) For a comprehensive review of the data describing the synthesis and stereochemistry of the two diastereoisomers see D. O. Holland, P. A. Jenkins and J. H. C. Naylor, *J. Chem. Soc.*, 273 (1953).

(7) R. N. Boyd and R. H. Hansen, *ibid.*, **75**, 5896 (1953).

(8) A similar observation has been reported by E. D. Bergmann, H. Bendas and W. Taub, *J. Chem. Soc.*, 2673 (1951). These workers report no 2-oxazoline isolated from the reaction between *erythro*-β-*p*-nitrophenylserine ethyl ester and ethyl iminobenzoate in refluxing dichloroethane, tetrachloroethane or dibromoethane. With the corresponding *threo* isomer, however, I. Elphimoff-Felkin, H. Felkin and Z. Welvart, *Compt. rend.*, **234**, 1789 (1952), report a facile conversion to the 2-oxazoline with ethyl iminobenzoate. With the β-phenylserine ethyl esters, however, both the *erythro* and *threo* isomers yield 2-oxazolines on treatment with ethyl iminobenzoate either in the presence or absence of solvent. See M. Viscontini and E. Fuchs, *Helv. Chim. Acta*, **36**, 1 (1953), and I. Elphimoff-Felkin, H. Felkin, B. Tchoubar and Z. Welvart, *Bull. soc. chim. France*, 252 (1952).

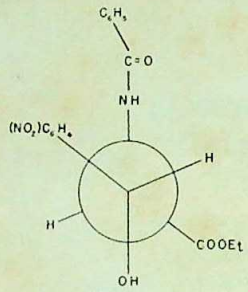
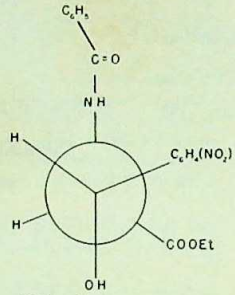
prior to cyclization. With the *erythro* isomer the necessary conditions at the transition stage for SNi displacement place the bulky *p*-nitrophenyl group between the hydrogen atom and the benzamido group (IXa). In the *threo* series the same conditions put the *p*-nitrophenyl group between the carbethoxy and benzamido groups in the transition state (IXb). Since the relative positions of the bulky groups are more favorable in case IXa, the *erythro* isomer should give the 2-oxazoline more readily by SNi displacement.

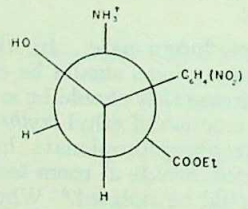


IXa, *erythro*

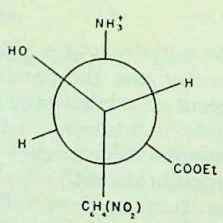


IXb, *threo*

The conversion of ethyl α-amino-β-hydroxy-β-*p*-nitrophenylpropionate hydrochloride to the corresponding 2-oxazoline with ethyl iminobenzoate should proceed more readily with the *threo* isomer. This cyclization requires a *cis* orientation of hydroxyl and amino groups in the transition state. Such a *cis* arrangement is spatially more compatible with the *threo* isomer Xb when the influence of the "*cis* effect" of the bulky groups is considered. The preferred orientations of the groups for this *cis* transition state are illustrated below.[10]



Xa, *erythro*



Xb, *threo*

The 2-oxazoline II was converted in 60% yield to 4-carbohydroxamido-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (IV) with sodium methoxide and hydroxylamine.[11] The 2-oxazoline hydroxamic acid IV on treatment with anhydrous hydrogen chloride in dioxane solution yielded the β-chloro acid, *erythro*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionohydroxamic acid (V).[12] When the hydroxamic acid V was cyclized with alkali at about 70°, the 2-oxazoline IV was the only crystalline product isolated (30% yield). As reported,[2] the course of the alkaline cyclization of α-benzamido-β-chloropropionohydroxamic acid was dependent upon the temperature. A lower temperature favored the 2-oxazoline while a higher temperature favored the 3-isoxazolidone. When the alkaline cyclization of the *erythro*-β-*p*-nitrophenyl analog V was carried out at 100°, the yield of 2-oxazoline IV dropped to 20%.

Consideration of molecular models of both *erythro*- and *threo*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionohydroxamic acid (V) shows that a *threo* isomer should offer the better opportunity for cyclization to a 3-isoxazolidone. Accordingly steps were undertaken to synthesize this isomer. The key compound in this sequence was ethyl *threo*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionate. Ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) was used to study the course of displacement of the hydroxyl with halogen, and the following observation was made. When I (*erythro*) was allowed to react with thionyl chloride in the absence of solvent, the corresponding β-chloro compound III was obtained in *ca.* 60% yield. The *erythro* configuration of III was established by identity with an authentic specimen of ethyl *erythro*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionate prepared from I (*erythro*) by first converting to the 2-oxazoline II using *p*-toluenesulfonyl chloride in pyridine and then opening the 2-oxazoline ring with anhydrous hydrogen chloride in dioxane. An inversion at the β-carbon in each step[7,13] of the latter synthesis leads to over-all retention of configuration. This result is in accord with the conclusion reached earlier[13] that the displacement of the hydroxyl of methyl *threo*-α-acetamido-β-hydroxy-β-phenylpropionate with halogen using thionyl chloride proceeds with retention of configuration.

When ethyl *threo*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (VI) was allowed to react with thionyl chloride in the absence of solvent, the only product which could be isolated was ethyl *erythro*-α-amino-β-benzoyloxy-β-*p*-nitrophenylpropionate hydrochloride (VII) (*ca.* 50% yield). The identity of the rearranged and inverted product was confirmed by the conversion of VII to ethyl *erythro*-α-amino-β-hydroxy-β-*p*-nitrophenylpropionate hydrochloride (VIII) by acid hydrolysis followed by esterification. The configuration was further confirmed by the conversion of VIII to ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) by benzoylation in the presence of sodium acetate.

The displacement of hydroxyl with halogen by thionyl chloride in the *erythro*-isomer with retention of configuration can occur in either of two ways. In one instance an SNi displacement by the halogen of the intermediate ester halide[14] would yield the corresponding halide with retention of configuration. On the other hand, the same intermediate ester halide can cyclize to the corresponding oxazoline which in turn can be converted to the chlorobenz-

(10) The stereochemical notations follow the suggestion of M. S. Newman, *Record Chem. Progr.*, **13**, 111 (1952).

(11) The racemization of optically active esters by bases is well known (see C. L. Bickel, THIS JOURNAL, **60**, 927 (1938)). Under these conditions, therefore, one would expect racemization at the α-carbon to give a mixture of *cis*- and *trans*-oxazolines. It has been found, however (D. F. Elliott, *J. Chem. Soc.*, 62 (1950)), that *cis*-oxazolines mutarotate at the α-carbon in alkali to give *trans*-oxazolines. The rate of mutarotation is even faster in alcoholic sodium ethoxide solution. Thus the *trans*-oxazoline ester II on treatment with sodium methoxide and hydroxylamine will yield the *trans*-oxazoline hydroxamic acid IV.

(12) For a discussion of the rearrangements of oxazoline hydrochlorides see E. M. Fry, *J. Org. Chem.*, **14**, 887 (1949); **15**, 438, 802 (1950).

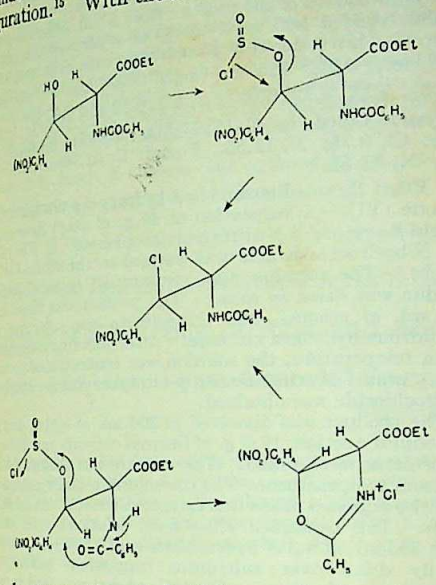
amido compound with over-all retention of configuration.[15] With the *threo* isomer in thionyl chlo-



ride, however, there is both benzoyl migration and inversion at the β-carbon rather than displacement of hydroxyl with halogen.[16] Since 1,2-*trans*-cyclization of the *threo* isomer to the 2-oxazoline II is unfavorable because of the role of "*cis*-effects," a mechanism involving cleavage of a 2-oxazoline to a rearranged and inverted product would not apply. Nitrogen-to-oxygen acyl migrations proceed by way of a cyclic transition state.[17] In this instance a 1,2-*cis*-cyclization[18] would lead to the oxazolidine XI; therefore, the acyl migration would not necessarily in itself be attended by inversion.[17] A suggested mechanism then in the case of the *threo* isomer might first involve migration of the benzoyl group from nitrogen to oxygen through 1,2-*cis*-cyclization and subsequent epimerization at the β-carbon to give the thermodynamically more stable[19] *erythro* configuration.

Experimental

Ethyl *erythro*-α-Benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I).—Five grams (0.017 mole) of *erythro*-β-*p*-nitrophenylserine ethyl ester hydrochloride[20] was suspended in a mixture of 50 ml. of water and 50 ml. of chloroform. Then 3.4 g. (0.043 mole) of sodium acetate and 2.4 g. (0.018 mole) of benzoyl chloride were added. The mixture was shaken for 2 hr. and then acidified by the addition of 1 ml. of concentrated hydrochloric acid. The product was isolated by filtration. The chloroform phase was separated, dried over magnesium sulfate and concentrated *in vacuo*. Recrystallization of the combined solid products from ethanol yielded 3.6 g. (60%) of ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate, m.p. 158.5–160.5°; $\lambda_{max}^{Nujol\ mull}$ 2.99, 5.75, 6.07, 6.2–6.28, 6.6 and 7.4 μ.

Anal. Calcd. for $C_{18}H_{18}N_2O_6$ (358.34): C, 60.33; H, 5.06; N, 7.82. Found: C, 60.31; H, 5.17; N, 7.65.

4-Carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (II).—Ten grams (0.028 mole) of ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) was dissolved in 40 ml. of anhydrous pyridine. The solution was cooled and 5.3 g. (0.028 mole) of *p*-toluenesulfonyl chloride was added. After standing overnight at room temperature, the solution was poured into 100 ml. of 10% aqueous sodium bicarbonate, and the product was isolated by chloroform extraction. The chloroform extract was washed with water, dried over anhydrous magnesium sulfate and concentrated *in vacuo*. Removal of the pyridine by distillation *in vacuo* at 75–80° yielded a 9.1-g. residue.

The residue was triturated with 100 ml. of dry ether and the mixture was filtered; 2.5 g. of starting material, m.p. 158–160°, was isolated. Concentration of the ether solution *in vacuo* yielded 6 g. of the 2-oxazoline. Recrystallization of the product from 20 ml. of ethanol gave 4.2 g. (45%) of 4-carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline, m.p. 88–91°, λ_{max}^{EtOH} 255 mμ (log ε 4.240); $\lambda_{max}^{CCl_4}$ 5.77, 6.04, 6.2, 6.28, 6.5, 6.6 and 7.4 μ.

Anal. Calcd. for $C_{18}H_{16}N_2O_5$ (340.33): C, 63.51; H, 4.74; N, 8.23. Found: C, 63.29; H, 4.39; N, 8.21.

Ethyl *erythro*-α-Benzamido-β-chloro-β-*p*-nitrophenylpropionate (III). (a) From 4-Carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline.—One and nine-tenths milliliters of an anhydrous dioxane solution of hydrogen chloride (0.776 *N*) was added to 500 mg. (1.47×10^{-3} mole) of 4-carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (II) dissolved in 10 ml. of anhydrous dioxane. The solution was heated on the steam-bath and concentrated *in vacuo*. Final traces of dioxane were removed by dissolving the residue in ether and concentrating *in vacuo* several times. Crystallization of the product from ethanol–ether–petroleum ether yielded 280 mg. of material melting at 120–122°. The product was taken up in chloroform and the solution was washed with water, dried over anhydrous magnesium sulfate, filtered and concentrated *in vacuo*. Recrystallization of the product from ethanol–ether–petroleum ether gave 140 mg. of ethyl *erythro*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionate, m.p. 121–124°.

(15) The experimental conditions do not allow a choice between these two mechanisms.

(16) The difference in the course of reaction of the two diastereomers is not unusual. Thus, J. Weijlard, K. Pfister, E. F. Swanezy, C. A. Robinson and M. Tishler, THIS JOURNAL, **73**, 1216 (1951), report that *N*-formyl-*erythro*-2-amino-1,2-diphenylethanol is 1,2-*trans*-cyclized with inversion to the oxazoline salt by thionyl chloride under conditions which do not affect the *N*-formyl derivative of the *threo* isomer. On the other hand, G. Fodor, V. Bruckner, J. Kiss and G. Ohegyi, *J. Org. Chem.*, **14**, 337 (1949), showed that *N*-acetyl-*threo*-2-amino-1,2-diphenylethanol undergoes nitrogen-to-oxygen acyl migration through 1,2-*cis*-cyclization to the oxazolidine with alcoholic hydrogen chloride, while similar conditions leave the *erythro*-isomer unchanged.

(17) L. H. Welsh, THIS JOURNAL, **71**, 3500 (1949).

(18) The rate of 1,2-*cis*-cyclization will be greater for the *threo*-isomer since the smaller rather than the large groups are eclipsed in the intermediate or planar transition state (see D. H. R. Barton and R. C. Cookson, *Quart. Revs.* (*London*), **10**, 51 (1956)). Examples of this effect are found in the slower rates of acyl migration observed in *erythro*-1,2-amino-alcohols as compared to the rates with corresponding *threo* isomers (see L. H. Welsh, ref. 17, and G. Fodor, *et al.*, ref. 16).

(19) According to D. H. R. Barton and R. C. Cookson, *Quart. Revs.* (*London*), **10**, 49 (1956), the *erythro* isomer is the more stable isomer of diastereoisomeric pairs of non-polar compounds in which differences of free energy are mainly due to differences in compression energy. This order of stability has been established experimentally by direct equilibration or by the introduction of a second asymmetric center in reactions known to result (by mechanism) in mixtures approximating to the equilibrium mixture.

Anal. Calcd. for $C_{15}H_{17}ClN_2O_5$ (376.80): C, 57.36; H, 4.55; Cl, 9.41; N, 7.44. Found: C, 57.14; H, 4.37; Cl, 9.96; N, 7.58.

(b) From Ethyl *erythro*-α-Benzamido-β-hydroxy-β-*p*-nitrophenylpropionate.—One gram (2.8×10^{-3} mole) of ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I) was dissolved in 3 ml. of thionyl chloride. The mixture was cooled until solution was complete. After standing at room temperature for 3 hr., the solution was concentrated *in vacuo*. Ether was added to the residue and final traces of thionyl chloride were removed by concentration *in vacuo*. The residue was triturated with ether and the product was isolated by filtration; 650 mg. of product, m.p. 122–124°, was obtained.

Recrystallization of a portion of the product (250 mg.) from ethanol–ether–petroleum ether yielded 150 mg. of ethyl *erythro*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionate, m.p. 122–124°. Admixture with an authentic specimen of this compound (IIIa) caused no depression in the melting point of the specimen.

The infrared spectrum of the compound in chloroform solution showed functionality consistent with the proposed structure; $\lambda_{max}^{CHCl_3}$ 2.93, 5.76, 6.01, 6.2 and 6.28, 6.5–6.6 and 7.4 μ.

4-Carbohydroxamido-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (IV). (a) From 4-Carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline.—One gram of hydroxylamine hydrochloride was dissolved in 25 ml. of warm ethanol. When the solution had cooled to room temperature, 13.8 ml. of methanolic 1.16 *N* sodium methoxide was added. The mixture was cooled and filtered. The filtrate was added to a solution of 4.06 g. (0.012 mole) of 4-carbethoxy-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (II) in 50 ml. of ethanol. The reaction mixture was cooled to *ca.* 0°, and 10 ml. of methanolic 1.16 *N* sodium methoxide was added slowly. The solution turned red; in the course of ten minutes the color of the solution faded to pale yellow.

After standing at room temperature for 1 hr., the solution was concentrated *in vacuo* to a volume of *ca.* 20 ml. The mixture was diluted with 50 ml. of water and acidified with 14.2 ml. of 0.99 *N* hydrochloric acid. The product was isolated by filtration and dried *in vacuo* over phosphoric anhydride. Recrystallization of the product from dioxane–ether yielded 2.25 g. (60%) of 4-carbohydroxamido-5-*p*-nitrophenyl-2-phenyl-2-oxazoline, m.p. 201–203° dec., λ_{max}^{EtOH} 255 mμ (log ε 4.255); $\lambda_{max}^{Nujol\ mull}$ 3.1, 5.95, 6.05, 6.2, 6.28 and 6.54 μ.

Anal. Calcd. for $C_{16}H_{13}N_3O_5$ (327.28): C, 58.73; H, 3.88; N, 12.84. Found: C, 58.74; H, 3.88; N, 12.80.

(b) From *erythro*-α-Benzamido-β-chloro-β-*p*-nitrophenylpropionohydroxamic Acid.—A suspension of 500 mg. (1.4×10^{-3} mole) of *erythro*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionohydroxamic acid (V) in 5 ml. of ethanol was gently refluxed and titrated with 0.99 *N* sodium hydroxide until the phenophthalein end-point was permanent for several minutes (2×10^{-3} equivalent of alkali was consumed). The solution was cooled in an ice-bath and 10 ml. of water was added. The mixture was acidified with 1 ml. of 0.99 *N* hydrochloric acid and stirred. The product was isolated by filtration and dried *in vacuo;* 320 mg. of material melting at 175–178° dec. was obtained.

The product was boiled with 25 ml. of ethanol and the mixture was filtered. The residue (90 mg.) melted at 194° dec. The ethanolic filtrate was cooled and filtered; an additional 30 mg. of product, m.p. 194° dec., was obtained. The two crops of crystalline product (120 mg.) were combined and characterized as 4-carbohydroxamido-5-*p*-nitrophenyl-2-phenyl-2-oxazoline, m.p. 194° dec.; λ_{max}^{EtOH} 250 mμ (log ε 4.297).

The infrared spectrum of the product was identical to that of an authentic specimen of 4-carbohydroxamido-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (IVa). Admixture of the product with the same authentic specimen (IVa) gave no depression in the melting point.

***erythro*-α-Benzamido-β-chloro-β-*p*-nitrophenylpropionohydroxamic Acid (V).**—Two milliliters of an anhydrous dioxane solution of hydrogen chloride (1.09 *N*) was added to a suspension of 640 mg. (0.002 mole) of 4-carbohydroxamido-5-*p*-nitrophenyl-2-phenyl-2-oxazoline (IVa) in 6 ml. of anhydrous dioxane. The mixture was warmed on the steam-bath for five minutes. The solution was cooled, and the product which precipitated was collected by filtration; 660 mg. of hydroxamic acid, m.p. 179–182° dec., was obtained. Recrystallization of the product from 40 ml. of hot isopropyl alcohol yielded 200 mg. (28%) of *erythro*-α-benzamido-β-chloro-β-*p*-nitrophenylpropionohydroxamic acid, m.p. 182–183° dec.; λ_{max}^{EtOH} 235 mμ (log ε 4.129) and 260 mμ (log ε 4.099); λ_{max}^{solid} 3.12, 6.09, 6.2, 6.9, 6.52 and 6.67 μ.

Anal. Calcd. for $C_{16}H_{14}ClN_3O_5$ (363.75): C, 52.84; H, 3.88; Cl, 9.75; N, 11.55. Found: C, 52.84; H, 3.47; Cl, 9.5; N, 11.55.

Ethyl *threo*-α-Benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (VI).—A suspension of 49 g. of ethyl *threo*-α-acetamido-β-acetoxy-β-*p*-nitrophenylpropionate[21] in 500 ml. of 2.5 *N* hydrochloric acid was warmed on the steam-bath for 2.5 hr. The solution was concentrated *in vacuo* and the residue was dried *in vacuo*. The product was dissolved in 250 ml. of ethanol, and the solution was saturated with anhydrous hydrogen chloride. After standing overnight at room temperature, the solution was concentrated *in vacuo*. Forty grams of crude *threo*-β-*p*-nitrophenylserine ethyl ester hydrochloride was obtained.

The product was dissolved in 300 ml. of water, and 28 g. of sodium acetate, 19.2 g. of benzoyl chloride and 300 ml. of chloroform were added. The mixture was shaken for 2 hr. at room temperature. The chloroform phase was separated and the aqueous phase was extracted with 200 ml. of chloroform. The combined chloroform solutions were washed with 350 ml. of 0.3 *N* hydrochloric acid, then with water and finally dried over anhydrous magnesium sulfate. The chloroform solution was filtered and concentrated *in vacuo*. Crystallization of the residue (44 g.) from 100 ml. of ethanol yielded 16 g. of product melting at 126–134°. Recrystallization of this fraction from ethanol yielded 11 g. of ethyl *threo*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate, m.p. 136–138°. The infrared spectrum in chloroform solution confirms the presence of an N-benzoyl function; $\lambda_{max}^{CHCl_3}$ 2.98, 5.78, 6.0, 6.2, 6.3, 6.55 and 7.4 μ.

Anal. Calcd. for $C_{18}H_{18}N_2O_6$ (358.34): C, 60.33; H, 5.06; N, 7.82. Found: C, 60.59; H, 5.13; N, 7.77.

Reaction of Ethyl *threo*-α-Benzamido-β-hydroxy-β-*p*-nitrophenylpropionate with Thionyl Chloride. (a) Ethyl *erythro*-α-Amino-β-benzoyloxy-β-*p*-nitrophenylpropionate Hydrochloride (VII).—A mixture of 4 g. of ethyl *threo*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate and 4 g. of anhydrous calcium carbonate[22] was added to 25 ml. of thionyl chloride. After standing at room temperature for three days, the reaction mixture was filtered and concentrated *in vacuo*. Trituration of the residue with ether and filtration yielded 3.45 g. of product. Recrystallization of the product from ethanol–petroleum ether (1:1) gave 1.9 g. of product melting at 180° dec. The infrared spectrum of the product in the solid state was consistent with a structure containing two ester functions and an amine hydrochloride function.

Recrystallization of the product (660 mg.) from ethanol yielded 250 mg. of ethyl *erythro*-α-amino-β-benzoyloxy-β-*p*-nitrophenylpropionate hydrochloride, m.p. 197° dec.; λ_{max}^{solid} 3.5–4.4, 5.70, 5.85, 6.21, 6.35, 6.57 and 7.38 μ.

Anal. Calcd. for $C_{18}H_{19}ClN_2O_6$ (394.81): C, 54.75; H, 4.85; Cl, 8.98; N, 7.10. Found: C, 54.81; H, 4.75; Cl, 9.03; N, 7.09.

(b) Confirmation of Configuration of VII. (i) Ethyl *erythro*-α-Amino-β-hydroxy-β-*p*-nitrophenylpropionate Hydrochloride (VIII).—A mixture of 900 mg. of VII and 15 ml. of 2.5 *N* hydrochloric acid was warmed on the steam-bath. Ethanol was added to make the mixture homogeneous, and the solution was warmed on the steam-bath for 2 hr.

The reaction mixture was concentrated *in vacuo*, and the residue was leached with hot benzene to remove benzoic acid. The residue was taken up in ethanol, and the solution was saturated with anhydrous hydrogen chloride.

After standing at room temperature overnight, the solution was concentrated *in vacuo* and the residue was crystallized from ethanol; 350 mg. of ethyl *erythro*-α-amino-β-hydroxy-β-*p*-nitrophenylpropionate hydrochloride, m.p.

177° dec., was obtained. A second crystallization yielded 170 mg. of the compound melting at 188° dec. (lit.[23] *erythro*-, m.p. 182–184° dec.; *threo*-, m.p. 153–155° dec.

(ii) Ethyl *erythro*-α-Benzamido-β-hydroxy-β-*p*-nitrophenylpropionate (I).—A mixture of 40 mg. of VIII, 28 mg. of sodium acetate and 19 mg. of benzoyl chloride in 4 ml. of water and 4 ml. of chloroform was shaken for 2 hr. About 20 ml. of chloroform was added to the reaction mixture, and the aqueous phase was acidified with a few drops of 2.5 *N* hydrochloric acid. The chloroform phase was separated and dried over anhydrous magnesium sulfate. The chloroform solution was filtered and concentrated *in vacuo*. Crystallization of the residue from ethanol gave 30 mg. of ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate, m.p. 154–156°. A second crystallization from ethanol yielded 18 mg. of product melting at 158–160°. There was no depression in melting point on admixture of the product with an authentic specimen of ethyl *erythro*-α-benzamido-β-hydroxy-β-*p*-nitrophenylpropionate.

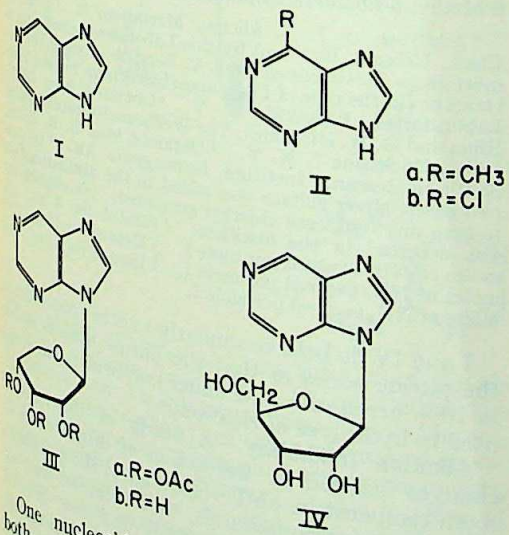
A Study of the Action of Acid and Alkali on Certain Purines and Purine Nucleosides[1]

BY MILTON PAUL GORDON,[2] VIRGINIA S. WELIKY AND GEORGE BOSWORTH BROWN

RECEIVED NOVEMBER 16, 1956

A series of glycosyl derivatives of various purines was found to be extremely labile toward dilute alkali at room temperature. In studies with 9-β-D-ribofuranosylpurine two products resulting from cleavage of the imidazole ring, with loss of carbon-8 but without loss of the ribosyl group, were partially characterized. Purine, its ribofuranosyl and ribopyranosyl derivatives evolve formic acid when heated with *p*-toluenesulfonic acid. Studies of the reaction indicate a complex decomposition pattern, including some loss of carbon-8. Syntheses of 9-D-ribopyranosylpurine and 6-methyl-D-ribofuranosylpurine are described.

In the course of studies of the properties of several derivatives of purine (I to IV), it was observed that the spectrum of 9-β-D-ribofuranosylpurine (IV, nebularine)[3] and of related glycosyl derivatives, underwent drastic and irreversible changes in dilute aqueous alkali at room temperature. It was also observed that 9-(2′,3′,4′-tri-*O*-acetyl-D-ribopyranosyl)-purine (IIIa) and other derivatives of purine yielded anomalous "acetyl" analyses. Such chemical behaviors have not previously been observed with any nucleosides of purines.



One nucleoside, namely, IV, which possesses both of these unusual properties occurs in the mushroom *Agaricus* (*Clitocybe*) *nebularis* Batsch.[4a,b,5] It is inhibitory toward *Mycobacteria*,[4a,b] is highly toxic to mammals[3,6,a,b] and exhibits selective toxicity toward cells of mouse sarcoma 180 in culture.[7] Purine I, IV and other purine derivatives, 6-methylpurine (IIa) and 6-chloropurine (IIb), have some selective inhibitory effects on the growth of experimental tumors.[8]

Investigations of these unusual chemical behaviors, including attempts to elucidate the structural factors responsible and of possible correlations with the pharmacodynamic properties of certain of these compounds are in progress.[9] Consideration of these newly recognized chemical behaviors was necessary in studies of the metabolic fates of IV[10a] and I[10b] as well as in the work described in the following three papers; these properties must be considered when investigating new purine derivatives from natural sources.

Results and Discussion

Acid Instability.—The analysis for the formation of volatile acids involved heating the compound in question with a 25% aqueous solution of *p*-toluenesulfonic acid at 100° for 4 hr., steam distillation

Digitized by Arya Samaj Foundation Chennai and eGangotri

and titration of the volatile acid produced.[11] The volatile acid obtained from I (*ca.* 0.9 mole/mole I) was identified as formic acid through conversion to the S-benzylisothiouronium salt,[12] by its conversion to benzimidazole and benzimidazole picrate[13] and by its reconversion to I.

When purine-8-C^{14} was similarly treated, the formate carbon of the S-benzylisothiouronium derivative had approximately one-third of the specific activity of the 8-carbon of the parent I. The residue after the completion of the steam distillation was quite dark, evolved ammonia with alkali and gave a test for reducing agents with alkaline phosphomolybdate.[14] When purine-8-C^{14} was treated for 12 hr., 1.8 moles of formic acid was evolved per mole of I, and this formic acid was reconverted to I before determination of the radioactivity. It was again found to have about one-third of the specific activity of the 8-carbon of the starting material.

The residue from the 12 hr. treatment contained 1.9 moles of ammonia per mole of I used. The ninhydrin positive[15] component found in the residue had the same paper chromatographic behavior as glycine in three different chromatographic systems. The presence of a small amount of unchanged I was also detected.

The evolution of formic acid, ammonia and the formation of glycine indicate extensive degradation. The threefold dilution of the radioactivity of carbon atom 8 may well be due to the more rapid liberation of formic acid from other parts of the molecule (*i.e.*, to the initial formation of imidazole derivatives, see below), since a maximum of two moles of acid was evolved on prolonged heating. The positive reactions with the Bratton–Marshall reagent,[16] diazotized sulfanilic acid[17] and alkaline phosphomolybdate,[14] the variable ratio of ammonia produced to formic acid evolved and the marked darkening of the reaction mixture all indicate a complex decomposition pattern. The three color tests were all positive with 4,5-diaminopyrimidine; however, 4-amino-5-imidazolealdehyde, which might result if carbon 2 was lost, would also be expected to react with these color reagents.

It is known that the purine ring system can be cleaved by acids under sufficiently rigorous conditions to yield carbon dioxide, ammonia, carbon monoxide and/or formic acid and glycine. (For a review of the older literature see ref. 18 and 19.) Less drastic hydrolyses of adenine and guanine result in the formation of 4-amino-5-imidazolecarboxamidine[18] and 4-guanidoimidazole,[20] respectively. Although 9-methylpurine and 2-hydroxypurine are decomposed by hot sulfuric acid,[21] I has been reported to be stable toward the action of hot dilute acids[22] or to undergo slight decomposition in more concentrated acid.[21,23] In our hands I appears to be one of the least stable purines toward the action of hot *p*-toluenesulfonic acid or sulfuric acid. In the pteridine series the parent compound was also found to be exceptionally unstable toward acid.[24]

A series of various purines and purine nucleosides were also analyzed for the formation of volatile acid. 9-Methylpurine and nucleosides of I were the only additional compounds that evolved appreciable amounts of volatile acid (Table I).

TABLE I

MOLES VOLATILE ACID EVOLVED PER MOLE OF COMPOUND[a]

Purine[b]	0.87,[f] 1.8,[g] 2.0[h]
9-Methylpurine[b]	0.63
6-Methylpurine[c]	Trace
6-Dimethylaminopurine[d]	0.0
6-Chloropurine[e]	.0
Adenine	.0
Guanine	.0
Xanthine	Trace
9-β-D-Ribofuranosylpurine	0.92
9-D-Ribopyranosylpurine	.84
9-D-(2′,3′,4′-Tri-*O*-acetylribopyranosyl)-purine	4.8
Adenosine	0.0
Guanosine	.0
6-Dimethylamino-9-β-D-ribofuranosyl-purine[d]	.0
6-Chloro-9-β-D-ribofuranosylpurine[e]	.0
6-Dimethylamino-9-β-D-(3′-amino-3′-deoxyribofuranosyl)-purine[d]	.0
6-Methyl-D-ribofuranosylpurine	Trace

[a] Analyses by J. F. Alicino, Metuchen, N. J.; H. B. Clark, Urbana, Ill.; and by this Laboratory, duplicates in most cases. [b] Obtained from A. Bendich of these Laboratories or (in the case of I) also purchased from Francis Earle Laboratories, Peekskill, N. Y. [c] Obtained from G. B. Elion and G. H. Hitchings, The Wellcome Research Laboratories, Tuckahoe 7, N. Y. [d] Obtained from B. R. Baker, Southern Research Institute, Birmingham, Ala. [e] In these two cases, silver sulfate was added to the distillation flask to trap any hydrogen chloride generated. No chloride ion was detected in the distillate. [f] Heated for 4 hr. 1.35 moles of NH_3 evolved per mole I. [g] Heated for 12 hr. 1.93 moles of NH_3 evolved per mole I. [h] Heated for 24 hr. 2.25 moles of NH_3 evolved per mole I.

I and IV do behave similarly to other members of the purine series in that the purine base is stable in 70% perchloric acid under conditions which are used to hydrolyze nucleic acids.[25]

Alkaline Instability.—A study of the spectral changes induced by the action of dilute alkali at room temperature on IV (see Fig. 1) showed that a compound (or compounds) were formed that exhibited two maxima in alkali and one in acid. Eventually the solution showed only non-specific end absorption. The similarity of the intermediate

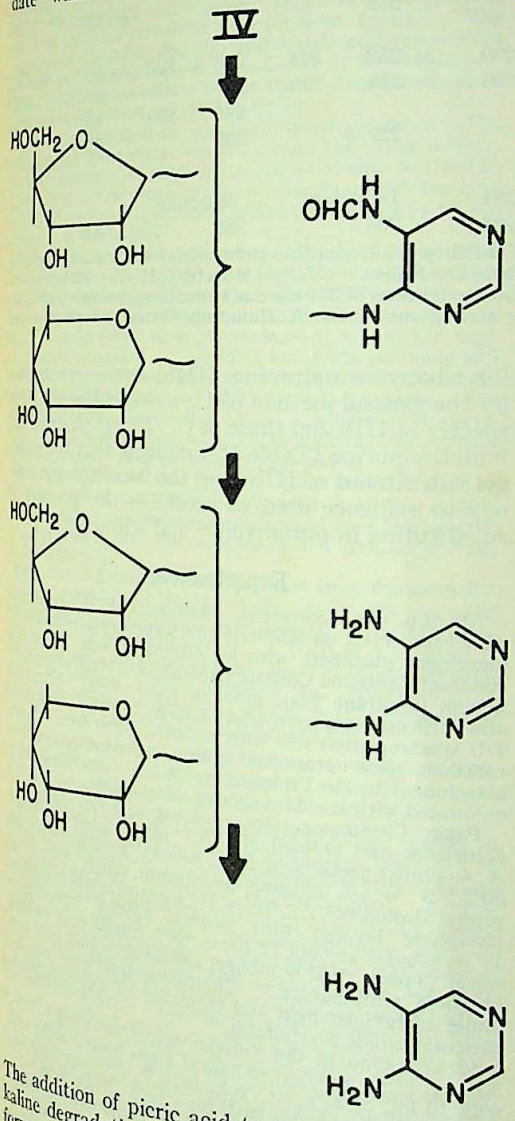
spectra with those of 4,5-diaminopyrimidine and 4-methylamino-5-aminopyrimidine strongly suggested that cleavage of the imidazole ring had occurred with the resulting formation of a derivative of 4,5-diaminopyrimidine. The solution was strongly reducing toward alkaline phosphomolybdate[14] which is also true for 4,5-diaminopyrimidine.



The addition of picric acid to a solution of the alkaline degradation products of IV resulted in the formation of 4,5-diaminopyrimidine picrate. Paper chromatography of the original reaction mixture indicated the presence of three components, each of which had spectra very similar to those of 4,5-diaminopyrimidine in acid and alkali. The fastest moving component, which was present in trace amounts, migrated with the R_f of 4,5-diaminopyrimidine. The two slower components gave positive tests for *cis*-glycol groups,[26] and these materials, when eluted from paper, gave strongly positive orcinol reactions.[27] The relatively large yield of the picrate of 4,5-diaminopyrimidine and the small amount of the free base in the reaction mixture indicate that some of the ribose-containing diamino compounds were cleaved by the aqueous picric acid.

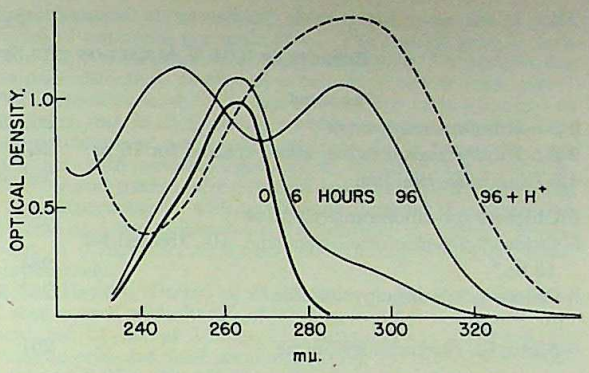


Fig. 1.—Spectral changes, with time, of 9-β-D-ribofuranosylpurine in 0.04 *N* sodium hydroxide.

The reaction which the nucleoside undergoes in alkaline solution may be related to the Bamberger reaction,[28] or it may be viewed as a reversal of the Traube purine synthesis.[29]

The reaction is depicted as in Scheme I.

Little evidence was obtained for intermediate formyl compounds, but they are logically expected.[30] The two ribosyl-4,5-diaminopyrimidines are depicted as furanose and pyranose forms, but the possibility of α- and β-isomers cannot be excluded.[32] Further decomposition of such products could lead to the formation of 4,5-diaminopyrimidine and its eventual decomposition products. The possibility that the two postulated ribosyl compounds could actually be Amadori-type rearrangement products was excluded by the following considerations: (a) the ready liberation of 4,5-diaminopyrimidine by picric acid, (b) the Amadori rearrangement is acid catalyzed,[33] whereas the reaction in question takes place in alkaline solution, (c) the intensities of the orcinol reactions of the glycosyl decomposition products of IV indicated the presence of *ca.* one mole of pentose per mole of 4,5-diaminopyrimidine. Products resulting from an Amadori rearrangement would be expected[34] to give very low values in a color test of this type, which depends upon a dehydration to a furfural derivative.

The ribofuranosyl derivatives of the IIa and IIb, as well as pyranosyl I (IIIb), were unstable in dilute aqueous alkali at room temperature. The

[a] 0.04 *N* sodium hydroxide. [b] 0.1 *N* hydrochloric acid. [c] 9-D-Ribopyranosylpurine gave similar spectral changes upon treatment with alkali. [d] The parent purine was stable under these conditions. [e] Values in water (*p*H 5) which agree more closely with those of the ribose derivative in acid. [f] There is also a maximum of 261 mμ due to unchanged starting material. A further study of the alkali lability of this compound is being carried out by Dr. A. Hampton. Some formyl compound has been detected among the reaction products.

absorption spectra of the decomposition products again indicated that the imidazole ring had been cleaved (Table II). A possible mechanism of this cleavage is considered in an accompanying paper.[31]

Examples of the instability of the 9-methylpurine[21] and of methylated oxypurines[35] in hot alkali have been reported. The formation of the compound $C_6H_7N_4Cl$ (which could be 4-amino-2-chloro-5-methylaminopyrimidine), by the action of hot potassium hydroxide on 2-chloro-7-methylpurine, could be explained by this same type of reaction.[36] Other known instances of the rupture of the purine ring system such as the cleavage of the imidazole ring of 2-methylmercaptopurine by mono- or dimethylamine[21] and the decomposition of 6-amino-2-methylmercaptopurine by alkylamines[37] are possibly due to similar mechanisms. The alkaline disruption of the pyrimidine ring of 3,5′-cyclo-6-dimethylamino-9-(3′-amino-3′-deoxy-β-D-ribofuranosyl)-purine-2′-3′-carbonate methanesulfonate[38] is not related. The stability[39] of most common naturally occurring purine nucleosides in dilute alkali at room temperature has been confirmed.[40]

TABLE III

ABSORPTION MAXIMA OF DERIVATIVES OF PURINE

	Max. in acid	Max. in water	Max. in base
Purine[a]	260	262.5	270
9-Methylpurine[a]	262.5	264	264
7-Methylpurine[a]	257.5	266.5	266.5
9-β-D-Ribofuranosylpurine[b]	262.5	262.5	262.5
9-D-Ribopyranosylpurine[c]	262.5	262.5	262.5

[a] Ref. 22. [b] Ref. 3. [c] See Experimental.

Syntheses.—Purine-8-C^{14} prepared from hypoxanthine-8-C^{14},[10] was diluted with non-radioactive I. The 6-methyl-D-ribofuranosylpurine and the 9-D-ribopyranosylpurine (IIIb) were synthesized by the general method of Davoll and Lowy.[41] The spectra of IIIb and those of IV, 7-methylpurine and 9-methylpurine (Table III) indicate that the glycosyl substituent of IIIb is on the 9-nitrogen, in analogy to evidence used to establish the position of substitution in puromycin[42] and adenosine.[43]

Experimental

All m.p.'s are corrected. Radioactivity determinations were carried out on infinitely thin samples plated on 10 cm.² aluminum planchets with an internal Geiger–Müller flow counter (Radiation Counter Laboratories, Mark 12, model 1, helium isobutane gas), probable error ±5%. Ultraviolet absorption spectra were determined with the Beckman model DU spectrophotometer with matched 1-cm. cells. Optical rotations were determined with a polarimeter, model D, attachment to the Beckman model DU spectrophotometer, calibrated with standard sucrose solutions.[44]

Paper Chromatography.—Solvent systems (descending, Schleicher and Schuell No. 597 paper) were (vol./vol.): A = glacial acetic acid 20%, *n*-butyl alcohol 50%, water 30%, B = 1% aqueous ammonium sulfate 33⅓%, isopropyl alcohol 66⅔%,[45] C = 5% aqueous monobasic sodium phosphate layered with isoamyl alcohol (ascending)[46]; D = *n*-butyl alcohol 77 parts, 88% formic acid 10 parts, water 13 parts,[47]; E = *n*-butyl alcohol saturated with water at room temperature.[48] Chromatograms were inspected under ultraviolet light and examined for the formation of mercuric sulfide precipitates.[49]

Identification of the Volatile Acid from Purine (I).—A 200-mg. (1.66 mmoles) sample of I was heated under reflux with 10 ml. of 25% (w./vol., *ca.* 1.3 *M*) *p*-toluenesulfonic acid in a boiling water-bath for 4 hr.[11] Then 6 ml. of *ca.* 0.8 *N* sodium hydroxide was added to partially neutralize the *p*-toluenesulfonic acid. The volatile acid was steam distilled, and 50-ml. fractions were titrated to the phenolphthalein end-point with sodium hydroxide until a constant titer was obtained. This large-scale procedure yielded 1.44 mmoles of volatile acid. The solutions of the sodium salt of

Digitized by Arya Samaj Foundation Chennai and eGangotri

the volatile acid were combined and concentrated *in vacuo* to 2.0 ml. One-half of the sodium formate was converted to S-benzylisothiouronium formate.[12] The m.p. was 149–149.5°, mixed with the known formate derivative 149–149.5°, mixed with reagent 122–142° (capillary). The remaining sodium formate was converted to benzimidazole,[13] m.p. 172–173°, picrate 230–232°, no depression on admixture with known samples.

Action of Concentrated Perchloric Acid on I and the Purine Moiety of IV.—A 9.0-mg. sample of I was heated with 1 ml. of 70% perchloric acid for 1 hr. at 100°. The solution was diluted to 500 ml. with water, and the spectra in acidic and basic solutions were found to be unchanged. The values at the maximum and at the isosbestic point, 275 mμ,[11] indicated recoveries of 97 to 98%.

A 7.0-mg. sample of IV was hydrolyzed as above. The carbonaceous precipitate, resulting from the sugar moiety, was finely ground and thoroughly extracted with hot water. Spectrophotometric assay at the maximum and at the isosbestic point indicated recoveries of the purine moiety of 100 to 103%, respectively.

Action of Sulfuric Acid.—Two hundred mg. (1.66 mmoles) of I was heated 4 hr. at 100° with 15.0 ml. of 1.3 *N* sulfuric acid. The solution became bright yellow in 10 minutes and later brownish. Steam distillation, as above, yielded a total of 1.04 mmoles (0.62 mole per mole of I) of volatile acid. The residue contained 1.3 moles of ammonia per mole of I and gave positive tests with alkaline phosphomolybdate, the Bratton–Marshall, and the Ehrlich reagents. The spectrum of the diluted residue, at *p*H 4, indicated the presence of *ca.* 50% of unchanged I. A shoulder at 280 mμ indicated the presence of decomposition products.

Recovery of Formic Acid from *p*-Toluenesulfonic Acid.—A mixture of 3.41 mmoles of formic acid in 15 ml. of 25% aqueous *p*-toluenesulfonic acid was treated as in the analysis for acetyl groups, with the recovery of 3.47 mmoles of volatile acid (101%).

Formation of Radioactive Formic Acid from Purine-8-C^{14}.

A. Heating Period of 4 Hours.—Purine-8-C^{14}, 321 mg. (2.68 mmoles, 28.0 c.p.m./μmole) was treated with *p*-toluenesulfonic acid as described above. A total of 0.87 mole of formic acid and 1.35 moles of ammonia was found per mole of I. The sodium formate obtained was converted to S-benzylisothiouronium formate, which was recrystallized from aqueous ethyl alcohol, m.p. 149–149.5°.

Anal. Calcd. for $C_9H_{12}N_2O_2S$ (212.3): C, 50.9; H, 5.70; N, 13.2; S, 15.1. Found: C, 51.2; H, 5.66; N, 13.6; S, 15.3; specific activity, 8.2 c.p.m./μmole.

B. Heating Period of 12 Hours.—A 250-mg. sample of purine-8-C^{14} (2.08 mmoles, 86 c.p.m./μmole) yielded 3.72 mmoles of volatile acid. The neutralized steam distillate was concentrated and brought to exactly 5.00 ml. A 1.25-ml. (0.93 mmole) aliquot was placed in a 25-ml. flask with 102 mg. (0.93 mmole) of 4,5-diaminopyrimidine and 0.20 ml. of 5 *N* hydrochloric acid. The solution was refluxed 1 hr. at 100° and evaporated to dryness under nitrogen. The yellowish residue was heated at 210° for 5 minutes in a nitrogen atmosphere. The residue was dissolved in 15 ml. of water and 0.2 ml. of 70% perchloric acid, and excess 10% silver nitrate was added. The mixed silver chloride and silver salt of I were collected by centrifugation and washed twice with 10 ml. of water. The salts were decomposed by two hot 10-ml. portions of 1 *N* hydrochloric acid. The acidic solution of I was evaporated to dryness *in vacuo*, redissolved in water, adjusted to *p*H 7 and evaporated in a sublimation apparatus. Compound I was sublimed at 0.01 mm. pressure at a bath temperature of 120°, giving 39 mg. (0.33 mmole, 35% yield) of material melting at 213–215°. The admixed with an authentic sample of I, 214–215°. The spectrum was identical with that of I except for slight end absorption. Samples of the material were purified by chromatography on Whatman No. 3 MM paper in solvent systems D and E, with good separation from trace amounts of both a slower moving yellow and a fluorescent blue impurity. The spectra of aqueous solutions of samples thus purified were identical with that published. Radioactivity measurements gave values of 29.2 and 29.6 c.p.m./μmole for materials purified in solvents D and E, respectively (an average of 34% of the specific activity of the starting material).

The dark brown residue from the steam distillation of the formic acid was neutralized with 10 *N* sodium hydroxide and determination of ammonia[50] showed the presence of 1.93 moles of ammonia per mole of I. The residue gave a dark blue color with alkaline phosphomolybdate,[14] a pink in the Bratton–Marshall test[16] and a brownish-yellow with diazotized sulfanilic acid.[17] In the above color tests solutions of *ca.* 1 mg./ml. in 25% aqueous *p*-toluenesulfonic acid of I reacted uniformly negatively, whereas all of the tests were positive with similar solutions of 4,5-diaminopyrimidine. Glycine and purine were detected in the residue by ascending chromatograms, in which reference samples of purine and glycine and the unknowns gave identical R_f values: in solvent A, 0.73, 0.37; in B, 0.71, 0.29; and in C, 0.67, 0.84, respectively.

C. Heating Period of 24 Hours.—A 151-mg. sample of I was heated with 60 ml. of 25% aqueous *p*-toluenesulfonic acid for 24 hr. at 100°. The mixture was analyzed for volatile acid and base as above giving 2.0 moles of volatile acid and 2.25 moles of ammonia per mole of I, respectively. It was noticed that with the large excess of *p*-toluenesulfonic acid the solution did not darken appreciably.

Spectral Studies of Alkaline Instability.—A solution of IV with an optical density of about 1 at 260 mμ was prepared in 0.04 *N* sodium hydroxide. The solution was kept tightly stoppered in the dark, and at appropriate intervals the spectrum was determined on aliquots against the appropriate blank (Fig. 1). After 96 hr. the spectrum of an aliquot was determined both in acid and alkaline solution. A similar procedure was used to determine the alkali instability of the compounds listed in Table II.

Isolation of 4,5-Diaminopyrimidine from the Degradation of IV.—A 500-mg. sample of IV was treated with 40 ml. of saturated barium hydroxide for 4 days. At this time the spectrum in alkali exhibited the two peaks characteristic of 4,5-diaminopyrimidine. The solution was neutralized with carbon dioxide, filtered, the precipitate washed and the filtrate and washings combined to give 60 ml. of a clear yellow solution. This solution gave a deep blue color when tested with alkaline phosphomolybdate. A 10-ml. portion (estimated to contain 0.33 mmole of free and combined 4,5-diaminopyrimidine) was treated with 10 ml. of saturated aqueous picric acid, and a yellow crystalline precipitate formed immediately. This was collected, recrystallized from 15 ml. of 1:1 ethyl alcohol:water to yield 51 mg. (0.15 mmole, 47%) of material, m.p. 264–266° dec.; admixture with an authentic sample[51] of 4,5-diaminopyrimidine picrate did not lower the melting point.

Anal. Calcd. for $C_{10}H_9O_7N_7$ (339.2): N, 28.9. Found: N, 28.8.

Paper Chromatographic Studies.—A 10.7-mg. sample of IV was dissolved in 1.0 ml. of saturated barium hydroxide. Aliquots withdrawn at 0, 24, 72, 96 and 120 hr. were chromatographed (ascending, solvent E) in parallel with control spots of starting material, R_f 0.32, and 4,5-diaminopyrimidine, R_f 0.40. Upon visual inspection under ultraviolet light, the riboside spot was dark while that of the diaminopyrimidine was a fluorescent blue. After 24 hr. some starting material remained; however, two additional fluorescent blue spots of R_f's 0.084 and 0.17, respectively, had appeared. After 72 hr., these latter two spots had increased in intensity, and a small amount of material at the position of 4,5-diaminopyrimidine was evident. All three of these components showed ultraviolet absorption spectra identical to that of 4,5-diaminopyrimidine. The parent nucleoside was no longer detectable. Chromatograms at 96 and 120 hr. were similar to that after 72 hr.

Chromatograms prepared from the 96-hr. reaction mixture were examined more closely with the results shown in Table IV. If it is assumed that the molar extinction coefficients of these three components are equal, it may be concluded that about 90% of the 4,5-diaminopyrimidine was combined with a pentose moiety.

No evidence was seen for any formylated derivatives on the above chromatograms. When 0.04 *N* sodium hydroxide was used and the solution tested after 4 hr., the trailing edges of the two pentose-containing spots had a dark appearance characteristic of 5-formamido-4-aminopyrimidine; however, the separation from other components was very poor.

TABLE IV

PROPERTIES OF THE DEGRADATION PRODUCTS

Rf	*cis*-Glycol test[26]	Orcinol test[27]	Optical density at 288 mμ, *p*H 5.2[a]
0.084	+	+	0.78
.17	+	+	.75
.40	−	−	.16

[a] Determined on the material eluted from one lane with 4 ml. of water. Assuming an ϵ_{max} of 7250 for the products (ϵ_{max} at 289 = 7250 for the uncharged molecule of 4,5-diaminopyrimidine[52]), the two slow moving compounds each contained *ca.* one mole of ribose per mole of 4,5-diaminopyrimidine.

6-Methyl-D-ribofuranosylpurine.—A 402-mg. (3 mmoles) sample of IIa was converted to its chloromercuri derivative[41] giving 0.900 g. (2.44 mmoles, 81.5%) of product. The chloromercuri-6-methylpurine was condensed with 2,3,5-tri-*O*-acetyl-D-ribosyl chloride[53] prepared from 0.945 g. (3.0 mmoles) of tetraacetylribofuranose,[54] and the product was worked up as described below, except that the intermediate triacetyl compound was not obtained in crystalline form. Two recrystallizations of the crude 6-methyl-D-ribofuranosylpurine from ethyl alcohol gave 100 mg. (0.38 mmole, 12.5%) of product in the form of fine needles, m.p. 209–210°. In another preparation, from 2.6 g. of IIa, a yield of 21% was obtained.

Anal. Calcd. for $C_{11}H_{14}O_4N_4$ (266.3): C, 49.6; H, 5.29; N, 21.0. Found: C, 49.7; H, 5.50; N, 21.2.

The absorption maxima were: ϵ_{265} = 6340 at *p*H 1, ϵ_{261} = 7640 at *p*H 5.5 and 11 (when determined immediately).

9-D-Ribopyranosylpurine (IIIb).—A 1.00-g. (8.3 mmoles) sample of I was converted to its chloromercuri derivative (2.74 g., 7.8 mmoles),[3] and the dried, powdered chloromercuri salt was condensed with 2.8 g. (9.5 mmoles) of crystalline 2,3,4-tri-*O*-acetyl-D-ribosyl chloride[55] by refluxing in xylene for 4 hr. By previously described procedures,[41] 3.19 g. of crude crystalline 9-D-triacetylribopyranosylpurine (IIIa) was obtained, which, when recrystallized from ethyl alcohol, gave 1.1 g. of product (2.9 mmoles, 35%) melting at 169–171°.

Treatment of 570 mg. of IIIa (1.45 mmoles) for 16 hr. at 5° with methanolic ammonia gave 410 mg. of IIIb. After two recrystallizations from *n*-butyl alcohol, the product, 280 mg. (1.1 mmoles), melted at 250–252° (76% yield from the acetyl derivative, 13% over-all yield from I). A sample recrystallized from ethyl alcohol was analyzed.

Anal. Calcd. for $C_{10}H_{12}O_4N_4$ (252.2): C, 47.5; H, 4.80; N, 22.2. Found: C, 47.6; H, 4.73; N, 21.7; $[\alpha]^{20}_{546m\mu}$ −33.8°; $[\alpha]^{20}_{589m\mu}$ −28.7° (0.5% in water).

The absorption spectrum possessed a maximum at 262.5 mμ, the position of which did not change in acid or alkali (when determined immediately). The ϵ_{max} at *p*H 0.3 was 5.65 × 10³, at *p*H 7.7 was 6.91 × 10³ and at 12.3 was 7.06 × 10³. There were two isosbestic points: one at 231.5 mμ with ε 2.64 × 10³ and one at *ca.* 268 mμ with ε 4.67 × 10³. The apparent pK_a was found to be 1.80 ± 0.05 by the procedure outlined by Fox and Shugar.[56]

Acknowledgments.—The authors wish to thank Dr. Aaron Bendich for making available samples and spectra of 6-chloro-4,5-diaminopyrimidine, 4,5-diaminopyrimidine, 4,5-diamino-6-methylpyrimidine and 5-amino-4-methylaminopyrimidine; and Dr. Jack J. Fox for the determination of the rotation of IIIb. The assistance of Mrs. Orsalia Intrieri and Mr. Bernard Nidas is gratefully acknowledged.

Synthesis of an Isopropylidene Derivative of an Alkali-labile Nucleoside: 2′,3′-O-Isopropylidene-9-β-D-ribofuranosylpurine[1]

BY ALEXANDER HAMPTON AND DAVID I. MAGRATH

RECEIVED NOVEMBER 16, 1956

2′,3′-*O*-Isopropylidene-9-β-D-ribofuranosylpurine can be prepared in good yield by condensation of 9-β-D-ribofuranosylpurine with acetone in the presence of zinc chloride or in the presence of *p*-toluenesulfonic acid. The techniques should be useful for the preparation of isopropylidene derivatives of other alkali-labile purine nucleosides. With *p*-toluenesulfonic acid the conversion is rapid and quantitative at room temperature and the method may be applicable to nucleosides in general.

2′,3′-*O*-Isopropylidene-9-β-D-ribofuranosylpurine was desired for the synthesis of 9-β-D-ribofuranosylpurine-5′-phosphate,[2] and a number of procedures for its preparation have been examined.

The 2′,3′-*O*-isopropylidene derivatives of many nucleosides[3–6] have been prepared by condensations with acetone in the presence of zinc chloride. The resulting complex of the product with zinc chloride was in each case decomposed with warm barium hydroxide. 9-β-D-Ribofuranosylpurine[7] and its 2′,3′-*O*-isopropylidene derivative were found to be alkali-labile, and application of the usual work-up led to considerable losses. Milder conditions for breakdown of the zinc chloride complex were investigated. Ion-exchange chromatography of an aqueous solution of the reaction products using Dowex-50 resin (NH_4^+) effected the removal of the zinc ions without decomposition of the isopropylidene derivative, but a large excess of resin was required and 60% of the product was retained on the column. A more satisfactory procedure was treatment of the reaction mixture at 0° with aqueous sodium carbonate, whereupon the 2′,3′-*O*-isopro-

pylidene compound could be isolated in 80% yield.

Weakly basic ribonucleosides, *e.g.*, uridine,[8] or ones that form acetone-soluble sulfates[9] have given 2′,3′-*O*-isopropylidene derivatives when treated with acetone in the presence of sulfuric acid and anhydrous copper sulfate, but 9-β-D-ribofuranosylpurine did not react under these conditions. It has been shown in the case of 2-methylmercapto-6-dimethylamino-9-β-D-xylofuranosylpurine that the yield of the 3′,5′-*O*-isopropylidene derivative can be improved by replacing the sulfuric acid with ethanesulfonic acid, thereby forming a more acetone-soluble salt.[10] In the present work, when *p*-toluenesulfonic acid was substituted for sulfuric acid, 50% of the 9-β-D-ribofuranosylpurine was converted to the isopropylidene derivative, with dissolution of some copper (presumably as copper *p*-toluenesulfonate) and concomitant production of sulfuric acid, and prolonging the reaction yielded no more isopropylidene compound. The effect of omitting copper sulfate from the mixture was accordingly examined. In the presence of a sufficient quantity (10 equivalents) of *p*-toluenesulfonic acid monohydrate, 9-β-D-ribofuranosylpurine formed a salt which was readily soluble in acetone, and in 30 minutes quantitative conversion to the isopropylidene derivative occurred.

Conversions to isopropylidene derivatives by the acetone–sulfuric acid–copper sulfate method are either slow[8] or incomplete[9,10] and the use of acetone and *p*-toluenesulfonic acid monohydrate (or anhydrous) may prove generally useful.

Experimental

Paper chromatograms were run by the ascending method using Schleicher and Schuell No. 597 paper and were inspected in ultraviolet light.

Zinc Chloride Method.—A solution of zinc chloride (43 g.) in acetone (450 cc., distilled from a slight excess of potassium permanganate, then dried over sodium sulfate) was filtered into a dry flask containing 9-β-D-ribofuranosylpurine (13.7 g., dried over phosphorus pentoxide for 3 hr., 110°, 0.4 mm.). The cloudy solution was refluxed for 30 hr.[11] with exclusion of moisture. About half the acetone was removed under vacuum and the pale yellow solution poured into a solution of anhydrous sodium carbonate (43 g., 30% excess) in water (450 cc.) containing ice (50 g.). The mixture was stirred for 10 minutes and the zinc carbonate collected, washed with water and then with acetone. A solution of barium chloride dihydrate (33 g., 50% excess) in water (100 cc.) was added to the combined filtrate and washings and the barium carbonate collected. The filtrate was evaporated to dryness *in vacuo* and the residue dried azeotropically with benzene, then triturated with hot benzene (2 × 100 cc.). The benzene extract was concentrated *in vacuo* to *ca.* 80 cc., treated with charcoal (0.5 g.) and evaporated to dryness *in vacuo*. A solution of the yellow gum (14.6 g.) in methanol (25 cc., concentrated to *ca.* 15 cc.) furnished white hygroscopic needles (dried over phosphorus pentoxide at 0.1 mm.; 12.8 g., 80% yield), m.p. 44–45° (uncor.); light absorption in water, maximum 262.5 mμ; R_f 0.80 and 0.87 for paper chromatography in 1-butanol–water and in 1-butanol–water–acetic acid (5:3:2), respectively.

Anal.[12] Calcd. for $C_{13}H_{16}N_4O_4$: C, 53.40; H, 5.52; N, 19.17. Found: C, 53.03; H, 5.75; N, 19.03.

***p*-Toluenesulfonic Acid Method.**—*p*-Toluenesulfonic acid monohydrate[13] (7.5 g., 10 equivalents; dried over NaOH) was added to a magnetically-stirred suspension of dry 9-β-D-ribofuranosylpurine (1.0 g.) in acetone (150 cc., dried with Drierite and distilled). The pale yellow solution was kept at 25° and protected from moisture. At intervals, portions were withdrawn, treated with a small excess of 0.5 *N* sodium bicarbonate and examined by paper chromatography, using ethanol (85%)–water(15%) as the solvent system. After 30 minutes, conversion of the ribosylpurine (R_f 0.53) to the isopropylidene derivative (R_f 0.79) was complete. The solution was then added to 0.5 *N* aqueous sodium bicarbonate (170 cc.) and the mixture evaporated to dryness *in vacuo*. The residue was extracted with benzene and the product purified as described above, giving white needles, m.p. 44–45°, of the isopropylidene derivative (1.05 g., 90%).

When a solution of the product in 0.2 *N* NaOH was allowed to stand at room temperature for 24 hr., the initial single-peak ultraviolet spectrum (262.5 mμ) was replaced by a spectrum showing two well-defined maxima at 249 and 288 mμ, respectively (ratio of ϵ_{249} to ϵ_{288} = 0.92). This is similar to the spectrum[2,14] of 4,5-diaminopyrimidine in alkaline solution and to the ratio of ϵ_{246} to ϵ_{289} of 0.93[14] for that pyrimidine.

Acknowledgment.—The authors wish to thank Dr. George Bosworth Brown for continued interest and encouragement and for helpful discussions.

The Synthesis of 9-β-D-Ribofuranosylpurine-5′-phosphate and its Behavior Toward Aqueous Alkali[1]

BY DAVID I. MAGRATH[2] AND GEORGE BOSWORTH BROWN

RECEIVED NOVEMBER 16, 1956

The synthesis of 9-β-D-ribofuranosylpurine-5′-phosphate is reported. Two substances formed by the action of dilute aqueous alkali on the nucleotide, and also isolated as by-products during its synthesis, have been tentatively identified as 5-amino and 5-formamido derivatives of 4-(5′-phosphoribofuranosylamino)-pyrimidine.

In studies of potential tumor-inhibiting agents, 9-β-D-ribofuranosylpurine (I) was synthesized in this Laboratory and shown[3,4] to be identical with nebularine, a toxic, naturally occurring material.[4-6] The metabolism[7] of this compound led to three derivatives of purine-C^{14} in the soluble nucleotide fraction from the liver. From their behavior on the ion-exchange resin, these were postulated to be the 5′-mono-, di- and triphosphates of the administered ribosylpurine. Since it was desirable to have an authentic specimen for comparison and for investigation of potential pharmacodynamic properties, the synthesis of 9-β-D-ribofuranosylpurine-5′-phosphate (II) was undertaken.

2′,3′-*O*-Isopropylidene-9-β-D-ribofuranosylpurine[8] was treated with dibenzylphosphorochloridate in pyridine solution to give 2′,3′-*O*-isopropylidene-9-β-D-ribofuranosylpurine-5′-dibenzylphosphate. Hydrogenation effected smooth removal of both benzyl groups, and the isopropylidene group could then be removed from the product by allowing the free acid to stand in aqueous solution.[9]

Examination of this solution by paper chromatography revealed the main product and two other phosphorus-containing, ultraviolet light-absorbing materials, as well as a small amount of free ribosylpurine. The contaminants were separated from the main product by chromatography over a column of powdered cellulose. The main product contained organically-bound phosphorus and a *cis*-glycol[10] system and, in several paper chromatographic systems, gave only one ultraviolet light-absorbing spot with R_f values of the order to be expected of a mononucleotide. Further purification over Dowex-50 resin furnished the free acid as a pale cream-colored solid. Its ultraviolet spectrum in acid, alkali and water was almost identical with that of 9-β-D-ribofuranosylpurine,[3] and analysis indicated it to be a monohydrate of the 5′-monophosphate. It was eluted as a single, sharp peak from a Dowex-2 (formate) ion-exchange column at a position on the elution diagram consistent with its being a mononucleotide.

9-β-D-Ribofuranosylpurine-5′-phosphate was not unstable in 0.1 *N* acid at room temperature but in alkali was decomposed readily to give a mixture of two substances similar to the by-products formed during its synthesis.[12] A mixture of the latter, recovered as a cream-colored powder from the cellulose column, yielded, upon acid hydrolysis, a number of products. The main ultraviolet light-absorbing component had R_f values and spectral characteristics the same as 4,5-diaminopyrimidine. Examination of chromatograms showed a pattern of phosphorus and aniline phthalate-positive (*i.e.*, reducing carbohydrate[13]) spots identical with that obtained with a similar hydrolysate of adenosine-5′-phosphate: namely, two aniline phthalate-positive spots, one faint and having R_f values similar to D-ribose, the other, present in considerable amount, containing phosphorus and having R_f values similar to D-ribose-5-phosphate. Inorganic phosphate was distinguished from the sugar phosphate on chromatograms run in acetone–water–acetic acid.[14]

The two by-products were separated on a small scale by chromatography on paper. Both contained organically bound phosphate and a *cis*-glycol system and migrated on paper chromatography and electrophoresis as typical mononucleotides. The chromatographically faster-moving by-product could be converted into the slower-moving component by further alkaline hydrolysis.

The slower-moving component appeared as a fluorescent blue spot under ultraviolet light, gave positive reactions in the alkaline phosphomolybdate test[15] and the Bratton–Marshall test[16] and had a spectrum in acid, alkali and water generally similar to that of 4,5-diaminopyrimidine (Fig. 1). Its pK_a, determined spectrophotometrically, was 5.7 (4,5-diaminopyrimidine, 6.03).[17] The chromatographically faster-moving by-product gave a negative reaction in both the above color tests. The

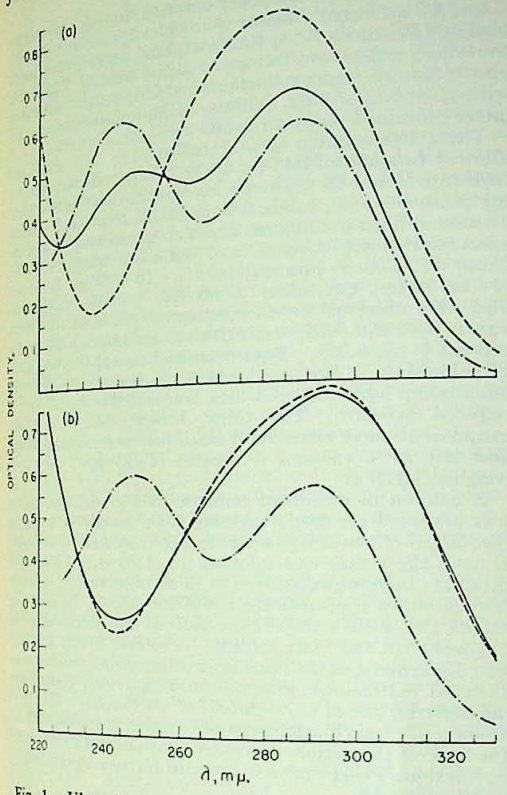

Fig. 1.—Ultraviolet spectra of: (a) 4,5-diaminopyrimidine; (b) chromatographically slower-moving by-product. In 0.1 *N* HCl (.....), 0.1 *N* NaOH (—·—·) and H_2O (——, *p*H 6.48 and 4.51, respectively).

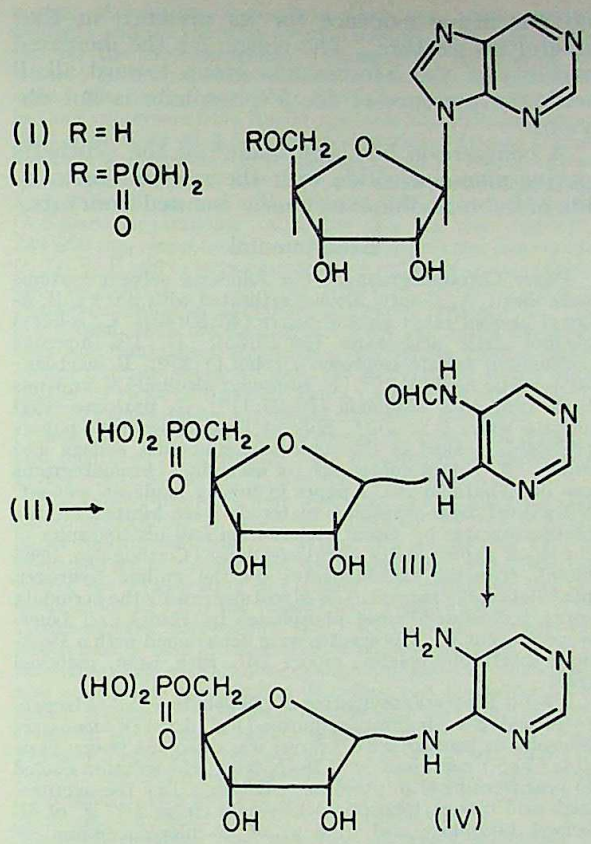
similarity of its ultraviolet spectrum with that of 4-amino-5-formamidopyrimidine[18] is apparent (Fig. 2). The latter was found to possess a pK_a value of 11.40, which may be attributed to the 5-formamido group, and a value of 11.43 was found for the by-product.

It appears that the two substances produced by the alkaline hydrolysis of 9-β-D-ribofuranosylpurine-5′-phosphate, and also found as by-products during its synthesis, are 5′-phosphoribofuranosyl derivatives of 4,5-diaminopyrimidine (III and IV), one (III) still carrying the 8-carbon atom of the original molecule as a formyl group attached to the primary[19] amino group of IV. The presence of the 5′-phosphate group precludes furanose–pyranose isomerization, although mutarotation at the glycosyl linkage is still possible for either compound.

The initial step in the alkaline degradation of the purine nucleoside[11] and of this nucleotide probably involves a nucleophilic attack on the 8-carbon atom by hydroxyl ion; the subsequent ring opening is perhaps facilitated by conjugation of the resulting ionized formamido group with the pyrimidine ring.



The alkali degradation products of 9-β-D-ribofuranosylpurine are thought[11] to be ribofuranosyl and -pyranosyl derivatives of 4,5-diaminopyrimidine, which had resulted from the loss of the 8-carbon atom. The degradation was postulated as proceeding by way of the intermediate formation of the 5-formamido compound, although there was

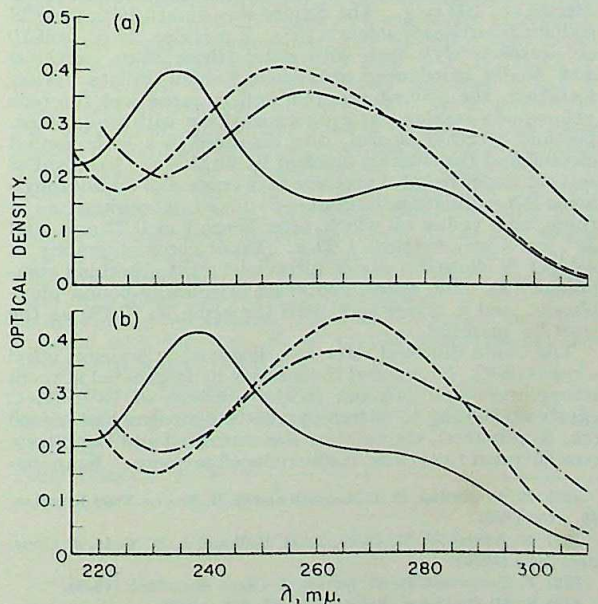


Fig. 2.—Ultraviolet spectra of: (a) 4-amino-5-formamidopyrimidine; (b) chromatographically faster-moving by-product, in 0.1 *N* HCl (.....), 0.1 *N* NaOH (—·—·) and H$_2$O (——, *p*H 5.88 and 5.23, respectively).

(18) Authentic samples of this and related compounds were kindly sent us by Professor Adrien Albert and Dr. D. J. Brown, Department of Medical Chemistry, the Australian National University. For proof of the position of the formyl group see D. J. Brown, *J. Applied Chem.*, **5**, 358 (1955).

(19) A formyl group attached to the ribosylamino group of IV should not give rise to the pK_a value of 11.4 observed for the faster-moving by-product.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

no conclusive evidence for its presence in that hydrolysis mixture. The reason for the increased stability of the 5-formamido group toward alkali with the presence of the 5′-phosphate is not obvious.

A comparison has been made[20] of the synthetic purine mononucleotide with the relevant metabolite of 9-β-D-ribofuranosylpurine isolated from rats.

Experimental

Paper Chromatography.—The following solvent systems were used: A, *n*-butyl alcohol saturated with water; B, *n*-butyl alcohol–ethyl alcohol–water (45:30:40); C, *n*-butyl alcohol–acetic acid–water (50:20:35); D, 1% aqueous ammonium sulfate–isopropyl alcohol (1:2)[21]; E, acetone–30% acetic acid (1:1)[14]; F, isopropyl alcohol–1% aqueous boric acid–10% ammonia (50:25:1)[22]; G, pyridine–ethyl acetate–water (1:2:2).[23] Solvent D was used with papers previously soaked in 1% aqueous ammonium sulfate and dried. R_f values quoted are for ascending chromatograms run on Whatman No. 1 paper in freshly made up solvent. Ultraviolet light-absorbing materials were located on the chromatograms by visual examination and photography of the dried papers under ultraviolet light (Corning No. 9863 filter), reducing carbohydrates by the aniline hydrogen phthalate spray reagent,[13] *cis*-glycol systems by the periodate spray technique[10,24] and phosphates by Hanes and Isherwood reagent.[25] The spectra were determined with a Beckman spectrophotometer, model DU, with 1-cm. matched cells.

9-β-D-Ribofuranosylpurine-5′-phosphate.—2,3-*O*-Isopropylidene-9-β-D-ribofuranosylpurine (1 g., dried *in vacuo* over phosphorus pentoxide for 3 days) was dissolved in dry pyridine (5 cc.) contained in a 25-cc. flask, the solution cooled to near freezing (f.p. pyridine −42°) in a Dry Ice–acetone-bath and dibenzylphosphorochloridate (from 2.17 g. of dibenzyl phosphite and 1.44 g. of N-chlorosuccinimide)[26] added and the residual reagent washed from the container with *ca.* 3 cc. of cold pyridine. The flask was stoppered and the reaction mixture kept in a semi-frozen condition for 5 hr., then left in the cooling bath overnight. After removal from the cooling bath, a solution of sodium acetate (4 g. anhydrous) in water (10 cc.) was added and the mixture shaken vigorously for 1.5 hr., then evaporated to dryness under reduced pressure (bath temperature <30°). The crystalline residue was thoroughly triturated with chloroform and the solid collected and washed with more solvent (total filtrate *ca.* 100 cc.). The filtrate was shaken with ice-cold sodium bicarbonate solution (5%; 2 portions, 25 cc. and 10 cc., respectively), then with water (three 25-cc. portions) and finally dried over anhydrous sodium sulfate. After filtration, the solvent was removed *in vacuo* and the pale yellow, oily residue was evaporated down with three 10-cc. portions of ethyl alcohol, then dissolved in a little methyl alcohol and the solution clarified by filtration. Removal of solvent under reduced pressure gave crude 2′,3′-*O*-isopropylidene-9-β-D-ribofuranosylpurine-5′-dibenzylphosphate as a thick, pale yellow oil which, after keeping at 0.22 mm. and 30° for 2 hr., weighed 1.69 g. Paper chromatography in solvent A showed a major ultraviolet light-absorbing component (R_f 0.89) which contained organically-bound phosphorus, and a minor spot with the same R_f (0.79) as the starting material.

The crude dibenzyl ester was dissolved in aqueous ethyl alcohol (60%, 50 cc.) and the solution hydrogenated at room temperature and pressure in the presence of 10% Pd-C catalyst (160 mg.). After uptake of hydrogen had ceased (*ca.* 50 minutes), the catalyst was separated and the filtrate concentrated to *ca.* 5 cc. under reduced pressure. Examination of this solution by paper chromatography (solvents A, B and C) indicated a major ultraviolet light-absorbing component (R_f values 0.14, 0.60 and 0.61, respectively) which contained phosphorus but no *cis*-glycol system. There were also traces of isopropylideneribosylpurine and a substance with R_f values of 0.02, 0.40 and 0.36, respectively, and the latter contained phosphorus and a *cis*-glycol system.

The above solution was diluted to 30 cc. with water and allowed to stand at 24° for 48 hr. Paper chromatography (solvents B and C) showed a major ultraviolet light-absorbing component (R_f values 0.40 and 0.36, respectively) which contained both phosphorus and a *cis*-glycol system, and the spectra of which in water, acid and alkali closely resembled those of 9-β-D-ribofuranosylpurine. In addition to a trace of the latter, two other ultraviolet light-absorbing spots also were observed on chromatograms run in solvent B (R_f values 0.34 and 0.26, respectively); they ran as one spot in solvent C (R_f 0.26). Both contained phosphorus and a *cis*-glycol system. The solution was adjusted to *ca.* *p*H 7 with ammonium hydroxide and then evaporated to dryness under reduced pressure. The thick, brown, oily residue was evaporated three times with small portions of ethyl alcohol and left in a vacuum desiccator (P_2O_5) for 2 days. It weighed 1.126 g.

A column of powdered cellulose (350 g., 6.5 cm. diam.) was prepared by firmly pressing down successive additions (*ca.* 50 g.) of the dry powder, and then washed with solvent C until the eluate was colorless (*ca.* 1300 cc.). The crude product above was dissolved in 10 cc. of solvent C, the solution carefully applied to the top of the column, the container rinsed out with a little more solvent and the column developed with the same solvent. The first 230 cc. of eluate was discarded and the remainder collected in fractions of *ca.* 18 cc. at 7–10 minute intervals until ultraviolet light-absorbing material ceased to be eluted (*ca.* fraction 60). The small amount of ribosylpurine present appeared in fractions 19–31, the bulk of the major ultraviolet light-absorbing component in fractions 34–41 and a mixture of the two by-products in fractions 49–58.

Fractions 34–41 were combined and evaporated to dryness *in vacuo;* small white crystals separated during the latter stages of the evaporation. The pale brown residual sirup was evaporated down once with methyl alcohol and then left in a vacuum desiccator (P_2O_5) overnight, when it became converted to a hygroscopic frothy solid, weight 0.61 g. Paper chromatograms of this material, run in solvent C, showed only one ultraviolet light-absorbing spot (R_f 0.36), giving tests for both phosphorus and a *cis*-glycol system. The molybdate spray reagent, however, revealed the presence of a small amount of inorganic phosphate[27] traveling just ahead of the ultraviolet light-absorbing compound. A further 61 mg. of almost chromatographically pure material was recovered from fractions 42–44.

The solid (0.60 g.) was dissolved in water (10 cc.), the *p*H adjusted to *ca.* 7 with dilute ammonium hydroxide and the solution applied to a column (1 cm. diam.) of Dowex-50 ion-exchange resin (H^+; 5 cc. wet resin).[28] The column was then washed with water until ultraviolet light-absorbing material ceased to be eluted and early fractions of eluate, containing inorganic phosphate[29] but no ultraviolet light-absorbing material, were discarded. Vacuum evaporation of the eluate (bath temperature <25°) gave a semi-solid residue which was redissolved in water (10 cc.) and the ice-cooled solution brought to *p*H 8–9 by the dropwise addition of 7% aqueous barium hydroxide (*ca.* 5 cc.), with any excess being removed quickly by passing in carbon dioxide. Only a very slight precipitate of barium phosphate formed. The solution was concentrated somewhat under reduced pressure, then clarified by filtration and the filtrate concentrated to 5–10 cc. This solution was applied to a second column of Dowex-50 resin (H^+; 5.5 cc. of wet resin), which was then washed with water and the eluate collected and evaporated as before. The gummy residue was evaporated

(27) In an early experiment most of the inorganic phosphate was removed at this stage by precipitation as barium phosphate.

(28) The use of a larger quantity of resin should permit the complete removal of inorganic phosphate at this stage and thus make unnecessary the further steps of purification described.

(29) Reducing phosphorylated carbohydrate was also present, indicating that some hydrolysis of the glycosyl linkage had occurred on the resin. This could be minimized by jacketing the column with circulating ice-water.

down once with a little methyl alcohol and twice with ethyl alcohol, giving 9-β-D-ribofuranosylpurine-5′-phosphate as a pale cream-colored solid, melting with decomposition at 149–150°. After drying in a vacuum desiccator (P_2O_5) for 3 days, it weighed 0.32 g. (26.5%, based on the isopropylidenepurineriboside used). *Anal.*[30] Calcd. for $C_{10}H_{13}O_7N_4P \cdot H_2O$: C, 34.30; H, 4.32; N, 16.00; P, 8.85. Found: C, 34.16; H, 4.57; N, 15.92; P, 8.75. Light absorption in water at *p*H 3.9, 0.1 *N* hydrochloric acid and 0.1 *N* sodium hydroxide: λ_{max} 263 mμ (ε 7350, 5900 and 7500, respectively); λ_{min} 223.5, 235.5 and 227.5 mμ, respectively. The substance was freely soluble in water and gave a single ultraviolet light-absorbing spot on paper chromatograms run in solvents A, B, C and D (R_f values, 0.02, 0.40, 0.36 and 0.47, respectively), which gave a positive reaction in the molybdate spray test for phosphorus and in the periodate spray test for *cis*-glycols. It was free of inorganic phosphate and was eluted from a column (11 × 1 cm.) of Dowex-2 (formate), using 0.1 *M* formic acid which was 0.02 *M* with respect to sodium formate as eluent, as a single, symmetrical peak.[31] Fractions of 11 cc. were collected every 18–20 minutes, the highest O.D. at 260 mμ occurring at fraction 71. When subjected to electrophoresis in sodium phosphate–citric acid buffer (*p*H 8.25), on an 18.8-cm. wide strip of Whatman No. 3 mm. paper, at 860 volts and 90 milliamp. for 45 minutes, it migrated 10 cm. toward the anode (adenosine-5′-phosphate, 9.3 cm.; ribosylpurine moved 1.4 cm. toward the cathode).

Action of Acid and Alkali.—Hydrochloric acid (0.1 *N*) for 48 hr. at 24° had no appreciable effect. Sodium hydroxide (0.1–0.2 *N*) for 24 hr. at 24° caused extensive decomposition to a mixture of two substances having the same chromatographic, electrophoretic and ultraviolet spectral characteristics and giving the same color reactions as the two by-products formed in the synthesis. To provide material for the spectral measurements and color tests, 2-mg. lots of the 5′-phosphate were dissolved in *ca.* 0.2 *N* sodium hydroxide (0.23 cc.), and the solution was allowed to stand at 24° for 30 hr. After neutralization with dilute hydrochloric acid, the solution was applied as a band to a 19 cm. wide strip of Whatman No. 1 paper (previously treated with 1% aqueous ammonium sulfate[21]), the chromatogram developed with solvent D and the various bands eluted with water. Determination of the O.D. at 263 mμ (OH^-) of the eluate containing the residual purine nucleotide indicated that *ca.* 69% had been decomposed.

Isolation and Nature of the By-products Formed in the Synthesis.—Fractions 49–58 from the cellulose column experiment were bulked and worked up as described for the ribosylpurine-5′-phosphate. A cream-colored powder (0.079 g.) was obtained, which on chromatography in solvents B and D gave two ultraviolet light-absorbing spots, one (R_f values, 0.34 and 0.29, respectively) dark and the other (R_f values, 0.26 and 0.15, respectively) fluorescent blue; like 4,5-diaminopyrimidine, the latter tended to become brown on the dried chromatogram. Both compounds contained phosphorus and a *cis*-glycol system, and both were eluted from a column of Dowex-50 resin (H^+) with water. On electrophoresis they migrated 9.6 cm. toward the anode, as one spot.

A solution of this material (1–2 mg.) in 0.5 *N* sulfuric acid (0.2 cc.) was heated in a stoppered tube at 100° for 2.5 hr. The dark solution was cooled, neutralized with ammonium hydroxide and examined for ultraviolet light-absorbing and reducing-carbohydrate components by paper chromatography. Adenosine-5′-phosphate (1–2 mg.) was treated similarly and the resulting solution used as a reference material on the chromatograms. Commercial samples of D-ribose-5-phosphate and D-ribose were also included as standards. The major ultraviolet light-absorbing spot present in the hydrolysate from the by-products had R_f values identical with those of 4,5-diaminopyrimidine. It was eluted from chromatograms run in solvents C and D, and its ultraviolet spectra in 0.1 *N* acid and 0.1 *N* alkali were determined: λ_{max} 283–284 mμ and 245–246, 288–289 mμ, respectively (4,5-diaminopyrimidine, λ_{max} 284–285 mμ and 246–247, 289–290 mμ, respectively). Chromatograms run in solvents C, D, E, F and G were examined for reducing carbohydrate and phosphorus by spraying with the aniline hydrogen phthalate and acid molybdate reagents, respectively. In every case, both the hydrolysate from the mixed by-products and that from adenosine-5′-phosphate gave a faint aniline phthalate-positive spot, the R_f values of which were similar to those of D-ribose, and a much more intense spot with R_f values similar to those of D-ribose-5-phosphate. Inorganic phosphate was also detected in both hydrolysates and separated from carbohydrate phosphates on chromatograms run in solvent E or, less efficiently, in solvent F.

The two by-products were separated in mg. quantities by chromatographing as bands on Whatman No. 1 or 3 MM. paper as described above. Where the presence of ammonium sulfate in the product was undesirable, most was removed by evaporating the eluate and extracting the organic material from the residue with methyl alcohol. The slower-moving component (*i.e.*, R_f 0.15 in solvent D) which had a blue fluorescence in ultraviolet light, gave a blue coloration with alkaline phosphomolybdate[15] and a positive reaction in the Bratton–Marshall test for diazotizable amino groups[16]; 4,5-diaminopyrimidine also reacted positively in both tests; light absorption in 0.1 *N* HCl, λ_{max} 294–294.5 mμ; in water (*p*H 4.51), 294–294.5 mμ; in 0.1 *N* NaOH, 249–249.5 and 294–294.5 mμ (Fig. 1b); pK_a value (determined spectrophotometrically), 5.70 ± 0.05 (4,5-diaminopyrimidine, 6.03[17]). The values for λ_{max} of 4,5-diaminopyrimidine, the spectrum of which is shown in Fig. 1a, are given by Mason.[17]

The faster-moving component (*i.e.*, R_f 0.29 in solvent D), which appeared as a dark spot on chromatograms viewed in ultraviolet light, gave a negative reaction in both the above tests; light absorption in 0.1 *N* HCl, λ_{max} 267.5 mμ; in water (*p*H 5.23), 238 mμ with a pronounced shoulder at about 275 mμ, in 0.1 *N* NaOH 264 mμ with a shoulder at about 290 mμ (Fig. 2b). The spectrum of 4-amino-5-formamidopyrimidine is shown in Fig. 2a: in 0.1 *N* HCl, λ_{max} 253 mμ; in water at *p*H 5.88, at both 234 mμ and 278.5 mμ; in 0.1 *N* NaOH, 258.5 mμ with a shoulder at 285 mμ; pK_a values, spectrophotometric, 3.82 ± 0.05, 11.40 ± 0.1 (4-amino-5-formamidopyrimidine, 4.42 ± 0.05, 11.43 ± 0.1). A sample of the material was dissolved in 0.2 *N* NaOH and the solution set aside at 24°. At 24 and 48 hr. the solution was chromatographed in solvent D; the spots applied to the origin were dried in a stream of carbon dioxide. Examination of the chromatograms in ultraviolet light showed that the material was being converted gradually (*ca.* one-third after 24 hr.) to a phosphorus-containing, blue-fluorescent substance having the same R_f as the slower-moving by-product. The substance was eluted, and its ultraviolet spectra in 0.1 *N* acid, 0.1 *N* alkali and water were determined and found to be identical to those of the slower-moving by-product. After 48 hr., a small amount of material with the same R_f as 4,5-diaminopyrimidine was also present in the hydrolysate.

Acknowledgment.—The authors wish to acknowledge the capable assistance of Mrs. Elizabeth Carroll.

The Identification of Phosphorylated Metabolites of 9-β-D-Ribofuranosylpurine[1]

BY MILTON PAUL GORDON,[2] DAVID I. MAGRATH[3] AND GEORGE BOSWORTH BROWN

RECEIVED NOVEMBER 16, 1956

9-β-D-Ribofuranosylpurine-5′-phosphate and 5′-diphosphate have been obtained from the livers of rats previously injected with the corresponding nucleoside. The possible implications of this finding are discussed.

Previous studies of the metabolism of 9-β-D-ribofuranosylpurine-8-C^{14} (I-8-C^{14}) in the rat have shown that the purine moiety of this nucleoside is converted to polynucleotide adenine and guanine and is catabolized to urinary allantoin. The presence of three derivatives of purine in the perchloric acid extracts of rat liver was demonstrated.[4] The pattern of their elution from a column of Dowex-1 (formate)[5] suggested the possibility that these materials are, respectively, the 5′-mono-, di- and triphosphoric acid derivatives of 9-β-D-ribofuranosylpurine. A comparison has now been made of synthetic 9-β-D-ribofuranosylpurine-5′-phosphate (II)[6] and the major component of the first peak (the postulated monophosphate). The purine-containing material in the second peak (the postulated diphosphate) also has been partially characterized.

Results and Discussion

In these experiments it was desirable to obtain the largest possible amount of the metabolites without death of the animals from the toxicity of the 9-β-D-ribofuranosylpurine. Single intraperitoneal injections at the level of 100 mg./kg. were found to be suitable for these studies.[7] Material with an 8-C^{14} label was used to facilitate isolation procedures.

The cold perchloric acid soluble fraction from the livers of the injected animals was chromatographed by the use of a column of Dowex-1 (formate). Only 6% of the radioactivity placed on the column was removed by the water wash (in which purine and Compound I would appear). This compares favorably with the amount of radioactivity not retained by the resin (5%) when the animals were given much smaller injections of 9-β-D-ribofuranosylpurine-8-C^{14}.[4] Since previous experience had indicated that the purine-containing compounds undergo decomposition on anion exchange resins,[8] the present fractionations were done at 4°. Three main peaks of radioactivity were again found in the positions[4] where nucleoside-5′-mono-, di- and triphosphoric acids are normally eluted. The radioactive material in the first peak was shown to be identical with synthetic II by means of the following criteria: (a) migration in four paper chromatographic systems with concomitant positive tests for the *cis*-glycol[9] and the phosphate moieties,[10] (b) ultraviolet absorption spectra in acid, neutral and alkaline solutions, (c) electrophoretic mobility and (d) in two solvent systems the radioactivity, determined by radioautography, migrated with II. The relative specific activity of the II obtained was, within experimental error, identical with that of the administered nucleoside, and the probable absence of an endogenous pool of purine nucleoside or nucleotides is indicated.

The purine-containing compound in the second peak was admixed with other ultraviolet absorbing materials. Electrophoresis permitted the separation of a material which migrated at the rate characteristic of a diphosphate. This material gave a positive test for *cis*-glycol groups, gave spectra in acid, neutral and alkaline solutions similar to those of I, and its relative specific activity was approximately identical with that of the administered compound. These properties indicate that 9-β-D-ribofuranosylpurine-5′-diphosphate was the major radioactive component of the second peak.

High salt concentration made work with the third peak difficult; however, the above results strengthen the possibility that it was 9-β-D-ribofuranosylpurine-5′-triphosphate.

It has been postulated that the extreme toxicity of 9-β-D-ribofuranosylpurine is due to formation of analogs of normal nucleoside phosphates.[4] Thus, the 9-β-D-ribofuranosylpurine-5′-phosphate and the corresponding di- and triphosphates may interfere with some of the myriad metabolic reactions of the corresponding normal metabolites, adenosine-5′-phosphate (AMP), diphosphate (ADP) and triphosphate (ATP).[11]

(7) A. P. Truant and H. E. D'Amato, *Fed. Proc.*, **14**, 391 (1955), report a subcutaneous LD_{50} of 220 mg./kg. for this compound in rats. Death occurred 6 to 48 hr. after injection.

(8) In previous work with these materials, poor recovery of the total radioactivity was obtained,[4] and attempts to purify purine-containing components by rechromatography on the same resin resulted in complete loss of the material. In view of the decomposition of the synthetic II on Dowex-2 (formate),[6] we believe the previous poor recoveries of radioactivity were due to a decomposition of the topically labeled carbon atom 8.

(11) It is significant that the toxicity of I toward tissues in culture is most effectively reversed by AMP and ATP; J. J. Biesele, M. C. Slautterback and M. Margolis, *Cancer*, **8**, 87 (1955); II is as inhibitory as I, and the alkali degradation products of either are inhibitory only at 100-fold greater concentrations; I and II show equal toxicity in Swiss mice, and the alkali degradation products of I show no toxicity at 30-fold greater doses; Dr. D. C. Clarke, private communication. The fact that 5′-deoxy-9-β-D-ribofuranosylpurine also did not lead to toxicity (H. M. Kissman, B. R. Baker and M. J. Weiss, N. Y. Section, Meeting in Min., March, 1957) can be correlated with the impossibility of the formation of a 5′-phosphate from it.

Experimental

Radioactivity determinations were carried out on infinitely thin samples plated on 10 cm.[2] aluminum planchets with an internal Geiger–Müller flow counter (Radiation Counter Laboratories, Mark 12, model 1, helium–isobutane gas), probable error ±5%, except when otherwise specified. Ultraviolet absorption spectra were determined with the Beckman model DU spectrophotometer with matched 1-cm. quartz cells.

Toxicity Studies.—Male Sherman strain rats (obtained from Rockland Farms, New City, N. Y.) weighing 200 to 300 g. were used in these studies. Animals given intraperitoneal injections of 9-β-D-ribofuranosylpurine (I) at levels of 200, 150 and 100 mg./kg. died after 3, 5 and 20 hours, respectively.

Formation of Phosphorylated Derivatives of 9-β-D-Ribofuranosylpurine.—Eleven male Sherman strain rats, each weighing *ca.* 140 g., were given single intraperitoneal injections of 9-β-D-ribofuranosylpurine-8-C^{14} (I-8-C^{14}) (prepared by diluting I-8-C^{14} [4] with non-radioactive I to give material with a specific activity of 2280 c.p.m./μmole) at the level of 100 mg./kg. After 4 hr. the livers were excised under ether anesthesia and immediately frozen on Dry Ice to give 70 g. of material. All of the subsequent manipulations were done at 4°. The livers were extracted with 3% and then with 2% perchloric acid. The combined extracts were neutralized with 5 *N* potassium hydroxide and clarified by filtration through a Celite pad. The clear filtrate (520 ml.) contained 8840 optical density units[12] and radioactivity totaling 156,000 c.p.m. The material was fractionated by gradient elution chromatography which made use of a 1-liter mixing chamber and a 21.5 × 2 cm. column of Dowex-1 ion exchange resin (formate). After the entire sample of liver perchloric acid-soluble material had been absorbed on the resin, the column was washed with water until the optical density at 260 mμ of the effluent had fallen to 0.06. The water wash contained 1300 optical density units and a total of 9000 c.p.m. The column was then successively eluted with 2.5 *N* formic acid (fractions 1–100, 2 ml. each; fractions 101–520, 4 ml. each), 4.0 *N* formic acid (fractions 521–640, 5 ml. each), 8.0 *N* formic acid (fractions 641–820, 10 ml. each), 8.0 *N* formic acid + 0.4 *M* ammonium formate (fractions 821–900, 10 ml. each) and finally 8.0 *N* formic acid + 1 *M* ammonium formate (fractions 901–960, 10 ml. each). Major peaks of radioactive material were located in tubes 471–500, 760–800 and 881–900. Radioactive fractions were combined and lyophilized in groups consisting of tubes 471–480, 481–489, 490–499, 761–800 and 881–900. Spectral studies indicated that the pooled fractions 471–480 contained the largest amount of a derivative of I uncontaminated by other materials.

The Identification of 9-β-D-Ribofuranosylpurine-5′-phosphate (II).—The R_f values (ascending) of synthetic II, of the major component of fractions 471–480, of 9-β-D-ribofuranosylpurine and of adenosine-5′-phosphate, are, respectively, as follows: (A) 0.50, 0.50, 0.74, 0.35 (1% aqueous ammonium sulfate 33⅓%, isopropyl alcohol 66⅔%)[13]; (B) 0.83, 0.84, 0.72, 0.67 (5% aqueous monobasic sodium phosphate layered with isoamyl alcohol[14]; (C) 0.44, 0.45, 0.58, 0.48 (isopropyl alcohol 75 ml., water 25 ml., trichloroacetic acid 5 g., 28% ammonia 0.3 ml.)[15]; (D) 0.39, 0.39, 0.65, 0.29 (glacial acetic acid 20%, *n*-butyl alcohol 50%, water 30%). The unknown material corresponding to II in each of the above solvent systems gave positive tests for *cis*-glycol groups[9] and for organically bound phosphate[10] (except in solvent B). The spectrum of the material eluted from papers developed using solvent A was identical with that of II, in 0.1 *N* hydrochloric acid, water at *p*H *ca.* 5 and 0.1 *N* sodium hydroxide. The specific activity, calculated with the ε for synthetic II, of the material eluted from papers developed using solvent D was 2100 c.p.m./μmole. Radioautographs prepared from papers developed in solvents B and D showed that the only detectable radioactivity was associated with the material with R_f values corresponding to II, although faint AMP spots were detectable by inspection with ultraviolet light.

Electrophoresis was carried out at *p*H 8.25 as described.[6] The principal component of fractions 471–480, 9-β-D-ribofuranosylpurine-5′-phosphate, and adenosine-5′-phosphate migrated 9 to 10 cm. toward the anode, while 9-β-D-ribofuranosylpurine migrated 1.4 cm. toward the cathode.

The only other component detected in fractions 471–480 during these studies was a small amount of adenosine-5′-phosphate.

The Partial Identification of 9-β-D-Ribofuranosylpurine-5′-diphosphate.—The *p*H of the material in pooled fractions 761–800 was adjusted to 5 with ammonium hydroxide and submitted to electrophoresis. The conditions were the same as those above except that the *p*H of the buffer was 5.25 and the duration of the run was 75 minutes. Seven compounds clearly separated. Guanosine-5′-diphosphate was used as a marker because previous experience[4] indicated that it would be the major contaminant of the metabolite. The guanosine-5′-diphosphate and the major rapidly moving component of the mixture migrated 15 to 16 cm. toward the anode. The latter material gave a positive test for *cis*-glycol groups; its spectrum in 0.1 *N* hydrochloric acid, water and 0.1 *N* sodium hydroxide was very similar to that of 9-β-D-ribofuranosylpurine. The specific activity of the material (assuming an ε at 263 mμ equal to that of the monophosphate) was 1900 ± 200 c.p.m.[16]

Acknowledgments.—The authors wish to thank Mrs. Orsalia Intrieri for competent assistance, and Miss Eva Simmel for the radioautographs.

(12) Optical density units equal the optical density at 260 mμ times the volume in ml.

(14) C. E. Carter, THIS JOURNAL, **72**, 1466 (1950).

(15) J. P. Ebel, *Bull. soc. chim. France*, 1089 (1953).

(16) A correction factor for the salt present was determined by plating small amounts of 9-β-D-ribofuranosylpyrine-8-C^{14} in the presence of buffer. In view of this correction factor and the use of an uncertain ϵ_{max}, there is no significant difference between this specific activity and those of the II and the administered I.

Tosyl-α-amino Acids. I. Degradation of the Acid Chlorides and Azides by Aqueous Alkali

BY A. F. BEECHAM

RECEIVED OCTOBER 15, 1956

The decompositions resulting from the treatment of certain tosyl (*p*-toluenesulfonyl)-α-amino acid chlorides and azides with aqueous alkali are described and the mechanisms discussed.

In 1952, Wiley, *et al.*,[1a] observed that α-(benzenesulfonamido)-phenylacetyl chloride undergoes decomposition when treated with aqueous sodium hydroxide forming benzenesulfonamide, benzaldehyde and carbon monoxide. Wiley and Davis[1b] later

(1) (a) R. H. Wiley, H. L. Davis, D. E. Gensheimer, N. R. Smith, THIS JOURNAL, **74**, 936 (1952); (b) R. H. Wiley and R. P. Davis, *ibid.*, **76**, 3496 (1954).

found that several α-(arylsulfonamido)-propionyl and -phenylacetyl chlorides were similarly degraded. The present author, unaware until recently of this work, already has reported briefly[2] that certain tosyl-α-amino acid chlorides undergo this reaction in the presence of cold aqueous alkali with the formation of *p*-toluenesulfonamide, a carbonyl compound arising from the α-carbon atom with its side chain or chains, carbon monoxide and the chloride ion.

$$CH_3C_6H_4SO_2NHCRR'COCl + OH^- \longrightarrow CH_3C_6H_4SO_2NH_2 + RR'CO + CO + Cl^-$$

Tosylglycyl chloride is only slightly decomposed, being largely hydrolyzed to the parent acid, but with the tosylated chlorides of those α-amino acids in which the α-carbon atom is alkyl substituted, degradation is the main reaction. The amount of carbon monoxide evolved from each of the compounds tested is shown in Table I.

TABLE I

Tosylated acid chloride	R	R′	CO, %
Glycyl	H	H	<2
Alanyl	CH_3	H	86
α-Amino-*n*-butyryl	CH_3CH_2	H	94
α-Amino-isobutyryl	CH_3	CH_3	94
Norleucyl	$CH_3[CH_2]_3$	H	97
Leucyl	$(CH_3)_2CHCH_2$	H	99
Valyl	$(CH_3)_2CH$	H	99
β-Alanyl	tos.NHCH$_2$CH$_2$COCl		0
Propyl			0
Pyroglutamyl			0

The tosyl-α-amino acid azides undergo a similar reaction. Tosyl-DL-alanyl and -valyl azides both dissolve with effervescence in cold aqueous sodium hydroxide, the production of gas amounting to 11 and 50%, respectively, of the volumes expected from the equation. The tendency to degradation is, therefore, less pronounced than with the corresponding chlorides under like conditions. Also the degradation takes a somewhat different path since, although *p*-toluenesulfonamide and the aldehyde are again produced, the evolved gas is nitrogen containing no trace of carbon monoxide. The residual solution contains the cyanate ion

$$CH_3C_6H_4SO_2NHCHRCON_2 + OH^- \longrightarrow CH_3C_6H_4SO_2NH_2 + RCHO + N_2 + NCO^-$$

Since both the chlorides and the azides appear to be unaffected by suspension in cold water alone and since the chlorides are hydrolyzed normally when such a suspension is heated, it may be assumed that the first step in the alkaline degradation of either class of derivative is formation of the sulfonamide anion. All the susceptible chlorides can ionize in this way, whereas tosyl-L-prolyl chloride, a tosylated secondary amine, cannot and is not degraded.

$$tos.NHCRR'COCl(N_3) + NaOH \longrightarrow tos.\bar{N}CRR'COCl(N_2) + Na^+ + H_2O$$

In the anion formed the tendency to undergo hydrolysis would be reduced by the increased electron density at the carbon atom of the modified carboxyl group resulting from the negative charge on the nitrogen. It would also seem that acquirement of the negative charge imparts a degree of instability to the structure. Apparently with tosylglycyl chloride this is not sufficient for breakdown to predominate over hydrolysis, but in those chlorides in which the α-carbon atom carries an alkyl substituent the disruption becomes the main reaction. Presumably this is due to an added increase in electron density at the carbonyl carbon atom arising from the alkyl group. As may be seen from Table I, in the chlorides tested the extent of degradation increases with increasing electron-releasing power of the alkyl side chain. The same holds for the two azides examined. Of course, steric hindrance to hydrolytic attack would also favor the disruptive reaction.

It was suggested earlier[1a] that, in the chloride degradation, breakdown of the sulfonamide anion might proceed by severance of the ion fragment, $COCl^-$, from which carbon monoxide and the chloride ion might be expected to arise immediately. Similarly, in the azide degradation, ejection of CON_3^- giving rise to nitrogen and the cyanate ion might be postulated. However, if this were so, there seems to be no reason why similar fragments should not be evolved from tosyl α-amino acid derivatives other than the chlorides and azides: esters, for instance, giving $COOR^-$ and amides $CONH_2^-$. But the amides and ethyl esters of tosyl-DL-alanine and -DL-valine were found to be hydrolyzed quantitatively, if sluggishly, by aqueous alkali with regeneration of the tosyl α-amino acids.

Alternatively then, it may be proposed that, in the chloride degradation, the sulfonamido anion breaks down by fission of the carbon–chlorine bond with the chlorine retaining the bonding electrons. The combined electron-releasing effects of the charged nitrogen and the alkyl side chain acting on the already highly polar carbon–chlorine link would be expected to favor this ionization. Such a process would be less likely in the less polar esters and amides. After severance of the chloride ion, internal neutralization of charge in the residual dipolar structure, with elimination of carbon monoxide, would be expected to follow.

$$tos.\bar{N}CRR'COCl \longrightarrow tos.\bar{N}CRR'—\overset{+}{C}O + Cl^-$$

$$\downarrow$$

$$tos.NH_2 + RR'CO \xleftarrow{H_2O} tos.N{=}CRR' + CO$$

Wiley[1b] suggests that the chloride degradation may involve displacement at the α-carbon atom of the un-ionized sulfonamido acid chloride in the following way

$$ArSO_2NHCHRCOCl + OH^- \longrightarrow ArSO_2NHCHR + COCl^-$$

$$|$$

$$OH$$

$$ArSO_2NH_2 + RCHO \longleftarrow$$

However, this proposal appears to be invalidated by the fact that tosyl-L-prolyl chloride is not de-

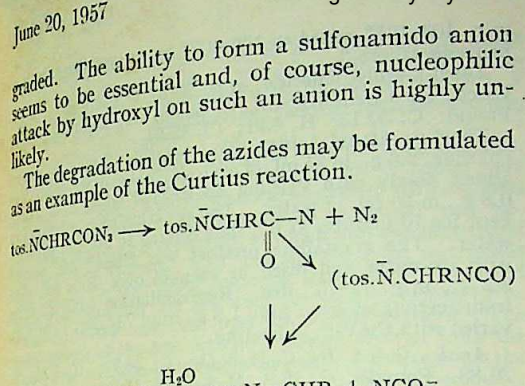
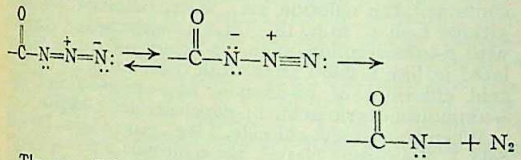
graded. The ability to form a sulfonamido anion seems to be essential and, of course, nucleophilic attack by hydroxyl on such an anion is highly unlikely.

The degradation of the azides may be formulated as an example of the Curtius reaction.

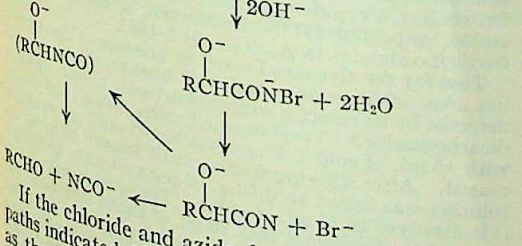


Here the same electron-releasing factors would be operating within the sulfonamido anion as in the chloride reaction and would be expected to promote the evolution of a molecule of nitrogen. Analogously in the Hofmann and Lossen rearrangements the rate-determining release of X^- from the intermediate $RCONX^-$ is favored by electron-releasing substituents at R.[3,4] The nitrogen evolution is akin to an ionization since it leaves an electron-deficient nitrogen atom attached to the organic residue.[3]



The remaining entity may then be visualized either as losing the cyanate ion directly or as rearranging to the organic isocyanate with subsequent loss of the cyanate ion. In view of the negative charge present, perhaps the former alternative is the more likely.

It is interesting to recall that α-hydroxy acid amides when subjected to degradation by alkaline hypohalite yield the next lower aldehyde and the cyanate ion.[5] It may be suggested that this mode of breakdown is favored by electronic factors similar to those operating in the alkaline degradation of the tosyl α-amino acid azides.



If the chloride and azide degradations follow the paths indicated, both give rise to a tosylated imine as the precursor of the carbonyl compound and sulfonamide finally obtained. It is assumed that this imine adds water and disrupts to give the observed products. An attempt was made to isolate the intermediate by dropwise addition of the calculated quantity of aqueous sodium hydroxide to a dioxane solution of tosyl-DL-valyl chloride, followed at once by extraction with ether. Under these conditions, with the chloride dissolved before the base is added, degradation is so rapid that the solution is never more than faintly and transiently alkaline. However, the solid isolated from the ether was *p*-toluenesulfonamide, indicating that the imine, if formed, suffered rapid hydrolysis even in the absence of alkali. The moisture sensitivity of similar structures is mentioned by Lichtenberger, Fleury and Barette.[6]

As shown in Table I, three of the chlorides tested gave no carbon monoxide. If the factors affecting the degradation are those suggested, tosyl-β-alanyl chloride would be expected to be inert, both because the α-carbon atom carries no side chain and because the acid chloride function is insulated from the seat of charge in the sulfonamido anion by the extra methylene group. In tosyl-L-prolyl chloride the nitrogen atom is tertiary so that salt formation is not possible. This also applies to tosyl-L-pyroglutamyl chloride which, however, unlike the prolyl compound, contains an alkali-labile lactam bond. For alkaline degradation to occur, through a sulfonamido anion intermediate, hydrolysis of the lactam system would need to be more rapid than hydrolysis of the acid chloride group. That Swan and du Vigneaud[7] were able to hydrolyze the compound to tosyl-L-pyroglutamic acid using aqueous magnesia indicates that the reverse is true and this is indirectly confirmed by the absence of degradation in the present work.

There are obvious ways in which the range of the degradations described here could be further explored. The tosylated acid chlorides and azides of the more complex α-amino acids might be tested. The reactions are probably general for those compounds capable of forming a sulfonamido anion and bearing an electron-releasing side chain at the α-carbon atom.[1a,b] The arylsulfonyl group might be varied with the expectation that degradation would still occur with derivatives of those amino acids whose tosyl compounds were disrupted.[1a,b] As well as the acid chlorides and azides, other anhydride-type structures might evince instability. Some reference to the effect of bases other than aqueous alkali is made in a subsequent article[8] which deals with the use of tosyl α-amino acid chlorides in the synthesis of peptides.

Experimental[8a]

Tosylamino Acids.—These compounds were prepared by the method used by Harington and Moggridge[9] for tosyl-L-glutamic acid. *p*-Toluenesulfonyl chloride, 0.1 mole, was

added to a solution of the amino acid, 0.1 mole, in 100 ml. of water containing NaOH, 0.2 mole (0.3 mole for L-glutamic acid), and the suspension heated at 70–80° with shaking until a clear solution resulted (5–10 minutes). After cooling, acidification caused the product to precipitate except in the case of tosyl-L-glutamic acid which was isolated as described[9] and recrystallized from methyl ethyl ketone–carbon tetrachloride. The products from glycine[10] and DL-alanine[10] were immediately crystalline; those from DL-norleucine,[10] L-leucine,[10] β-alanine[11] and L-proline[12] were oils which crystallized on standing, tosyl-L-proline being hydrated. This last compound was obtained as the hemibenzenate[12] after azeotropic drying.

Tosyl-α-aminoisobutyric Acid.—Acidification gave a clear solution from which the product crystallized during 2 hr. at 0°, yielding 23%, softening 145°, m.p. 148.5–149.5° raised to 149–150° by recrystallization from water (lit.[13] m.p. 147°).

Anal. Calcd. for $C_{11}H_{15}NO_4S$: C, 51.34; H, 5.88; N, 5.44; O, 24.87; S, 12.46. Found: C, 51.71; H, 5.97; N, 5.13; O, 24.4; S, 12.88.

Further crystalline material obtained by concentration of the mother liquor from this preparation consisted largely of a second acidic substance, melting 205–218°, equivalent weight ≃400. This was not further characterized, but may have been the crude ditosyl compound.

Tosyl-DL-α-amino-*n*-butyric Acid.—The compound crystallized rapidly in 62% yield, m.p. 151–152°, after softening at 145°. A sample recrystallized twice from water had m.p. 152–153°.

Anal. Calcd. for $C_{11}H_{15}NO_4S$: C, 51.34; H, 5.88; N, 5.44; O, 24.87; S, 12.46. Found: C, 51.81; H, 5.88; N, 5.16; O, 24.59; S, 12.49.

Tosyl-DL-valine.—The product crystallized rapidly in 71% yield, m.p. 165–166° raised to 166–167° by recrystallization from acetone–water.

Anal. Calcd. for $C_{12}H_{17}NO_4S$: C, 53.12; H, 6.32; N, 5.16; O, 23.59; S, 11.82. Found: C, 53.31; H, 6.18; N, 5.09; O, 23.9; S, 12.26.

Tosylamino Acid Chlorides.—The tosylamino acid, 0.01 mole, and PCl_5, 0.015 mole (0.025 mole for tosyl-L-glutamic acid), were suspended in 20–30 ml. of anhydrous ether (200 ml. for the isobutyryl derivative) and shaken until all the organic material had dissolved, then for a further 30 minutes. Excess PCl_5 was removed by filtration, 100 ml. of anhydrous petroleum ether, b.p. 80–100°, added and the solution set aside at 0° for several hours. The crystalline acid chlorides were then filtered off, washed with petroleum ether and dried in vacuum over solid caustic soda and paraffin wax. The following compounds were prepared in this way.

Tosylglycyl chloride, m.p. 82–84° (lit.[14] m.p. 82–83°).

Tosyl-DL-alanyl chloride, m.p. 93–94°. *Anal.* Calcd. for $C_{10}H_{12}NO_3SCl$: C, 45.89; H, 4.62; Cl, 13.55. Found: C, 46.16; H, 4.69; Cl, 13.37.

Tosyl-DL-α-amino-*n*-butyryl chloride, m.p. 56–57°. *Anal.* Calcd. for $C_{11}H_{14}NO_3SCl$: C, 47.91; H, 5.12; Cl, 12.86. Found: C, 48.21; H, 5.06; Cl, 12.86.

Tosyl-α-amino-isobutyryl chloride, m.p. 115–116°. *Anal.* Calcd. for $C_{11}H_{14}NO_3SCl$: C, 47.91; H, 5.12; Cl, 12.86. Found: C, 47.58; H, 5.09; Cl, 12.76.

Tosyl-DL-valyl chloride, m.p. 76–78°. *Anal.* Calcd. for $C_{12}H_{16}NO_3SCl$: C, 49.74; H, 5.57; Cl, 12.24. Found: C, 49.66; H, 5.59; Cl, 12.13.

Tosyl-DL-norleucyl chloride, m.p. 70–72°. *Anal.* Calcd. for $C_{13}H_{18}NO_3SCl$: C, 51.39; H, 5.97; Cl, 11.67. Found: C, 51.29; H, 6.03; Cl, 11.45.

Tosyl-L-leucyl chloride, m.p. 83–85°. *Anal.* Calcd. for $C_{13}H_{18}NO_3SCl$: C, 51.39; H, 5.97; Cl, 11.67. Found: C, 51.47; H, 6.03; Cl, 11.66.

Tosyl-β-alanyl chloride, m.p. 82–84°. *Anal.* Calcd. for $C_{10}H_{12}NO_3SCl$: C, 45.89; H, 4.62; Cl, 13.55. Found: C, 46.17; H, 4.72; Cl, 13.58.

Tosyl-L-pyroglutamyl chloride, m.p. 103–105° (lit.[12] m.p. 103–105° raised to 106–107° by recrystallization from benzene–ether).

Tosyl-L-prolyl chloride, m.p. 56–57.5° (lit.[12] oil). *Anal.* Calcd. for $C_{12}H_{14}NO_3SCl$: C, 50.08; H, 4.91; Cl, 12.32. Found: C, 50.13; H, 4.91; Cl, 12.24.

Tosyl-DL-Alanyl Azide.—To a solution of tosyl-DL-alanyl chloride, 2.6 g., in 35 ml. of acetone, cooled in ice-water, was added slowly with swirling an ice-cold solution of NaN_3, 0.8 g., in 20 ml. of water. The resulting clear solution was kept for 10 minutes at 0°, then diluted to 200 ml. with ice-water. The crystalline product was filtered off, washed with ice-water and dried in vacuum over silica gel, yield 2.2 g., m.p. 72–73° dec. Reprecipitation with ice-water from acetone solution gave 1.9 g., m.p. 74° dec. The m.p. varied with the rate of heating.

Anal. Calcd. for $C_{10}H_{12}N_4O_3$: C, 44.77; H, 4.51; N, 20.88. Found[15]: C, 45.8; H, 4.7; N, 18.0.

Tosyl-DL-valyl Azide.—Tosyl-DL-valyl chloride, 2.9 g., was converted to the azide by the procedure used for the alanyl derivative, yield 2.8 g., m.p. 65–66° dec. Reprecipitation gave 2.8 g., m.p. 66° dec. The m.p. varied with the rate of heating.

Anal. Calcd. for $C_{12}H_{16}N_4O_3S$: C, 48.63; H, 5.44; N, 18.91. Found[15]: C, 49.7; H, 5.6; N, 15.9.

The Action of Aqueous NaOH on the Tosylamino Acid Chlorides.—When tosyl-DL-valyl chloride, 2.9 g., was added to 20 ml. of cold 1 *N* aqueous NaOH, the crystals dissolved with effervescence leaving a solution smelling strongly of isobutyraldehyde. Acidification with concentrated HNO_3 gave a crystalline precipitate, 1.64 g., m.p. 135–137°, after drying in a vacuum at 70°. The filtrate contained the chloride ion. Recrystallization from water yielded 1.45 g., m.p. 137–137.5°, undepressed on admixture with *p*-toluenesulfonamide. *p*-Toluenesulfonamide was isolated in like fashion after alkali treatment of the tosylated acid chlorides of DL-alanine, DL-α-amino-*n*-butyric acid, α-aminoisobutyric acid, DL-norleucine and L-leucine.

When tosylglycyl chloride, 1.0 g., was added to 10 ml. of cold 1 *N* aqueous NaOH, the compound dissolved with no apparent effervescence. After 10 minutes, concentrated HCl was added causing separation of tosylglycine, 0.8 g., m.p. and mixed m.p. 147–148° after recrystallization from water. Similarly tosyl-β-alanyl chloride or tosyl-L-prolyl chloride dissolved without effervescence in 1 *N* aqueous NaOH, and addition of HCl caused separation of the regenerated tosylamino acid. Tosyl-L-pyroglutamyl chloride dissolved without effervescence in cold 1 *N* aqueous NaOH. Acidification with concentrated HNO_3 caused no separation of sulfonamide or other material. Addition of $AgNO_3$ solution produced a copious precipitate of AgCl.

The Action of Aqueous NaOH on Tosyl-DL-valyl Azide.—The azide, 1.0 g., on treatment with 10 ml. of cold 1 *N* aqueous NaOH dissolved, with effervescence, leaving a solution smelling of isobutyraldehyde. This was filtered to remove a small amount of gummy material and the filtrate acidified with 1 ml. of 10 *N* HCl to give a crystalline precipitate, 0.60 g., m.p. 103–107°, which was added to 10 ml. of 1 *N* aqueous $NaHCO_3$. Part of the solid dissolved in the cold with effervescence, the remainder dissolved on heating. On cooling, crystals separated, 0.22 g. of *p*-toluenesulfonamide, m.p. 136–137°. Acidification of the filtrate gave tosyl-DL-valine, 0.18 g., m.p. 164.5–166°.

Test for the Cyanate Ion.—The presence of the cyanate ion after alkaline degradation of tosyl-DL-valyl azide was detected by its reaction with semicarbazide to form hydrazodicarboxamide.[5] Tosyl-DL-valyl azide, 1.46 g., was shaken with 15 ml. of cold 1 *N* aqueous NaOH until gas evolution ceased. After filtering from a small amount of gum, the solution was added to 0.56 g. of semicarbazide hydrochloride dissolved in 10 ml. of water. The solution was allowed to stand for 5 minutes, then 20 ml. of glacial acetic acid was added. After 10 minutes the resulting solution deposited crystals, 0.12 g., m.p. 251–252° dec. This material did not depress the m.p. of hydrazodicarboxamide prepared from semicarbazide hydrochloride, sodium acetate and potassium cyanate.

The Action of Aqueous NaOH on Tosyl-DL-alanyl Azide.—The azide, 0.51 g., dissolved with effervescence in 10 ml. of cold 1 *N* aqueous NaOH, producing the odor of acetalde-

hyde. Addition of 1 ml. of 10 *N* HCl gave an oil which quickly crystallized; 0.33 g., m.p. 136–138°. This material dissolved with effervescence in 10 ml. of cold 0.5 *N* aqueous $KHCO_3$. Acidification yielded tosyl-DL-alanine, 0.26 g., m.p. 137–138°.

Identification of Volatile Products from the Degradations.—Crystals of the tosylamino acid chloride or azide were allowed to react in a closed evacuated system with aqueous sodium hydroxide. Volatile material produced was isolated in a liquid-air cooled trap, in which part condensed and part remained gaseous. The mass spectra of the permanent gas and of the condensed material were then determined separately, showing the gas from the acid chlorides to be carbon monoxide and that from the azides, nitrogen. The mass spectra of the less volatile products evolved from the alanyl and α-amino-isobutyryl derivatives showed, as the main components, acetaldehyde and acetone, respectively. Also present were trace amounts of material of higher mass, presumably resulting from self-condensation of the carbonyl compounds. With the remaining tosyl derivatives which underwent degradation, the appropriate aldehyde was the sole volatile product apart from the permanent gas. In each case the mass spectrum of the carbonyl compound evolved was identical with that obtained from an authentic specimen.

Measurement of Gas Evolved in the Degradations.—The tosylated acid chloride or azide was allowed to react with 1 *N* aqueous NaOH in a closed system and the evolved gas collected over water. The results were reproducible to within 1%.

Attempted Isolation of the Tosylated Imine.—Ten ml. of cold 1 *N* aqueous NaOH was run into a solution of tosyl-DL-valyl chloride, 2.9 g., in 10 ml. of dioxane, producing effervescence. Seventy ml. of ether was added at once, the mixture shaken and the aqueous layer separated. This gave a neutral reaction. The ether solution was dried over Na_2SO_4, filtered, diluted with 80 ml. of dry petroleum ether, b.p. 60–80°, and partly evaporated. Crystals formed, 1.4 g. Two recrystallizations from dry ether–petroleum ether gave 0.7 g., m.p. 124.5–125.5°.

Anal. Calcd. for $C_{11}H_{15}NO_2S$ (tosylated imine): C, 58.64; H, 6.71; N, 6.22; S, 14.23. Calcd. for $C_7H_9NO_2S$ (*p*-toluenesulfonamide): C, 49.10; H, 5.30; N, 8.18; S, 18.73. Found: C, 49.43; H, 5.36; N, 8.12; S, 18.80.

Recrystallization from water gave material of m.p. 137–137.5° not depressed on admixture with *p*-toluenesulfonamide. The substance, m.p. 124.5–125.5°, is apparently a dimorph of *p*-toluenesulfonamide.

Hydrolysis of Tosyl-DL-valyl Chloride.—The chloride, 1.0 g., was suspended in cold water. Over 30 minutes there was no effervescence, no odor of aldehyde and little of the solid dissolved. On heating under reflux the solid reverted to oily drops, which did not dissolve at 100°. After 5 minutes at this temperature, crystallization commenced. Dilution to 300 ml. with boiling water gave a clear solution from which, on cooling, tosyl-DL-valine separated; 0.7 g., m.p. 165.5–166.5°.

Samples of tosylglycyl chloride and tosyl-DL-valyl chloride were each suspended in 2% aqueous $AgNO_3$. The suspension of the glycine derivative became cloudy within one minute, that of the valyl compound remained clear for several minutes.

Tosyl-DL-alanine Ethyl Ester.—Tosyl-DL-alanyl chloride, 5.2 g., was dissolved in hot ethanol to form the ester and the product crystallized from benzene–petroleum ether; yield 5.1 g., m.p. 66–67° (lit. m.p. 66–67°,[16] m.p. 68°[17]).

Tosyl-DL-valine Ethyl Ester.—Tosyl-DL-valyl chloride, 2.9 g., was dissolved in hot ethanol. On removal of the solvent under reduced pressure, the ester crystallized; yield 2.7 g., m.p. 86–88° unchanged after recrystallization from petroleum ether, b.p. 60–80°.

Anal. Calcd. for $C_{14}H_{21}NO_4S$: C, 56.16; H, 7.07; N, 4.68; O, 21.38. Found: C, 56.27; H, 6.98; N, 4.54; O, 21.2.

The Action of Aqueous NaOH on the Esters.—Tosyl-DL-valine ethyl ester, 0.29 g., was added to 2 ml. of 1 *N* aqueous NaOH. The solid dissolved slowly to give an odorless solution which was heated at 70° for 8 hr., cooled and treated with 2 ml. of 1 *N* aqueous HCl. A crystalline precipitate formed; 0.25 g., m.p. 165–166°, not depressed when mixed with tosyl-DL-valine. Tosyl-DL-alanine ethyl ester, similarly treated, yielded tosyl-DL-alanine. When either ester was dissolved in 2 equivalents of *N* aqueous NaOH and the solution allowed to stand at room temperature for 8 hr., hydrolysis was not complete. Acidification in each case caused precipitation of material only part of which was soluble in cold aqueous bicarbonate.

Tosyl-DL-alanyl Amide.—Tosyl-DL-alanyl chloride treated with concentrated aqueous ammonia gave the amide, m.p. 195–196°, in 95% yield.

Anal. Calcd. for $C_{10}H_{14}N_2O_3S$: C, 49.57; H, 5.82; N, 11.56; O, 19.81; S, 13.23. Found: C, 49.64; H, 5.83; N, 11.32; O, 20.05; S, 13.58.

Tosyl-DL-valyl Amide.—Tosyl-DL-valyl chloride on suspension in concentrated aqueous ammonia was converted quantitatively to the amide, m.p. 245–246°.

Anal. Calcd. for $C_{12}H_{18}N_2O_3S$: C, 53.31; H, 6.71; N, 10.36; O, 17.76; S, 11.86. Found: C, 53.67; H, 6.68; N, 9.71; O, 17.9; S, 11.96.

The Action of Aqueous NaOH on the Amides.—Tosyl-DL-alanyl amide, 0.65 g., dissolved in 6 ml. of 1 *N* aqueous NaOH without the production of any aldehyde odor. The solution was heated under reflux for 3 hr., cooled and acidified with 6 ml. of 1 *N* aqueous HCl. An oil separated which crystallized on standing; 0.55 g., m.p. 133–135°, raised to 137–138° by recrystallization, undepressed by admixture with tosyl-DL-alanine. Tosyl-DL-valyl amide, 1.3 g., was dissolved in 10 ml. of 1 *N* aqueous NaOH and heated under reflux for 7.5 hr., during which time the solution became cloudy. Dilution with water to 100 ml. gave a clear solution. After addition of 10 ml. of 1 *N* HCl and cooling, there separated 0.62 g. of unchanged amide, m.p. 245–246°. The filtrate, on evaporation to 10 ml., yielded crystalline material which dissolved in aqueous bicarbonate. Acidification gave tosyl-DL-valine, 0.57 g., m.p. 164–165°.

Solutions of each amide in 2 equivalents of 1 *N* aqueous NaOH, after standing at room temperature for 24 hr., gave, on acidification, unchanged amide, with over 90% recovery.

Tosyl-α-amino Acids. II. The Use of the Acid Chlorides for Peptide Synthesis in the Presence of Aqueous Alkali

BY A. F. BEECHAM

RECEIVED OCTOBER 15, 1956

Degradation of those tosyl-α-amino acid chlorides in which the side chain is strongly electron-releasing proceeds more rapidly than peptide formation (with glycine) in strong aqueous alkali. To inhibit degradation, the alkalinity must be reduced to a level at which coupling is slow. Hydrolysis of the acid chloride then interferes.

It has been shown recently that tosyl-α-amino acid chlorides,[1a] like other arylsulfonyl-α-amino acid chlorides,[1b] are liable to rapid degradation by cold aqueous alkali in accordance with the scheme

$$\text{tos.NHCRR'COCl} + \text{OH}^- \longrightarrow \text{tos.NH}_2 + \text{RR'CO} + \text{CO} + \text{Cl}^-$$

Evidence was presented[1a] consistent with the postulates that, for such decomposition to occur, the tosylated acid chlorides must be capable of forming a sulfonamido anion, $\text{tos.}\overline{\text{N}}\text{CRR'COCl}$, and must carry an electron-releasing side chain at the α-carbon atom. It was apparent that this reaction would need to be taken into account if the susceptible compounds were to be used for peptide syntheses in basic aqueous media. Some experiments designed to test the extent of interference with the peptide forming reaction were, therefore, carried out.

It was shown readily that where the tosylamino acid chloride is not degraded, coupling with a second amino acid dissolved in aqueous alkali proceeds smoothly. When tosyl-L-prolyl chloride was caused to react with L-hydroxyproline under these conditions, the tosylated dipeptide was obtained in excellent yield. In tosyl-L-prolyl chloride the nitrogen is tertiary so that sulfonamide salt formation is not possible.[2] Under similar conditions tosylglycyl-L-proline was prepared, with tosylglycyl chloride as the acylating agent. Although this chloride is capable of conversion to the sulfonamido anion, no side chain is present and degradation is slight.[1a]

Tosyl-DL-alanyl chloride is degraded by cold aqueous sodium hydroxide to the extent of 86% as measured by the amount of carbon monoxide evolved.[1a] This compound in the L-form was used by Schönheimer[3] for peptide synthesis, his technique being to shake a benzene solution of the chloride with a solution of the second amino acid in aqueous sodium hydroxide. In the present work, tosyl-DL-alanyl chloride and glycine were coupled by this method. With the reagents in the proportions required by the equation, the peptide was obtained in 80% yield. When solid tosyl-DL-alanyl chloride was added to a solution of glycine in aqueous sodium hydroxide, efferverscence was apparent as the chloride dissolved and the odor of acetaldehyde became evident, but the coupling product was again isolated in 80% yield.

$$\text{tos.NHCHRCOCl} + \text{NH}_2\text{CH}_2\text{COOH} + 2\text{NaOH} \longrightarrow \text{tos.NHCHRCONHCH}_2\text{COONa} + \text{NaCl}$$

Tosyl-L-leucyl chloride is 99% degraded by cold aqueous sodium hydroxide.[1a] When this compound was substituted for tosyl-DL-alanyl chloride under either of the foregoing conditions, a different result was obtained. Effervescence was more pronounced and no coupling product could be isolated. Tosyl-DL-valyl chloride, which is also 99% degraded by cold aqueous sodium hydroxide,[1a] reacted similarly to the leucyl compound. Addition of tosyl-DL-valyl chloride to the solution of glycine in aqueous sodium hydroxide resulted in evolution of 60% of the theoretical quantity of carbon monoxide and *p*-toluenesulfonamide was isolated from the solution.

These results may be interpreted as follows. As already has been shown,[1] when tosyl-α-amino acid chlorides capable of sulfonamido anion formation are treated with aqueous alkali, both hydrolysis and degradation occur. Degradation predominates where the α-carbon atom bears an electron-releasing side chain and predominates increasingly as the inductive power of the side chain increases. When the aqueous alkali contains a second amino acid, a third reaction competes, namely, attack on the acid chloride function by the amino group to form a peptide bond. Under strongly alkaline conditions, the second amino acid is almost wholly in the anionic form and coupling proceeds more rapidly than hydrolysis. With tosyl-DL-alanyl chloride, whose methyl side chain is only weakly electron releasing, coupling is also faster than degradation; but with tosyl-L-leucyl and tosyl-DL-valyl chlorides, which carry the more strongly inductive isobutyl and isopropyl side chains, respectively, degradation is again the main reaction.

A comparison of the proportions of reagents required by the coupling reaction with those recorded by Schönheimer[3] is interesting. To prepare tosyl-L-alanyl-L-leucine he used tosyl-L-alanyl chloride (1 part), L-leucine (1.7 parts) and sodium hydroxide (2.2 parts), but for tosyl-DL-leucylglycine he employed tosyl-DL-leucyl chloride (1 part), glycine (2.5 parts) and sodium hydroxide (0.85 part). Evidently in the second case he found a reduction in alkalinity necessary, although he makes no comment on this.

Reducing the alkalinity seemed the obvious way of modifying the reaction conditions for peptide syntheses involving the more easily degraded chlo-

rides. Tosyl-DL-valyl chloride was chosen for study, since in this compound susceptibility to degradation is high and steric obstruction to coupling is considerable. Reaction with glycine in aqueous media of various alkalinities was attempted, but no conditions were found under which interference was suppressed. At *p*H <8 hydrolysis was the main reaction and at *p*H >8 degradation occurred. For glycine, $pK'_2 = 9.60$,[4] so that at *p*H 8, although degradation proceeds at a much reduced rate, coupling is also slow, since the concentration of the glycine anion is low. The best yields of tosyl-DL-valylglycine (36–38%) were obtained when a dioxane solution of the chloride was added portionwise to ice-cold aqueous glycine, kept at *p*H 8–9 with sodium hydroxide or containing excess solid magnesium oxide. In the latter case the initial *p*H of the aqueous solution was 10.5, but this quickly dropped to lower values as dissolved base was consumed.

Tosyl-L-isoleucyl chloride would be expected to be as readily degraded by aqueous alkali as tosyl-DL-valyl chloride, but Katsoyannis and du Vigneaud[5] have used the compound, in the presence of aqueous magnesia, to prepare tosyl-L-isoleucyl-L-glutamine and tosyl-L-isoleucyl-L-glutaminyl-L-asparagine. The yield of the dipeptide obtained was low but that for the tripeptide was 55–60%. These results are probably accounted for by the different concentrations of the anions of the second component in the two cases; pK'_2 for glutamine is 9.13.[4] The value for glutaminylasparagine is not recorded, but it would be expected to be below 8 (since, *e.g.*, glutaminylglycine has $pK'_2 = 7.52$[4]).

Experimental[6]

Tosyl-L-prolyl-L-hydroxyproline.—To a solution of L-hydroxyproline, 1.31 g. (0.01 mole) in 1 *N* NaOH, 20 ml., was added tosyl-L-prolyl chloride, 2.875 g. (0.01 mole), and the whole shaken with ice cooling for 20 minutes. Addition of 1 *N* HCl, 10 ml., to the resulting solution caused precipitation of an oil which quickly crystallized to give 3.4 g. of material, m.p. 219–221°. After several recrystallizations, from water or by precipitation with acid from bicarbonate solution, the product had m.p. 224–224.5°, $[\alpha]^{36}D$ −198° (*c* 1 in 0.5 *N* $KHCO_3$).

Anal. Calcd. for $C_{17}H_{22}N_2O_6S$: C, 53.39; H, 5.80; N, 7.33; O, 25.10; S, 8.28. Found: C, 53.19; H, 5.98; N, 6.89; O, 24.9; S, 8.51.

Tosylglycyl-L-proline.—To a solution of L-proline, 5.75 g. (0.05 mole), in a mixture of 1 *N* NaOH, 100 ml., and dioxane, 100 ml., was added tosylglycyl chloride,[7] 12.4 g. (0.05 mole), in portions, with swirling to dissolve after each addition. After standing for 18 hr., the solution was brought to *p*H 6 by addition of hydrochloric acid, concentrated to 30 ml. and acidified. The oily precipitate crystallized after 3 days at 0°; 13.6 g., m.p. 176–180° after softening at 170°. Three recrystallizations from bicarbonate solution by addition of acid gave 8.2 g. of product, m.p. 183–184°, $[\alpha]^{27}D$ −71° (*c* 1 in 0.5 *N* $KHCO_3$).

Anal. Calcd. for $C_{14}H_{18}N_2O_5S$: C, 51.52; H, 5.57; N, 8.58; O, 24.51; S, 9.82. Found: C, 51.48; H, 5.46; N, 8.57; O, 24.6; S, 9.99.

Tosyl-DL-alanylglycine.—A solution of tosyl-DL-alanyl chloride, 2.61 g. (0.01 mole), in 80 ml. of benzene was shaken with 20 ml. of 1 *N* NaOH containing glycine, 0.75 g. (0.01 mole), for 16 hr. The benzene layer was separated, the aqueous solution warmed to 90°, 10 ml. of 1 *N* HCl added and the solution allowed to cool slowly. Crystals of the tosyl dipeptide separated, 2.35 g., m.p. 149–150° (lit. m.p. 147° cor.,[3] m.p. 150–151° cor.[8]).

When tosyl-DL-alanyl chloride, 2.61 g., was added to a solution of glycine, 0.75 g., in 20 ml. of 1 *N* NaOH, the solid dissolved slowly with effervescence and the production of the odor of acetaldehyde. From the solution, after acidification, was obtained 2.4 g. of the crude tosyl dipeptide, m.p. 147–149°. Recrystallization from 50 ml. of water yielded 1.9 g., m.p. 149–150°.

Tosyl-DL-valylglycine. A.—Tosyl-DL-valyl chloride, 2.895 g. (0.01 mole), was added to a solution of glycine, 0.75 g. (0.01 mole), in 20 ml. of 1 *N* NaOH and the evolved gas collected. The volume of gas produced indicated that 60% of the chloride had suffered degradation. The aqueous liquor contained suspended solid, from which was obtained by recrystallization from aqueous bicarbonate *p*-toluenesulfonamide, 0.7 g., m.p. 136–137.5°.

B.—Addition of the chloride (0.01 mole) to aqueous glycine (0.01 mole) containing triethylamine (0.02 mole) at *p*H 12 resulted in strong effervescence. The products were not examined.

C.—The chloride, 2.895 g., glycine, 0.75 g., and MgO, 1.0 g., were shaken for 6 hr. in a mixture of 20 ml. of water and 20 ml. of dioxane. After standing overnight the mixture was acidified, the oily precipitate taken into ether, the ether solution dried over Na_2SO_4, evaporated to dryness and the residue dissolved in 400 ml. of hot anhydrous benzene. On cooling crystals separated, 1.3 g., m.p. 165–168° after softening at 160°. This material after three recrystallizations from water yielded tosyl-DL-valylglycine, 0.7 g., m.p. 174–175°.

Anal. Calcd. for $C_{14}H_{20}N_2O_5S$: C, 51.20; H, 6.14; N, 8.53; O, 24.36; S, 9.76. Found: C, 51.25; H, 6.14; N, 8.06; O, 24.2; S, 9.83.

From the benzene filtrate was obtained tosyl-DL-valine, 0.4 g., m.p. 165–166° unchanged when mixed with an authentic sample.[1a]

D.—To a solution of glycine, 0.75 g., in 20 ml. of water containing magnesium oxide, 1.0 g., at *p*H 10.5 was added, over 20 minutes with shaking and ice cooling, a solution of tosyl-DL-valyl chloride in 20 ml. of dioxane. Shaking with cooling, was continued for 10 minutes, the suspension set aside for 20 minutes and then filtered. The filtrate (*p*H 8) was acidified and the resulting oily suspension shaken with ether when crystallization commenced. The crystalline material, 1.4 g., m.p. 160–165°, dissolved in aqueous bicarbonate to yield, on acidification, tosyl-DL-valylglycine, 1.06 g., m.p. 173.5–174.5°.

Evaporation of the ether gave further crystalline material from which no pure compound could be obtained.

E.—A solution of glycine, 0.375 g., in 20 ml. of water was maintained at *p*H 9.6–9.7 by addition of aqueous sodium hydroxide while tosyl-DL-valyl chloride, 1.45 g., was added in portions. Effervescence was noticeable as the chloride dissolved and only *p*-toluenesulfonamide, 0.56 g., was obtained on working up.

F.—From an ice-cooled solution of glycine, 0.375 g., in 10 ml. of water and 10 ml. of dioxane kept at *p*H 9–10 with sodium hydroxide while tosyl-DL-valyl chloride, 1.45 g., was added, there was obtained *p*-toluenesulfonamide, 0.43 g., and tosyl-DL-valylglycine, 0.52 g.

G.—To a solution of glycine, 0.75 g., in 10 ml. of water were added a solution of tosyl-DL-valyl chloride, 2.895 g., in 20 ml. of dioxane, and 1 *N* sodium hydroxide at such a rate that the *p*H was kept at 8.5–9. Tosyl-DL-valylglycine, 1.2 g., and *p*-toluenesulfonamide, 0.22 g., were obtained as well as further material which could not be purified.

H.—A solution of glycine, 0.75 g., in water containing sodium bicarbonate had *p*H 8.2. After addition of tosyl-DL-valyl chloride there was obtained *p*-toluenesulfonamide, 0.77 g., and tosyl-DL-valine, 0.30 g.

I.—Addition of tosyl-DL-valyl chloride, 2.895 g., to a solution of glycine in aqueous pyridine at *p*H 7.6 resulted in the production of tosyl-DL-valine, 2.0 g.

Structural Effects of the Interaction of Human Serum Albumin with Sodium Decyl Sulfate[1]

BY GABOR MARKUS AND FRED KARUSH

RECEIVED JANUARY 23, 1957

The optical rotatory and viscosity behavior of human serum albumin was investigated as a function of sodium decyl sulfate concentration. At concentrations up to 5×10^{-3} *M*, *i.e.*, in the region where 10–14 molecules of detergent are bound per albumin molecule, the levorotation drops from 64 to 58°. A similar change is observed when the *p*H is raised from 8 to 9.4 in the absence of detergent. In both cases the reduced viscosity remains constant. Acetylated albumin fails to show a decrease in levorotation upon the addition of small amounts of detergent. It is concluded that the observed drop is associated with the loss of charge from ϵ-ammonium groups and arises from a small change in the secondary structure of the protein. Upon further increase in the detergent concentration the levorotation rises and reaches its maximum of 70° at 3.4×10^{-2} *M* decyl sulfate. A similar rise in levorotation (from 61 to 70°) can be brought about by raising the *p*H from 2 to 8 at a constant detergent concentration (0.1 *M*). In both cases these changes are interpreted as a result of the increase in the net charge of the protein. In the first case, the binding of the detergent anions neutralizes the cationic charges of the protein, in the second case, the ionization of the carboxyl groups increases the net charge. The rise in reduced viscosity which accompanies the rotatory change in both instances and the reversal of these changes in high salt concentrations support the interpretation that high detergent concentrations effect an increase in the hydrodynamic volume of the protein molecules due to the intramolecular electrostatic repulsion within the protein–detergent complex. The observed changes in the physical properties are discussed in reference to the secondary and tertiary structures of serum albumin.

Among the substances used in the study of protein denaturation detergents have lately received particular attention due to the relatively mild physical changes caused by them. Unlike urea and similar substances, the detergents are unable to compete for the peptide hydrogen bonds that stabilize the secondary structure of proteins. Their interaction must, therefore, be largely restricted to the side chains of the protein including both the charged groups and the non-polar groups. It should be noted, however, that the binding of ionic detergents may disrupt peptide hydrogen bonds indirectly. This effect would result from intramolecular electrostatic repulsion or from the competitive breaking by the detergent of non-polar side chain interactions whose integrity is required for the stabilization of the helical structure. The physical changes proteins undergo in the course of their interaction with detergents can, therefore, to a large degree, be evaluated in terms of changes in their tertiary structure. That some effects are also exerted on the helical organization of the peptide chain is indicated by changes in optical rotation, which regularly accompany the binding of detergent molecules. Since the measurement of viscosity yields information on changes in molecular volume and asymmetry, the combined measurement of these two physical properties greatly facilitates the characterization of a given structural state.

The interaction between the alkyl sulfate homologs and serum albumin has been the subject of several studies. Putnam and Neurath,[2] studying the interaction of dodecyl sulfate and horse serum albumin found that the uptake of detergent occurred in several successive steps involving distinct electrophoretic species with fixed numbers of detergent molecules attached. The number of detergent anions bound by the second new component (AD_{2n}) was found equivalent to the sum of the cationic groups of the protein. Karush and Sonenberg[3] working at low detergent concentrations measured the association constants for three alkyl sulfate homologs (C_8, C_{10}, C_{12}) with bovine serum albumin and found that the affinity increased with increasing chain length. Pallansch and Briggs[4] confirmed and extended the findings of these two groups of workers. As the result of these studies it has become apparent that combination with detergents involves interaction between the charged and the non-polar portions of both detergent and protein, and as a result of this interaction the protein undergoes structural changes. The character and the extent of these changes depends on the number of detergent molecules bound for each homolog.

The purpose of the present study was to evaluate the structural changes that accompany detergent binding by human serum albumin largely by the measurement of optical rotation and viscosity as a function of decyl sulfate concentration.

Experimental

Human serum albumin (HSA) was contributed by Cutter Laboratories and was 99% pure by electrophoretic analysis. A 9% stock solution was prepared in distilled water, adjusted to *p*H 7.4 with NaOH and stored in the frozen state. Its concentration was determined by micro-Kjeldahl analysis. Acetylated serum albumin was prepared according to the method described by Fraenkel-Conrat[5] with some modifications. It was found that unless the *p*H is kept near 8 by the dropwise addition of NaOH while the acetic anhydride is added, only 80% acetylation can be achieved, as against 97% when this modification is introduced. The acetylated protein was dialyzed at 5° against running distilled water for 5 days. The degree of acetylation was determined by the ninhydrin method of Harding and MacLean.[6] Sodium decyl sulfate (SDeS) was kindly prepared by Mr. Robert Marks according to the method of Dreger, *et al.*[7] It was twice recrystallized from *n*-butanol. Optical rotations were measured at room temperature with a Bellingham and Stanley polarimeter, which could be read to 0.01 of a degree, using a sodium vapor lamp and a 100 mm. cell. The specific rotations are accurate to ±1°. Viscosity measurements were made in Ostwald–Fenske viscosimeters in a 25° water-

bath. The blanks used for the determination of reduced viscosities differed from the samples only by the absence of protein. The uncertainty in the reduced viscosities is ±0.005. The titration of HSA was carried out in 20 ml. of a 0.89% solution of HSA in 0.1 *M* SDeS by addition of standard 1 *N* HCl and NaOH from a micro-buret.

The binding of sodium decyl sulfate to HSA was determined by equilibrium dialysis. The dialysis was carried out at 25° for a period of 14 days. This interval was necessary since the effective rate of diffusion at high concentrations is considerably reduced by the micellar structure of the detergent. Ten ml. of 0.89% HSA containing the detergent was dialyzed against 10 ml. of distilled water. Since no salt was added, it was possible to calculate the amount of bound SDeS from the Donnan distribution. For this purpose the determination of the equilibrium concentrations of detergent on both sides of the cellophane membrane were required. These were obtained by the determination of the Na^+ concentration on both sides by flame-photometric analysis. The outside concentration of Na^+ was assumed to be equal to the detergent anion concentration outside, and the concentration of free detergent inside the bag was then calculated from the Donnan equation

$$[DeS^-]_i = \frac{[Na^+]_o^2}{[Na^+]_i}$$

Correction was made for the small amount of $NaHCO_3$ contained in the SDeS stock solution. The quantities of detergent in each compartment were calculated by multiplication of the concentrations by the respective volumes. These were determined by the dilution the known original concentration of the protein had undergone, as measured by the biuret method we have previously employed.[8] The molecular weight of HSA was taken to be 65,000.

Results and Discussion

When a 1% solution of human serum albumin (HSA) containing 0.15 *M* NaCl and 0.02 *M* phosphate (*p*H 7.4), is treated with sodium decyl sulfate in concentrations ranging from 1×10^{-3} *M* to 2×10^{-1} *M* the optical rotation of the protein undergoes a characteristic series of changes (Fig. 1).

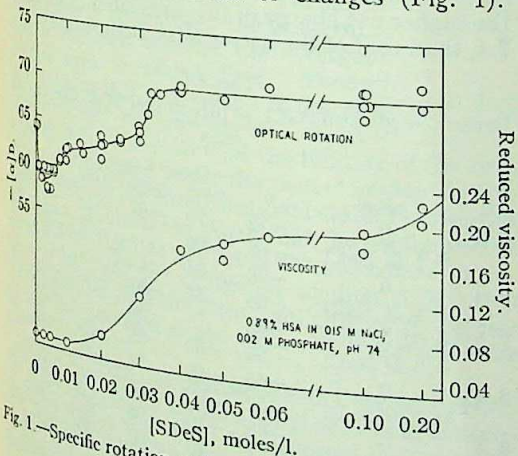

Fig. 1.—Specific rotation and reduced viscosity of HSA as a function of SdES concentration.

From 0 to 4×10^{-3} *M* sodium decyl sulfate the levorotation drops from the native value of 64° to about 58°. It then gradually increases to reach the value for the native protein at 3×10^{-2} *M* sodium decyl sulfate. Above this concentration the levorotation rises steeply and at 3.3×10^{-2} *M* reaches the value of 70°. Beyond this concentration the rotation stays at 70° up to 2×10^{-1} *M*, the highest concentration used.

Effect of Low Detergent Concentrations on the Optical Rotation.

—It will be convenient to consider first the initial phase of the rotation *versus* concentration curve, the one characterized by the decrease in levorotation. Figure 2 shows that this

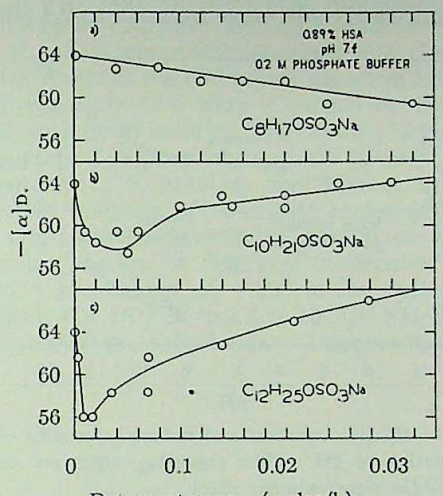

Fig. 2.—Specific rotation of HSA at low concentrations of three alkyl sulfate homologs.

drop is not restricted to sodium decyl sulfate, since both sodium octyl sulfate and sodium dodecyl sulfate cause a similar depression in the levorotation. The difference in their effectiveness is indicated by the variation of the detergent concentration at which the minimum occurs. The lowest homolog, octyl sulfate, reduces the rotation to 59° at a concentration between 2×10^{-2} to 3×10^{-2} *M*, whereas the highest homolog, dodecyl sulfate, causes the minimum of 56° to occur at 1×10^{-3} *M*. The order of effectiveness in evoking this decrease in levorotation corresponds to the order of the affinities of these detergents for bovine serum albumin as determined by Karush and Sonenberg.[3] From the data of these authors it can be calculated that for decyl sulfate at 4×10^{-3} *M* total concentration, there would be 11 moles of detergent bound per mole of protein. For dodecyl sulfate the binding of 10 molecules occurs at 1.9×10^{-3} *M*. In the above-mentioned study the cited values represent the highest ones measured and are close to the extrapolated maximum binding, *n*, which is taken to be 14. This *n* refers to the group of sites that are first to combine with detergent. Pallansch and Briggs[4] arrive at an *n* value of 10 for dodecyl sulfate under somewhat different conditions. Their work indicates that beyond this value the protein changes its binding properties. A new set of binding sites opens up accompanied by the appearance of a faster migrating electrophoretic component. This indicates that at this point some configurational change has occurred. Our results show that this change is associated with a transition from decreasing to increasing levorotation.

Since anionic detergents appear to interact with the cationic sites of the protein, the question may be asked whether the decrease in levorotation might not be associated with the charge neutralization of some of these cationic sites. It has been ob-

served by Jirgensons[9] that the optical rotation of native serum albumin decreases between *p*H 7 and 9.5 just before the steep rise at still higher *p*H values. We have confirmed this finding and found a drop of 6° in the optical rotation in that *p*H range (Fig. 3). In the *p*H range from 7.2 to 9.4 albumin

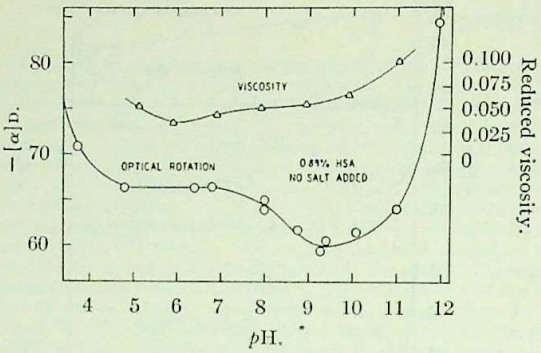

Fig. 3.—Specific rotation and reduced viscosity of HSA as a function of *p*H. (The viscosity values are not corrected for the electroviscous effect.)

dissociates about 15 H^+ ions,[10] some of which must come from the imidazolium groups (intrinsic pK 6.9), others from the ε-ammonium groups (pK 9.8). Since the dissociation of the former groups starts well below *p*H 6.9, where there is no change observed in the optical rotation, it is likely that the configurational change indicated by the decreased levorotation is associated with the loss of charge of the ε-ammonium groups.

Further evidence of the role of the ε-ammonium groups is provided by experiments with acetylated HSA in which these groups are masked. Figure 4a

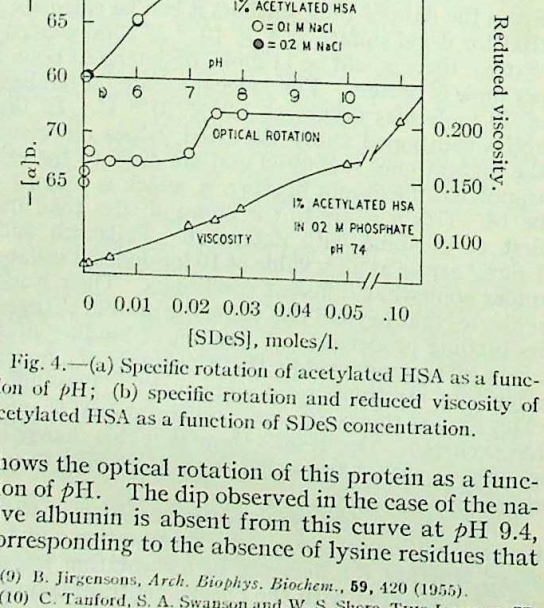

Fig. 4.—(a) Specific rotation of acetylated HSA as a function of *p*H; (b) specific rotation and reduced viscosity of acetylated HSA as a function of SDeS concentration.

shows the optical rotation of this protein as a function of *p*H. The dip observed in the case of the native albumin is absent from this curve at *p*H 9.4, corresponding to the absence of lysine residues that could be titrated in this *p*H region. The effect of the absence of these cationic groups, however, is implicit in this curve, since extrapolation to the region of insolubility, *i.e.*, to *p*H values below 5, would give a specific rotation of about −57°. Similarly, addition of SDeS to acetylated HSA at *p*H 7.4 (Fig. 4b) fails to cause the drop in levorotation observed in the native albumin at this *p*H. Since it can be shown (see below) that for the native HSA this effect is independent of the net charge within wide limits, as demonstrated by the same rotatory

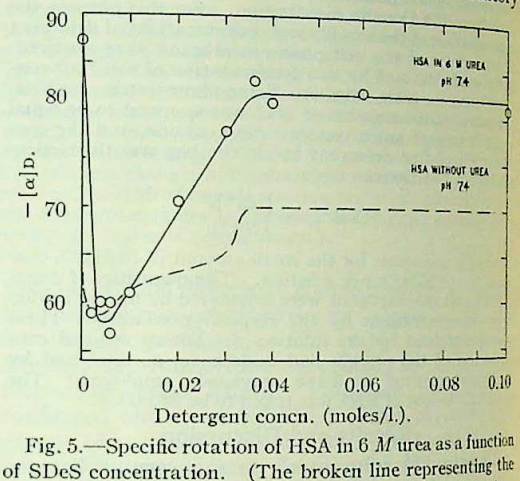

Fig. 5.—Specific rotation of HSA in 6 M urea as a function of SDeS concentration. (The broken line representing the same relation in the absence of urea is taken from Fig. 1.)

decrease upon the addition of detergent at *p*H 3 and *p*H 5 when 0.1 M NaCl is present (Table I), the elimination of the effect is not likely to be due to the higher net charge of the acetylated HSA at *p*H 7.4, than that of the native HSA at the same *p*H.

TABLE I

EFFECT OF *p*H AND NaCl ON $[\alpha]_D$ IN LOW SDeS CONCENTRATION

*p*H	Salt added	SDeS, moles/l. 0	0.001	0.002	0.003	0.004	Max. $\Delta[\alpha]_D$
3.0	0	−72	−70	−67	−64	−62	10
	0.1 M NaCl	−66	−65	..	−62	−60	6
5.0	0	−66	64	−61	61	..	5
	0.1 M NaCl	−65	65	−58	−58	−58	7
7.4	0.04 M NaCl	−65	..	−58	..	−57	9
	0.3 M NaCl	−64	−60	−58	−60	−60	6
8.0	0	−65	−60	58	−60	..	7
	0.1 M NaCl	−62	−62	58	−60	−58	4
9.4	0	−62	−60	−59	−59	−59	3
	0.1 M NaCl	−61	−62	−60	−60	−59	2

The intimate connection between the drop caused by titration with OH^- ions and with detergent anions is further revealed when HSA is treated with increasing concentrations of decyl sulfate at *p*H values between 3 and 9.4. Table I shows that the maximum levorotatory decrease in 0.1 M NaCl between *p*H 3 and 8 is 7°; at *p*H 9.4, however, it is only 2°. (The small value observed on the addition of the detergent at this *p*H indicates that the effective charge neutralization of only a fraction of the lysine residues is sufficient to suppress the effect. At high concentrations of detergent there is

levorotation (−70°) in 0.1 *M* SDeS at *p*H 9.4 (Fig. 6).) The influence which the partial neutralization of lysine residues exerts on the structure of the protein is a subtle one, since it is not accompanied by measurable changes in viscosity (Fig. 1, 3, 4). The effect probably is not due to the increase in net negative charge that occurs between *p*H 7 and 9.4, since increase in net charge tends to increase the levorotation rather than decrease it and usually causes a corresponding rise in the viscosity (see below). The observed phenomenon may be due to a *local* charge effect, whereby loss of the positive charge from neighboring residues permits a portion of the protein molecule to acquire additional secondary structure.

Protective Action of SDeS against Urea.—In 1948 the significant observation was made by Duggan and Luck[11] that certain organic anions at appropriate concentrations prevented the rise in viscosity of bovine serum albumin in 6 *M* urea. Among the anions studied, dodecyl sulfate was found most effective. Figure 5 shows the effect of sodium decyl sulfate concentration on the optical rotation of HSA in 6 *M* urea at *p*H 7.4. The most striking feature of this curve is that about 0.005 *M* SDeS completely prevents the rise in optical rotation caused by 6 *M* urea. The maximal protective effect thus occurs in the region of the minimal rotation caused by the decyl sulfate alone (Fig. 5, dotted line), *i.e.*, where 10–14 molecules of detergent are bound per molecule of HSA. The effect is completely reversible: the same rotation is obtained whether the detergent or the urea is added first. Though at this point it is not possible to describe unequivocally the mechanism of protection, it is quite clear that the binding of the first group of detergent molecules causes a very significant change in the configurational stability of serum albumin. It should be noted that the configuration assumed by HSA at *p*H 9.4 in the absence of detergent is in itself not protective against 6 *M* urea. This indicates that the structural change giving rise to the low rotation is not sufficient to provide the protective effect.

Effect of High Concentrations at Constant *p*H.—As indicated above, sodium decyl sulfate in concentrations above 4×10^{-3} *M* increases the levorotation of HSA to yield the native value of −64° at 3×10^{-2} *M*. Binding data are difficult to obtain in this region due to micelle formation by the detergent, but the best data available (Table II) indicate that it is between 2.7×10^{-2} and 3.4×10^{-2} *M* SDeS that the binding of 96 moles of detergent per mole of HSA occurs. This range includes the steep rise in optical rotation between 3×10^{-2} and 3.4×10^{-2} *M* SDeS (Fig. 1). The maximum observed rotation of −70° is reached at 3.4×10^{-2} *M* SDeS, i.e., in the concentration range where all the 96 cationic sites are probably combined with detergent.

(11) E. L. Duggan and J. M. Luck, *J. Biol. Chem.*, **172**, 205 (1948).

Subtracting the 10–14 molecules involved in the first phase of the interaction, we note that there are about 80 additional molecules bound when the levorotation of 70° is reached. We know from both binding and viscosity data that combination with the detergent continues beyond 3.4×10^{-2} *M* detergent. This concentration then is a significant one, for it marks the end of one aspect of the structural transformation that is caused by the interaction with decyl sulfate. The binding beyond this concentration is probably entirely hydrophobic in character, *i.e.*, it involves the interaction of the non-polar moieties of detergent molecules, either with non-polar residues of the protein, or with the non-polar portion of detergent molecules already bound. The change of −12° in the optical rotation from 4×10^{-3} *M* to 3.4×10^{-2} *M* SDeS is then the result of the attachment of approximately 80 additional molecules of detergent to one molecule of HSA.

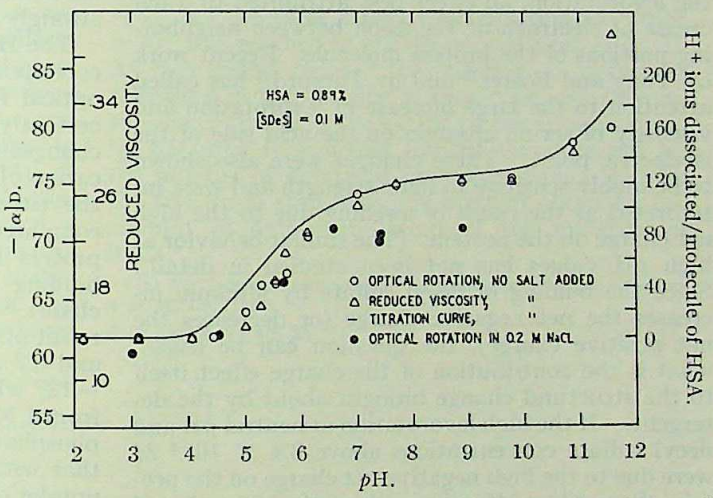

Fig. 6.—Specific rotation, reduced viscosity and H^+ ion dissociation of HSA in 0.1 *M* SDeS as a function of *p*H.

17.30	7.66	7.52	2.12	.099	158

The value of the maximum attainable levorotation depends on the alkyl sulfate homolog used. This value for octyl sulfate is 64° and for dodecyl sulfate 68°. These variations must be due to the effect of the non-polar portions of these detergents. A rotation of −80° obtained in a saturated solution of octadecyl sulfate indicates that the effect on the levorotation increases with increasing chain length.

Effect of High Detergent Concentrations as a Function of *p*H.—High values of levorotation and

viscosity caused by interaction with detergents make a partial unfolding or swelling of the protein molecule very probable, but the cause of this transformation has not been clearly defined. Table III shows the effect of salt concentration on the optical rotation of HSA in 0.1 *M* SDeS at

*p*H 7.4 and room temperature. These results demonstrate that increasing ionic strength depresses the levorotation, an effect best attributed to a decrease of electrostatic repulsion between neighboring portions of the protein molecule. Recent work by Yang and Foster[12] and by Tanford[13] has called attention to the large increase in levorotation and viscosity of serum albumin on the acid side of the isoelectric point. These changes were also shown to be highly sensitive to ionic strength and were interpreted as the result of swelling due to the high net charge on the protein. (The similar behavior at high *p*H values has not been studied in detail.) Since the binding of decyl sulfate by albumin increases the net negative charge (or decreases the net positive charge), the question can be asked, what is the contribution of the charge effect itself to the structural change brought about by the detergent. If the high levorotation at neutral *p*H and decyl sulfate concentrations above 3.4×10^{-2} *M* were due to the high negative net charge on the protein, then at low *p*H values, where the 100 carboxyl groups carry no charge, the net charge on the protein would be much less, and the levorotation should be markedly reduced, whereas in the *p*H range where the carboxyl groups dissociate the levorotation should increase. Figure 6 shows that this analysis is essentially correct. In this experiment 0.89% HSA in 0.1 *M* SDeS was adjusted to *p*H values ranging from 2.2 to 12.0 without added salt and in 0.2 *M* NaCl. When the ionic strength is high the flat portion of the curve on the acid side is at $-60°$ and the plateau in the neutral region at $-70°$. In the absence of detergent the optical rotation at *p*H 3 at high ionic strength is $-66°$. The difference of 6° between this value and the $-60°$ in 0.1 *M* dodecyl sulfate at the same *p*H corresponds to the specific effect of the ϵ-amino groups described in the first part of this paper. This difference is established at a concentration as low as 4×10^{-3} *M* SDeS, beyond which no further change in the optical rotation is observed.[14] Thus, beside this specific one, SDeS has no other effect on the optical rotation in this *p*H range.

However, the acquisition of negative charges by the dissociation of the carboxyl groups in the presence of 0.1 *M* SDeS increases the levorotation from 62 to 75° in the absence of added salt, and from 60 to 70° in 0.2 *M* added salt. This effect is associated with an increase in apparent hydrodynamic volume as indicated by the proportionally rising reduced viscosity. It is improbable that this effect would be due to further binding of SDeS molecules, since with higher *p*H values the negative net charge on the protein would reduce the binding rather than increase it.

In order to establish the correlation between the measured physical changes and the change in charge of the albumin molecule, the protein was titrated from *p*H 2 to 12 in the presence of 0.1 *M* SDeS and no added salt. In calculating the number of H^+ ions dissociated from HSA, correction was made for the titration curve of 0.1 *M* SDeS alone, since it was found that the detergent micelles strongly buffer in the region from *p*H 3 to 6.

The H^+ ion dissociation curve (Fig. 6) is seen to correspond fairly well to the *p*H-dependence of both optical rotation and viscosity. The agreement is certainly close enough to suggest that the physical changes are brought about by the ionization of the carboxyl groups. The shift of the buffering zone in the titration curve toward higher *p*H values, as compared to the corresponding zone in the native protein is due to the well-known effect of anion binding on the H^+ ion equilibria of protein side chains.[15] The rise of $-10°$ in optical rotation as a result of raising the *p*H from 2 to 7.4 in 0.1 *M* SDeS and 0.2 *M* NaCl can be compared with the rise of $-12°$ when the concentration of SDeS is increased from 4×10^{-3} to 3.4×10^{-2} *M* at *p*H 7.4 and 0.2 *M* phosphate buffer. In the latter case we concluded that within this concentration range there was an uptake of about 80 moles of detergent or the neutralization of about 80 positive charges.

Effects of High Concentrations on Acetylated HSA.—The findings on the acetylated serum albumin are in qualitative agreement with the above considerations. Here the maximum rotatory increase brought about by the addition of SDeS at *p*H 7.4 (Fig. 4b) is less than half of the corresponding change in the unmodified protein, in agreement with the 60% reduction in the number of available cationic sites. The data on the *p*H dependence of acetylated HSA in the absence of SDeS (Fig. 4a) indicates again that the increase in charge increases the levorotation. The protein when de-ionized with a mixed ion-exchange resin is insoluble and the supernatant has a *p*H of 4.5; at *p*H 5.0 the protein will stay in solution. Extrapolation of the curve to *p*H 4.5 yields $-57°$ for the isoelectric rotation. The difference of $-7°$ between this value and the $-64°$ characteristic for the unmodified protein at the isoelectric point shows, as mentioned above, the effect of the blocking of the ϵ-amino groups.

Unmasking of Disulfide Bonds.—A striking property of detergents, shared by other "denaturing agents," is their ability to make available groups for chemical reactions. In 0.2 *M* SDeS, *e.g.*,

(14) In bovine γ-globulin, where the specific effect on the lysine residues is absent, the addition of 0.1 *M* SDeS at *p*H 2 gives a $-[\alpha]_D$ of 45°, in agreement with the rotation of the native protein.

all of the 17 disulfide bonds of HSA are reduced by 0.1 M β-mercaptoethylamine–HCl, whereas only 1 disulfide bond is split in the absence of the detergent.[8] Furthermore, the facilitation of the reduction of disulfide bonds in HSA in 0.1 M reducing agent increases as the maximum initial rotation of $-70°$ has been attained at 0.03M. The relative viscosity increases further and binding data indicate that the number of detergent molecules combined has not reached its maximum even at 0.1 M concentration.

Structural Considerations.—What structural change of the protein is reflected in the constant optical rotation of $-70°$? Since optical rotation in polypeptides is regarded as a function of the degree of secondary organization of the chain, it is reasonable to assume that this value expresses the maximal transformation of the secondary structure caused by the combination with decyl sulfate. The continuing increase in viscosity and in the availability of disulfide bonds for reduction reflects further loosening of the molecule on the level of its tertiary structure. Electrostatic repulsion between neighboring polypeptide segments would be expected to separate these segments and thus to contribute to both viscosity and accessibility of bonds situated in the interior of the molecule. The latter function is more indicative of such a process than is viscosity because of the difficulty of ascertaining how much of the viscosity rise is due just to the increase in molecular volume and asymmetry caused by the attachment of a large number of detergent molecules. Since detergents do not compete for the H-bonds of the secondary structure, the rotation of $-70°$ probably represents the extent to which the secondary structure of HSA can be distorted by charge effects. In this connection it is significant that in preliminary studies on the rotatory dispersion of HSA we found that λ_0, the extrapolated intercept of the curve with the wave length axis in linear Drude plots, was 2660 Å. for both native HSA and the same protein in 8% sodium "lorol" sulfate ($-[\alpha]_D$ 72.0), whereas 10 M urea shifted λ_0 to 2340 Å. If the value of λ_0 is indicative of the degree of secondary structure,[16] this finding would indicate that, unlike urea, the detergent did not interfere extensively with the helical organization.

In this connection it is significant that the optical rotation of HSA in 6 M urea and increasing concentrations of SDeS reaches the plateau of $-81°$ at the same SDeS concentration at which $-70°$ was reached in the absence of urea (Fig. 5). As mentioned before, the binding of detergent measured in the absence of urea continues beyond this concentration; the extent of disruption caused by 6M urea is probably limited therefore not by the number of detergent molecules bound, but by the structural state which is brought about by the amount of detergent bound at the molarity of 0.034.

The Acetylcholinesterase Surface. VIII. Further Observations on Bifunctional Inhibition of the Enzyme[1]

BY S. L. FRIESS

RECEIVED FEBRUARY 8, 1957

It has been observed that the bifunctional aminoalcohol *cis*-2-dimethylaminocyclohexanol (I) at *p*H 7.4 acts as a mild inhibitor of the acetylcholinesterase system, with an unexpected strength about one order of magnitude greater than that of its methiodide derivative or the natural inhibitor choline. This inhibition appears to be of the reversible, non-competitive type at substrate concentration levels below 4×10^{-3} M, leading to the possibility that the Michaelis–Menten constant at these levels is a true equilibrium constant. This possibility is strengthened by the observation of Jenden, *et al.*, that a bis-quaternary salt III also displays non-competitive inhibition of AChE at the same substrate levels. The order of strength of I has been interpreted in terms of a zwitterion as the effective inhibitory species. Esterase inhibition by I is also found with the frog *rectus abdominis* preparation, with a discrepancy factor between *rectus* and *in vitro* estimations of strength approximating that found for the more potent inhibitor eserine. Further study of the inhibition produced by the bifunctional diamine N-(β-dimethylamino)-ethylpiperidine (II) in the 10^{-4}–10^{-7} M concentration range has revealed a decrease in effectiveness on incubation in glass which appears to depend largely on reaction volume and incubation time. This has been interpreted in terms of sorption on protein and on glass at these low levels, and is in accord with previous observations that appreciable amounts of II readily can be absorbed from solution by such proteins as gelatin and serum components. A further test of the steric requirements of the enzymatic surface between those loci capable of adsorbing the polar functions of inhibitors or substrates has been made with the compound 1,4-diazabicyclo[2,2,2]octane. Kinetic tests indicate that the size of the cage structure of this molecule exceeds the sterically acceptable limits of the surface.

Introduction

In continuation of previous studies designed to probe into chemical and stereochemical aspects of the catalytic regions on the surface of acetylcholinesterase (AChE), with aminoalcohols[2] and diamines[3] being used as bifunctional inhibitors to reveal ele-

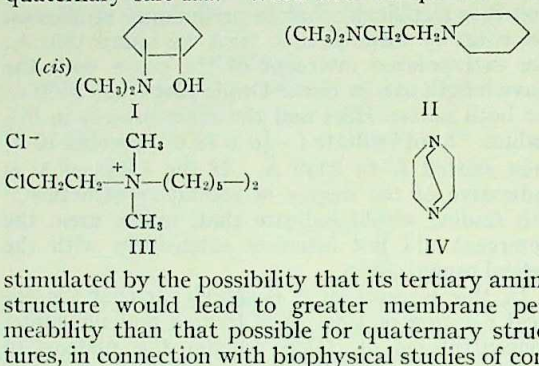
ments of surface detail, the present work deals with certain interesting features of the inhibition produced by the tertiary aminoalcohol I, the substituted ethylenediamines II and IV, and the bis-quaternary salt III. Work with compound I was



stimulated by the possibility that its tertiary amino structure would lead to greater membrane permeability than that possible for quaternary structures, in connection with biophysical studies of conduction in nerve,[4] while that with II was prompted by enzymatic indications[5] that its inhibitory effect at very low concentration levels depended on the time sequence of operations involved in the activity measurements. Experiments with compound III were undertaken to expand the picture of non-competitive inhibition developed with I, while tests of compound IV were made to continue the process of probing the nature of the steric requirements of the intersite surface of AChE.

Results

Inhibition with the Aminoalcohol I.—In the previous studies[2] of the AChE surface using stereospecific inhibitors as test agents it was observed that *cis*-derivatives in the 2-aminocyclohexanol series are in general more potent than the *trans*-isomers. A key intermediate in the preparation of these *cis*-compounds was the aminoalcohol I, and it was of considerable interest to determine whether at *p*H 7.4 compound I possessed any residual inhibitory activity so characteristic of its methiodide.[2] The results of these tests were surprising in several respects.

First, the compound was more active as an inhibitor than might have been expected from its tertiary aminoalcohol structure, with effective inhibition in the concentration range 10^{-4} to 10^{-5} M indicating a strength better by at least one order of magnitude than that displayed[2a] by its methiodide. But of greater interest was the observation that although its inhibition obeys the linear, competitive plot[6] (eq. 1) of v/v_I *vs.* [Inhibitor] at a fixed initial substrate concentration, the slope of this plot appears to be independent of substrate in its concentration range below 4×10^{-3} M. This kind of behavior has been taken[6] as one of the means of distinguishing between competitive and non-competitive inhibition of the reversible type, with the latter obeying an inhibition equation in a form independent of substrate concentration

$$v/v_I = 1 + [I] \frac{K_m}{K_I(K_m + [S]_0)} \qquad (1)$$

v_I = inhibited velocity
K_m = Michaelis–Menten constant
K_I = enzyme·inhibitor dissociation constant

$$v/v_I = 1 + \frac{[I]}{K_I} \qquad (2)$$

The results of v/v_I *vs.* [I] plots using eq. 1 and 2 for inhibition of the AChE–acetylcholine system at two levels of substrate concentration are summarized in Table I below. It is seen that over a twofold substrate range, the competitive K_I values vary by more than a factor of two, but the non-competitive K_I value of $6.0 \pm 0.4 \times 10^{-5}$ is roughly constant as predicted by eq. 2.

TABLE I

COMPETITIVE *vs.* NON-COMPETITIVE INHIBITION PLOTS
*p*H 7.4, 25.14°

Inhibitor	[Substrate]$_0$, $M \times 10^3$	Slope $\times 10^{-4}$ of v/v_I *vs.* [I] Plot	$K_I \times 10^4$ by eq. 1	$K_I \times 10^4$ by eq. 2
I	1.68	1.588 ± 0.027	8.4 ± 0.2	6.3
I	3.41	1.787 ± 0.027	4.0 ± 0.1	5.6
III	1.70	36.34	0.37	0.28
III	3.41	41.88	0.17	0.24

This result is of more than cursory interest in the field of AChE kinetics, in view of the generalization developed by Morales[7] that non-competitive inhibition for an enzyme system requires that the Michaelis–Menten constant K_m be a true equilibrium constant under the given conditions, and hence be a direct reflection of the strength of binding between enzyme and substrate.

Further support is added to this indication of the existence of non-competitive inhibitors by the observations of Jenden and Baldridge[8] on the anti-cholinesterase activity found in a series of bis-quaternary salts. In particular, the decamethylene derivative III was shown to be non-competitive in its inhibitory action, with the degree of inhibition over a given inhibitor range independent of substrate concentration, on the low side of the substrate concentration *vs.* activity profile. These results have been confirmed in the present study, with the data for compound III inhibition summarized in Table I. It is seen that the non-competitive K_I values again are essentially constant on changing initial substrate concentration, in accordance with eq. 2, whereas the competitive K_I values change with substrate level. This finding of non-competitive AChE-inhibitory characteristics in compounds as widely different in structure as I and III would appear to make the general theorem that K_m directly measures AChE–substrate binding, under these conditions, most attractive.

A further interesting comparison was afforded by the experimental evaluation[9] of the AChE-inhibitor dissociation constant for I on a frog *rectus*

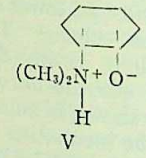
abdominis preparation, in which the effect of the inhibitor on potentiation of the action of acetylcholine through its blockade of tissue-localized enzyme is employed. This determination is somewhat clouded by neuromuscular block which sets in at the higher inhibitor concentrations, but readings of contracture at the lower levels led to a K_I value of about 2.1×10^{-3} at 37°. The ratio of K_I (frog rectus) to K_I (non-competitive) is therefore about 35, which approximates both in magnitude and in direction the discrepancy factor of about 20 found[9] for the competitive inhibitor eserine on comparing the kinetic and frog rectus values. It would appear then that the order of magnitude difference in K_I values afforded by these two techniques does not rest primarily on whether the AChE is inhibited competitively or non-competitively (eserine *vs.* I) or even on whether the inhibitor is comparatively strong (eserine) or moderate (I) in its action. A portion of this difference undoubtedly depends on the temperature difference between the two determinations.

On the point of the absolute inhibitory strength of I, its unexpected power against both isolated enzyme and tissue-localized enzyme has led to scrutiny of its tertiary structure for a clue as to its source of activity. One fruitful suggestion[10] draws upon the special geometry of I in respect to the relatively small (2.5 to 2.9 Å.) separation distance[11] between N and O atoms of the polar functions of I, leading to the possibility of prototropy and a stabilized zwitterion V as the effective inhibitory



V

species. Such a species would fulfill the previous postulated[3a] requirements (a polymethylated, charged N atom and a properly situated locus of high electron density) for strong binding at the bifunctional[12] catalytic unit of the enzymatic surface and account for the observed order of activity of the inhibitor.

Inhibition with the Diamine II.—In continued study of the enzymatic and physical properties of the diamine II, a mild detergency action in dilute solution was noted, leading to some speculation as to the concentration stability with time of the very dilute (10^{-6} to 10^{-7} *M*) solutions used in the inhibition work. Now, inhibition measurements have pointed out some peculiar features of the retention of power of dilute aqueous solutions of II, including an effectiveness varying with the volume of solution in contact with the Pyrex glass of the titration apparatus and with the contact time.

Initial enzymatic indications pointed[5] to a disappearance of effective inhibitory amounts of II in the 5×10^{-7} *M* range and upward on incubation with AChE in dilute buffer for periods of 5 minutes and more, when the reaction volume was of the order of 5 ml. or greater. Since these same concentrations of inhibitor were highly effective[3] in a smaller reaction volume of 3.20 ml., with constancy of action over a relatively long (10–15 minute) time interval, it was of considerable interest to investigate the influence of solution volume and incubation time, with or without enzyme, on the subsequent degree of inhibition of an initially fixed concentration of II.

The water-jacketed, cylindrical titration cell (27 mm. in diameter, 25 mm. deep) fitted with a pair of two-inch Beckman *p*H electrodes, capillary stirrer and microburet could accommodate reaction volumes up to 10 ml., so that for the present comparative study three sets of inhibition determinations at 3.20, 6.40 and 9.60 ml. (1×, 2×, and 3×) volumes were employed to furnish the volume variants. For certain comparisons at fixed enzyme concentration but varying volume it was also necessary to use one-, two- and threefold aliquots (1×, 2× and 3×) of enzyme solution. The initial inhibitor concentration was fixed at 1.1×10^{-6} *M* for the bulk of the determinations, all of which were carried out at *p*H 7.4 and 25.14°. Experiments to determine effects on inhibition were controlled with respect to the aging period in the cell of II dissolved in buffer, before the addition of enzyme (preincubation) and after enzyme addition (postincubation). The results of the total sequence of kinetic determinations are summarized in Table II. Figure 1 presents a representative

comparison of inhibition results at the three volume levels with initial enzyme (1X), substrate and inhibitor fixed, and total incubation times of the order of 5–10 minutes as in runs 3, 6 and 16.

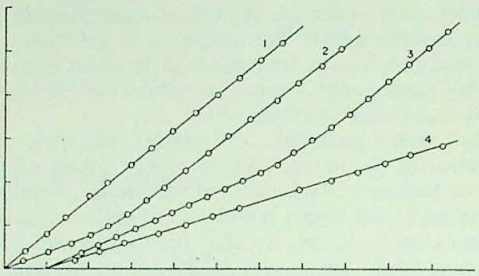

Fig. 1.—Rates of acetylcholine cleavage for: (1) uninhibited hydrolysis at 1× enzyme and 2× volume; (2) inhibited run 6 at 2× volume; (3) inhibited run 16 at 3× volume; (4) inhibited run 4 at 1× volume.

The results of Table II as illustrated in Fig. 1 seem to fit a pattern in which the time sequence of disappearance of inhibitory activity on incubation of a fixed inhibitor concentration depends on the volume of solution involved during the aging process, and also to some extent on the presence of enzyme in solution during this period. For example, keeping all variables constant except volume and time during incubation of inhibitor with buffer, runs 2 and 3 at the 1× volume level show relatively little difference created in the 50% inhibition mark by an additional period of 5 minutes of incubation after enzyme is added; at the 2× volume level (runs 6 and 7) essentially equal 5–6 minute periods of incubation *before or after* enzyme addition lead to the loss of virtually all inhibitory activity; and for the 3× volume (runs 13 and 16) further incubation of 5 minutes after enzyme addition causes a rapid drop to zero inhibition as contrasted with the smaller drop in inhibition when substrate is added 1 minute after enzyme. At both high and low volumes (runs 4, 14 and 15) periods of incubation in buffer ranging from 15 to 30 minutes prior to addition of enzyme are sufficient to lower the percentage inhibition to essentially zero.

The kinetic results at higher (2×, 3×) total amounts of enzyme for the most part show similar decreases in inhibition resulting from short-time incubation periods before or after addition of enzyme. Runs 8, 9, 11, 17 and 18 all show the effects of disappearing inhibition that seems to run to completion within about 15 minutes of total contact time. No order of magnitude differences in speed of disappearance as a function of total amount of enzyme can be detected, although runs 17 and 18 at 3× enzyme appear to show loss of inhibition somewhat more rapidly than runs 8 or 9 at 2× enzyme.

That this loss of inhibition can be completely independent of the presence of the enzyme during the aging process and also free of dependence on the geometry of the cell plus electrode system as incubating space is indicated by the results of run 20, in which aging in buffer for the extended period of 24 hours at 4° of an eightfold higher concentration of II than that in the rest of the runs was permitted to occur in a Pyrex volumetric flask. On pipetting of a sample into the titration cell, followed by the rapid addition of enzyme and substrate, only minimal inhibition was observed.

These results indicate that constancy of inhibition at the 10^{-6} to 10^{-7} M concentration levels generally employed in the *in vitro* enzymatic work with compound II is only to be found at the low volumes previously employed.[3] Further, severe limitations are also necessarily imposed on the preparation and storage of very dilute solutions of II in glass, considering the loss of inhibitory activity resulting from such storage in buffered medium as shown in run 20.

This disappearance of inhibitory activity by II has also been followed at inhibitor concentrations several orders of magnitude higher, with conclusive results following the pattern of those at the lower concentration levels. For example, in a representative set of experiments, a 2× concentration of enzyme in a final reaction volume of 6.40 ml. was subjected to the action of high concentrations of II in a controlled sequence. First, the incubation of enzyme at 25.14° in *p*H 7.4 buffer was allowed to occur in the presence of a 1.20×10^{-4} M concentration of II, for a 30-minute period. Following the addition of acetylcholine substrate (3.36×10^{-3} M) and kinetic assay for activity, it was found that only 42.7% inhibition of the standard activity remained. This value corresponds to the loss of 99.4% of the inhibitory power of II that might have been expected, based on the effectiveness[3a] of the thousand-fold lower concentrations of II in smaller reaction volume. That this effect is essentially independent of any direct denaturing action of II on the enzyme during this extended incubation time was shown in an accompanying experiment in which the incubation of a 1.31×10^{-4} M concentration of II in *p*H 7.4 buffer for 30 minutes prior to the addition of 2× enzyme, followed by addition of enzyme and only 5 minutes of further incubation before assay with substrate, produced virtually the same result; *i.e.*, a 39.4% inhibition of AChE activity which corresponds to a loss of 99.5% of the inhibitory power which the given aliquot of II would possess under high dilution–low volume conditions.

The striking inability of II to cause irreversible damage to the enzyme protein or in turn be irreversibly absorbed by the enzyme with subsequent loss of activity was illustrated by the following, high concentration level experiment. A buffered solution containing 15.6 mg. of enzyme protein (dry weight) and a 1.07×10^{-3} M concentration of II was incubated at 4° for a period of 2.78 hours. It was then placed in a cellophane dialysis sack and dialyzed against the standard *p*H 7.4 buffer in the cold for a period of 15 hours, with frequent changes of buffer to remove II. The residual solution in the sack was then diluted and assayed for total enzymatic activity, with a resulting small deviation (+ 2.7%) from the original standard activity well within the estimated uncertainty of the determination. Accordingly, incubation of the enzyme with even this relatively high concentration of the II results in no significant ir-

reversible loss of catalytic activity of the recovered protein.

It would appear from these data that the phenomenon of disappearance of inhibition recorded in the low concentration experiments of Table II is not unique to these low levels. It seems likely that it is related to a sorption process of II on both protein and glass, although the latter's ability in this respect is clouded by the observation that the smallest loss of activity occurs at 1× volume, where the surface/volume ratio is greatest.

The inference with respect to possible sorption of II on protein (both catalytic and non-catalytic portions) is supported by previous observations[13] that such polyelectrolyte solutions as diluted cat serum (containing its own serum esterase) or 0.10% gelatin in buffer can cause the disappearance of esterase inhibition to be expected from relatively large concentrations of II, on incubation with the inhibitor prior to kinetic analysis, and the related observation[13] that inhibition of AChE by the monomethiodide of I can be lowered by a factor of 50% after preincubation in the presence of 0.5% bovine serum albumin.

Inhibition with the Diamine IV.—An interesting type of interference with AChE surface binding of diamines of the type II was previously shown[14] in the inhibitory action of the α- and β-methyl substituted derivatives of II. It was observed that substitution of a methyl group on either of the methylene carbons of II seriously lowers the inhibitory activity, with a slight differentiation in effect of α *vs.* β-substitution reflecting a corresponding difference in steric requirements of the enzyme surface lying under these portions of a given adsorbed molecule. In an attempt to probe further into this region of protein surface between the dual sites[12] responsible for binding of the two polar functions of inhibitor or substrate, the compound IV has been prepared[15] as its dihydrochloride and tested for its inhibitory activity on the AChE–acetylcholine system at *p*H 7.4.

With the two nitrogen functions of IV serving for adsorption at the anionic and esteratic sites of AChE (one of the N atoms in all probability being monoprotonated at *p*H 7.4 in view of the nearly fixed pairs of pK_a' values observed[16] for these ethylenediamines) it was thought that the cage or barrel configuration lent to IV by the three N-linking $-CH_2CH_2-$ bridges would lead to a serious bulk problem on attempted adsorption at the protein surface. Models indicated that interference with a surface by the barrel structure of IV might be more serious than with either methylated derivative of II.

In terms of the resulting inhibition produced by adsorption at the catalytic region, this expectation has been fully borne out. It was observed that at *p*H 7.4 and 25.14°, compound IV is completely inactive as an inhibitor of AChE at concentrations ranging up to the high value of 1.1×10^{-2} *M*. Part of this lack of inhibitory activity may perhaps be due to a lack of methyl groups *per se* on the positively charged N atom, to lend additional binding strength *via* van der Waals interaction with the anionic site,[12] but the completeness of the phenomenon indicates that bifunctional adsorption to the surface over a region where chain-linked methyl groups interfere is entirely obviated by the steric requirements of the cage in IV.

Experimental

Kinetic determinations of enzymatic activity at 25.14 ± 0.03° and *p*H 7.4 were carried out by the constant-*p*H titration technique previously described.[3a] The enzyme preparations from electric eel tissue[17] assayed at 1.02×10^4 and 6.97×10^3 μmoles acetylcholine hydrolyzed/hr./mg. of dry weight protein at the substrate optimum of 3.3×10^{-3} *M*. Doubly recrystallized acetylcholine chloride, triply distilled water and a freshly distilled sample of II were used throughout. The aminoalcohol I was a freshly distilled sample prepared as in the previous work,[2] with m.p. 34–35°. The poorly poised buffer employed was 0.015 *M* in phosphate, 0.10 *M* in NaCl and 0.01 *M* in $MgCl_2$, and adjusted to *p*H 7.4. Compounds III and IV dihydrochloride were freshly recrystallized before use.

Incubations at any given volume level were carried out in the thermostated cell with constant stirring. Following completion of the final incubation after addition of the desired aliquot of enzyme, an aliquot of freshly prepared substrate solution was added and kinetic measurements started within one minute's time. Non-inhibited reference runs at the higher total amounts of enzyme (especially 3×) showed a pronounced tendency to decelerate slightly after some 5–10 minutes of reaction time, whereas hydrolysis rates at the 1× and 2× levels by and large remained quite constant with time over the 10–20% extent of reaction studied. The unit of enzyme designated as IX amounted to 6.2×10^{-4} mg. of protein on the dry weight basis in runs with II.

Rate runs with and without inhibitor were in general reproducible to within ±5%. K_I values were obtained from least-squares evaluation of the slopes of v/v_I *vs.* [I] plots, with a K_m value of 2.6×10^{-4} for these experimental conditions being employed in the slope calculations from eq. 1. The values tabulated were for a fixed temperature of 25.14 ± 0.03°.

Acknowledgment.—We are indebted to Dr. H. S. Polin for his generous aid in procurement of electric eel tissue and its initial extracts, to Dr. D. J. Jenden for the frog rectus assay, and to Mr. P. A. French for technical assistance.

Studies on the Mechanism of Enzymatic Decarboxylation[1a]

BY SIMON ROTHBERG[1b] AND DANIEL STEINBERG

RECEIVED JANUARY 14, 1957

A number of bacterial decarboxylases (aspartic acid, glutamic acid, tyrosine, malonic acid) were investigated in an attempt to determine the role of the carboxyl group in decarboxylation. Decarboxylations were carried out in the presence of H_2O^{18} and the evolved carbon dioxide was examined for oxygen-18 enrichment. There was very little enrichment and this was attributable to exchange reactions occurring even in the absence of decarboxylation. The level of enrichment was in any case too low to support any mechanism in which the water oxygen is stoichiometrically involved. The carbon dioxide evolved appears to be derived exclusively from the substrate with no labilization of the oxygen atoms. Similar results were found in the non-enzymatic metal catalyzed decarboxylation of oxalacetic acid. The results are compatible with the mechanism of Metzler, Ikawa and Snell[40] which proposed a non-hydrolytic cleavage of carbon–carbon bond with the release of the carboxyl group intact. The linkage of the carboxyl group to the enzyme surface may be electrostatic or possibly in the form of an ester, but an acyl intermediate is ruled out.

The mechanism of enzymatic amino acid decarboxylation has been the subject of a number of studies.[2–5] It appears to be well established that pyridoxal phosphate is an obligatory coenzyme for most, if not all, amino acid decarboxylases and that this coenzyme is tightly bound to the enzyme surface.[6–9] The decarboxylases are stereospecific[10] and one of the enzyme–substrate points of attachment is accounted for by the formation of a Schiff base between the α-amino group of the substrate and the aldehyde group of the bound coenzyme, as proposed originally by Werle and coworkers.[2a] More recent studies by Mandeles, Koppleman and Hanke,[3,5] showing that only one atom of deuterium from D_2O becomes incorporated into the product amine, led to a revision (proposed with F. Westheimer) of the Werle scheme with respect to the nature of the intermediate forms but the involvement of a Schiff base intermediate was confirmed.

In none of the studies to date has the possible involvement of the carboxyl group in enzyme–substrate complex formation been specifically investigated. Substrate specificity studies indicate that the carboxyl group must be free for scission of the C_1–C_2 bond and there is thus, presumably at least, an electrostatic binding of the carboxyl group to the enzyme. The present studies were undertaken in an attempt to further define the mechanism of decarboxylation by determining to what extent the oxygen atoms of the carboxyl group are labilized during the reaction and to what extent oxygen atoms of water in the medium participate in the CO_2 formation. Four bacterial amino acid decarboxylases and the malonic acid decarboxylase of *Pseudomonas fluorescens* were investigated. In addition, the metal catalyzed decarboxylation of oxalacetic acid was examined as a model of non-enzymatic decarboxylation.

Materials and Methods

Enzyme Preparation and Enzyme Assays.—*Clostridium welchii S.R. 12.* ATCC #8009 was grown and lyophilized as described by Meister and co-workers.[11] Reference is always to the dried cells of *Clostridium welchii* unless otherwise specified.[12] *Escherichia coli* ATCC #11246 was grown, harvested and an acetone powder prepared as described by Najjar and Fisher.[13]

Streptococcus faecalis R. cultured by the method of Gale[14] was used as an acetone dried powder.[12]

Pseudomonas fluorescens 23 was prepared as described by Hayaishi and Stanier[15] and purified as described by Hayaishi and Fraser.[16]

Enzyme activities were determined manometrically in the Warburg apparatus at 37° according to standard procedures.[17]

Partial Purification of Glutamic Acid Decarboxylase from *Clostridium welchii*.—Dried cells were ground with three aliquots of Alumina (Alcoa A-301) in a mortar. The material was centrifuged 20 minutes at 18,000 × g in a Servall angle-head centrifuge. The supernatant was brought to 80% saturation by the addition of solid ammonium sulfate. The sediment was separated and redissolved in water. This was divided into three crude fractions by ammonium sulfate precipitation—a fraction precipitated at 40% saturation (f_1), a fraction precipitated between 40 and 55% saturation (f_2), and the fraction soluble at 55% saturation (S_3). All fractions were dialyzed 18 hours against distilled water. The fractionations and dialyses were carried out at about 4°.

CO_2 Collection Technique.—A major technical problem was the elimination or minimizing of non-enzymatic exchange between CO_2 and H_2O^{18} during and subsequent to decarboxylation. A number of experimental arrangements were tried and discarded because of the considerable and variable non-enzymatic exchange observed. The extent of such exchange in closed vessels of various sizes and shapes

is indicated in Table I.[18] It will be noted that the extent of exchange was a direct function of the surface area of the liquid phase and an inverse function of the over-all volume of the vessel. From these studies it was clear that it would be necessary to remove the CO_2 from the H_2O^{18}-containing reaction vessel as rapidly as formed to reduce non-enzymatic enrichment. A system in which N_2 was constantly bubbled through the reaction vessel and into a CO_2 trap was tried but proved unsuitable. The experimental conditions finally settled on and used in all the experiments reported here virtually eliminated non-enzymatic enrichment by (1) removing the gas rapidly from the reaction vessel into a large collection bulb, (2) shortening the reaction time to a minimum necessary to obtain enough CO_2 for mass spectrometry and (3) running the decarboxylations at 25° instead of 37°.

TABLE I

NON-ENZYMATIC H_2O^{18}–CO_2 EXCHANGE AT 37°

Expt.	Vessel[a]	Vol. of vessel cc.	Vol. H_2O, cc.	Mole ratio H_2O/CO_2	% Enrichment at 15 min.	30 min.	45 min.	60 min.

42	C[1]	24.04	1.0	3550	12.1	25.2	36.8	..
44	D	236	2.0	8460	3.7	8.1	11.8	15.8

[a] The shapes and dimensions of the vessels used were as follows: A, simple equilibration tube—10 mm. × 135 mm.; B, simple equilibration tube—10 mm. × 135 mm. with bottom blown to diameter of 15 mm.; C, modified double-arm Sprinson-Rittenberg tube—1.0 cc. of H_2O^{18} all in one arm; C[1], same tube as in C, but 0.5 ml. H_2O^{18} in each arm; D, modified Sprinson–Rittenberg tube with 200-cc. bulb separating vacuum stopcock and arms.

Apparatus.—The *reaction vessel* used was a spherical 25-ml. flask containing the enzyme, H_2O^{18} and a magnetic stirrer. An *addition tube*, fitted to the reaction vessel with a standard taper joint, contained substrate, buffer and H_2O^{18}. The reaction vessel was connected through an over-flow trap and a manifold system to a series of 500-ml. *collection bulbs* fitted with vacuum stopcocks. The entire system, including the collection bulbs, was degassed and at time zero the contents of the *addition tube* were dumped into the *reaction vessel*. The CO_2 liberated during successive time intervals was collected in separate 500-ml. bulbs. When the collection bulb stopcock was closed at the end of a collection period Dry Ice was brought up beneath the bulb to condense water in an effort to minimize any continuing non-enzymatic exchange. Storing the gas in the collection bulb for as much as four hours under these conditions did not increase the enrichment. The special glassware used was fabricated at the glass shop, Instrument Section, National Institutes of Health.

Isolation and Purification of Products.—The decarboxylation was halted by immersion of the reactor tube in Dry Ice-alcohol. The reaction mixture was then thawed, centrifuged at 2° for 15 minutes at 3000 r.p.m. and the supernatant was immediately removed, frozen and lyophilized. Aliquots were streaked on specially washed[19] Whatman #3 paper and chromatographed ascending in 70% propanol: water in a tank 12" high by 9" in diameter. The partition was allowed to go for about seven hours and the paper was dried in a circulating oven at 65° for 15 minutes. The amino acid fractions eluted by water were lyophilized and the dried material was stored in a desiccator over $CaSO_4$.

Preparation of O^{18}-Organic Compounds for Mass Spectrometry.—The O^{18}-content of substrates and products was in every case determined by analysis of CO_2 derived from them. Two different pyrolysis techniques were employed for converting the oxygen of organic compounds quantitatively to carbon dioxide. The first, that of Doering and Dorfman,[20] was used only in the early part of the work. The second, that of Rittenberg and Pontocorvo,[21] was used for most of the studies reported here. The purified, dry compounds were pyrolyzed at 350° for 30 minutes with dried $HgCl_2$ as a catalyst.

The O^{18}-content of water[22] was determined by equilibration with carbon dioxide as described by Cohn and Urey.[23]

Mass Spectrometry.[24]—The O^{18}-content of the carbon dioxide liberated in decarboxylation experiments and that obtained in equilibration experiments was measured by obtaining the ratio of mass 46 to mass 44.[25,26]

Tank carbon dioxide[27] was obtained by passing the gas through a Dry Ice–alcohol trap and collecting in a bulb previously evacuated to better than 10^{-4} mm. Although ten micromoles of gas was necessary for optimal operational conditions, an accurate ratio could be determined with as little as one micromole of gas. The reproducibility of a ratio on the same sample was ±0.5%. Thus for a sample with 0.2 atom % excess O^{18} the maximum error was of the order of 1%.

In the manifold collection system, the gas in the 500-cc. bulb was passed through two traps, the first immersed in Dry Ice–alcohol and the second in liquid nitrogen. The carbon dioxide admitted to the inlet system passed back again through the first trap.

A special breakoff leading to the inlet system of the mass spectrometer[28] accommodated the tube used in the Rittenberg–Pontocorvo pyrolysis procedure.[21] The Dry Ice–alcohol non-condensable gases were passed into a quinoline trap and allowed to react so as to effect complete removal of HCl. The CO_2 was passed through a Dry Ice–alcohol trap and admitted to the inlet system of the spectrometer.

Results and Discussion

Control Experiments.—The degree of O^{18}-enrichment in CO_2 expected on the basis of factors other than the decarboxylation process itself was determined in control studies like those shown in Table II. Tank CO_2 was incubated with an approximately equimolar amount of product (γ-aminobutyric acid) under conditions otherwise paralleling those used in subsequent decarboxylation experiments. A sample of CO_2 taken at six minutes showed 4.8% enrichment. Omitting enzyme from the incubation did not decrease the rate of enrichment, showing that it was not attributable to a catalytic activity of *Cl. welchii*, but rather to non-enzymatic H_2O^{18}–CO_2 exchange. The somewhat greater enrichment observed in the second experiment probably is due to the use of a smaller quantity of CO_2.

In these experiments CO_2 was present in the gas phase *above* the medium throughout the incubation whereas in the decarboxylation experiments the gas is continuously formed *within* the H_2O^{18} medium during the incubation. As a control more nearly approximating the actual experimental conditions

(18) Throughout this paper the degree if O^{18} enrichment of substrates and products is expressed as a percentage of that expected if equilibration with the H_2O^{18} of the medium employed were complete:

$$\% \text{ enrichment} = \frac{\text{atoms \% excess } O^{18} \text{ in compd.}}{\text{atoms \% excess } O^{18} \text{ in } H_2O^{18} \text{ of medium}} \times 100.$$

(19) The Whatman #3 paper was prepared by percolation in water for four days and then in alcohol for four additional days. This was found to be necessary because of water-soluble oxygen-containing impurities in the paper as supplied.

TABLE II

% ENRICHMENT OF CARBON DIOXIDE IN CONTROL EXPERIMENTS

System: reaction vessel—106 mg. *Clostridium welchii*, 12.8 mg. γ-aminobutyric acid, 130 μmoles tank carbon dioxide. Addition tube—1.8 cc. H_2O^{18} (1.276 atoms % excess—final), 0.2 cc. 3 *M* acetate buffer (*p*H 4.9)

Time (min.)	6[a]	9[a]
% enrichment	4.8	7.8
% enrichment/min.	0.80	0.86
μmoles gas in sample	116	14

System: reaction vessel—13 mg. γ-aminobutyric acid, 65μ moles tank carbon dioxide. Addition tube—1.8 cc. H_2O^{18} (1.276 atoms % excess—final), 0.2 cc. 3 *M* acetate buffer (*p*H 4.9)

Time (min.)	6[a]	9[a]
% enrichment	5.7	11.4
% enrichment/min.	0.94	1.27
μmoles gas in sample	58	7

[a] CO_2 samples were withdrawn from the reaction flask at the end of the sixth and ninth minute of reaction.

the enrichment of CO_2 formed by addition of H_2O^{18}-containing acetate buffer (*p*H 4.9) to sodium bicarbonate was studied. The CO_2 derived in this manner had less than 0.5% enrichment.

The non-enzymatic, metal-catalyzed decarboxylation of oxalacetic acid was studied, again under conditions similar to those used in the subsequent enzymatic experiments and with a rate of decarboxylation approximately the same as that in the enzymatic experiments. The enrichment observed in the CO_2 was less than 5% and probably can be attributed to CO_2–H_2O^{18} exchange occurring *subsequent* to the decarboxylation process.

Glutamic Acid Decarboxylation.—The glutamic acid decarboxylase of *E. coli* gave CO_2 in which the % enrichment was less than 5% (Table III),

TABLE III

% ENRICHMENT OF CARBON DIOXIDE OBTAINED FROM L-GLUTAMIC ACID IN ENZYMATIC DECARBOXYLATION WITH *E. coli*.

Expt.	Temp., °C.	Time, min.	% Enrichment
120	25	1	2.7
121	25	0.5	4.2

as in the control experiments just described. The % enrichment in CO_2 formed by the action of the glutamic acid decarboxylase of *Cl. welchii* was somewhat higher and varied considerably from experiment to experiment, ranging from 5.9 to 12.8 (Table IV).

TABLE IV

% ENRICHMENT OF CARBON DIOXIDE OBTAINED FROM L-GLUTAMIC ACID IN ENZYMATIC DECARBOXYLATION WITH *Cl. welchii*.

Expt.	Temp., °C.	Time, min.	% Enrichment
60	25	1	7.7
64	25	1	5.9
76	25	5	12.8
83	25	3	11.5
92	25	1	7.4

While the enrichment observed in these experiments was well below that anticipated for any stoichiometric involvement of water in the decarboxylation process, as discussed later, it was nevertheless well above that anticipated from the control experiments on non-enzymatic CO_2–H_2O^{18} exchange.

The possibility of accelerated CO_2–H_2O^{18} exchange due to the presence of carbonic anhydrase in the preparation was considered. However, repetition of the experiments in the presence of 0.05 *M* Diamox, an effective inhibitor of carbonic anhydrase,[29] did not decrease the observed enrichment.

Non-enzymatic enrichment of unreacted substrate was ruled out by control incubations of glutamic acid and H_2O^{18}-containing medium under several different conditions. After 30 minutes incubation at 25° glutamic acid was reisolated from the medium by paper chromatography and O^{18} enrichment determined after pyrolysis. At *p*H 3.75 there was no measurable enrichment but at *p*H 1.5 there was 3.9% enrichment. Under the conditions used in the decarboxylation studies (*p*H 4.9), omitting only the enzyme, the glutamic acid substrate showed only 0.8% enrichment.

In the next experiments unreacted substrate and reaction product were isolated after 6 minutes incubation with *Cl. welchii* or with partially purified enzyme under the usual conditions. Both glutamic acid and γ-aminobutyric acid were found to be enriched in O^{18}. The relative enrichment in glutamic acid was 24.2 and 33.8% in two incubations. Because of the presence of endogenous γ-aminobutyric acid in the enzyme preparation, enrichment in the product could not be readily quantitated. However, the very high % enrichment in the unreacted glutamic acid under conditions in which the CO_2 liberated by the decarboxylase showed only up to 12.8% enrichment indicates that the γ-carboxyl group must be most heavily enriched. The O^{18} in the CO_2 most probably is due to enrichment in the α-carboxyl group catalyzed by one or more enzymes in the crude *Cl. welchii* preparation.

Incubations of the complete system were carried out in the presence of 0.01 *M* hydroxylamine, a concentration sufficient to inhibit completely the glutamic acid decarboxylase, probably by complexing with the coenzyme.[30] Despite the complete inhibition of the decarboxylation reaction, examination of the unreacted glutamic acid showed that enrichment had proceeded at about the same rate as in the fully active system (enrichment, 26.9%). This strongly suggests that the observed substrate enrichment is not catalyzed by the glutamic acid decarboxylase itself but rather by other enzymes in the *Cl. welchii* preparation. The possibility that the decarboxylase, while incapable of splitting off CO_2 in the presence of hydroxylamine, is still capable of catalyzing an exchange reaction cannot be ruled out, however. The observed substrate enrichment could be due to reversible reactions such as amide formation and splitting; it could also be due to a "virtual reaction" of the type catalyzed by chymotrypsin in the studies of Doherty and Vas-

low[31] and observed in several other enzymatic systems.[32–35]

Aspartic Acid Decarboxylation.—The CO_2 derived from decarboxylation of aspartic acid by *Cl. welchii* showed considerably higher % enrichment than that derived from the action of glutamic acid decarboxylase (Table V).

TABLE V

% ENRICHMENT OF CARBON DIOXIDE OBTAINED FROM L-ASPARTIC ACID DECARBOXYLATION IN ENZYMATIC DECARBOXYLATION WITH *Cl. welchii*

Expt.	Temp., °C.	Time, min.	% Enrichment
94	25	5	22.7
95	25	1	19.0
96	25	3	17.4

Again, however, the enrichment observed was less than that anticipated for a reaction involving a stoichiometric contribution from water oxygen. Examination of unreacted aspartic acid again revealed considerable substrate enrichment but the product, α-alanine,[11] was free of O^{18}, indicating that the exchange was limited to the β-carboxyl group.

As in the case of the glutamic acid decarboxylase, enrichment of substrate proceeded even in the presence of inhibitory concentrations of hydroxylamine, suggesting that the exchange was catalyzed by an enzyme or enzymes other than the decarboxylase itself. Further evidence for this was obtained by partial purification of the enzyme system. The fraction between 40 and 55% ammonium sulfate saturation (f_2), which was rich in glutamic acid decarboxylase activity, contained little or no aspartic acid decarboxylase activity. This fraction nevertheless was active in catalyzing enrichment of aspartic acid.

Tyrosine Decarboxylation.—CO_2 derived from decarboxylation of tyrosine by *Strep. faecalis* under conditions similar to those used above showed 8 to 12.2% enrichment. Substrate was not examined for possible enrichment.

Malonic Acid Decarboxylation.—This reaction has been studied by Gray[36] and Hayaishi[37] and has been shown to be a coenzyme-A dependent reaction. Wolfe and Rittenberg proposed that a malonyl-di-coenzyme-A complex plays a catalytic role and by a transfer reaction yields a monosubstituted derivative which is the form decarboxylated. Studies by Hayaishi suggest that only one of the carboxyl groups becomes conjugated with coenzyme A.

In the present studies decarboxylation in the presence of H_2O^{18} led to the formation of CO_2 with only 10.1 and 14.2% enrichment. The results are compatible with the different mechanisms proposed by Hayaishi[38] and Wolfe and Rittenberg[39] and indicate that the CO_2 originates from the carboxyl group beta to the coenzyme-A activated group.

Discussion

There are several mechanisms by which the carboxyl group might be involved in enzyme–substrate complex formation prior to decarboxylation. A number of these, listed below, should be readily distinguishable on the basis of enrichment in the CO_2 when decarboxylation proceeds in the presence of H_2O^{18} (Fig. 1).

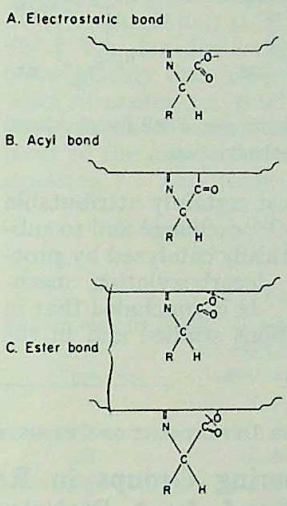

Fig. 1.—Possible modes of bonding between carboxyl group and enzyme surface.

1. Formation of an acyl–enzyme bond. Cleavage should yield CO_2 with one-half the atoms % excess O^{18} of that in the H_2O^{18} of the medium, *i.e.*, relative *per cent. enrichment*, 50.

2. Formation of an ester–enzyme bond. Cleavage on one side of the ester oxygen could yield CO_2 free of O^{18}; cleavage on the other side would yield CO_2 with 50% enrichment.

3. Exclusively electrostatic bonding to the enzyme surface. Elimination of CO_2 by simple carbon–carbon bond scission would result in no enrichment.

4. In each of the above schemes additional enrichment might occur due to hydration either before or after splitting off of CO_2. For example, in case 1 above, hydration of the CO_2 released from enzyme–substrate combination with 50% enrichment would enrich it further so that the CO_2 as collected would show 66⅔% enrichment. The expected enrichment would be the same if hydration of the enzyme–substrate complex occurred prior to CO_2 release.

In none of the five decarboxylation reactions studied did the enrichment of the released CO_2 approach the levels predicted for stoichiometric involvement of water oxygens in the mechanism. The minimal enrichment observed in the case of

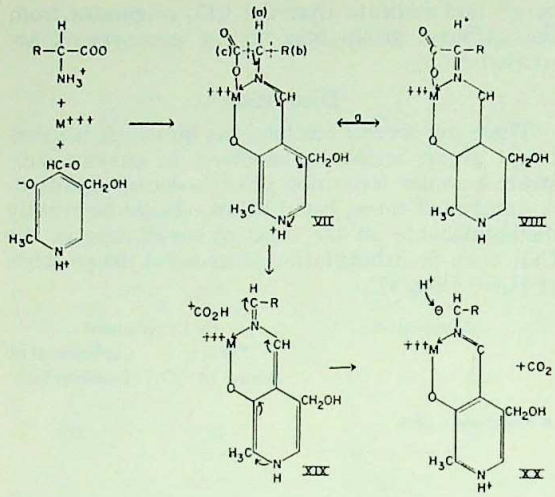

Fig. 2.—Scheme of Metzler, Ikawa and Snell for pyridoxal catalyzed decarboxylation.

some of the studies is almost certainly attributable to non-enzymatic CO_2–H_2O^{18} exchange and to substrate enrichment enzymatically catalyzed by processes independent of the decarboxylation mechanism, as discussed above. It is concluded that in all of the enzymatic reactions studied and in the metal-catalyzed decarboxylation of oxalacetic acid as well, the carboxyl group is released intact by simple cleavage of a carbon–carbon bond. Water does not appear to play a role in the CO_2-release mechanism nor does the CO_2 equilibrate with water in the course of the reaction except at the rate anticipated for non-enzymatic CO_2–H_2O^{18} exchange.

On the basis of these studies it is possible to rule out any of the mechanisms described above which would result in enrichment of the CO_2. The results are compatible with the mechanism recently proposed by Metzler, Ikawa and Snell on the basis of their studies of pyridoxal phosphate catalyzed reactions.[40] These workers propose that the formation of an amino acid–pyridoxal complex as shown in Fig. 2, with the carboxyl group involved only electrostatically can weaken the carboxyl carbon–α-carbon bond by electromeric displacement of electrons to the heterocyclic nitrogen. The enzyme or an enzyme–metal complex[41] is presumed to be equivalent to the simple metal ion used in the non-enzymatic model experiments. The present results show that splitting of this carbon–carbon bond does not involve water and that the carboxyl group is released intact.

The Role of Neighboring Groups in Replacement Reactions. XXII. Competition between *o*-MeO-5 and Ar_1-3 Participation in Solvolysis of *o*-Methoxyneophyl Toluenesulfonate[1,2]

BY R. HECK, J. CORSE, E. GRUNWALD AND S. WINSTEIN

RECEIVED JANUARY 7, 1957

Solvolysis of *o*-methoxyneophyl *p*-toluenesulfonate involves two competing anchimerically assisted ionization processes. One of the ionization modes is the Ar_1-3-assisted one; the other involves *o*-MeO-5 participation. From Ar_1-3-assisted ionization, rearranged substitution and elimination products are obtained. From *o*-MeO-5-assisted ionization is obtained mainly 3,3-dimethyl-4,5-benzodihydrofuran. From the composition of the isolated products it is possible to dissect the first-order rate constants of acetolysis and formolysis into component k_Δ^{Ar} and k_Δ^{OMe} values corresponding to each of the anchimerically-assisted ionizations. The ratio, $k_\Delta^{OMe}/k_\Delta^{Ar}$, is quite sensitive to the nature of the solvent, being much smaller in formic than in acetic acid. Ar_1-3-assisted ionization of *o*-methoxyneophyl toluenesulfonate is unusually slow in comparison with the *p*-isomer, while *o*-MeO-5-assisted ionization is approximately as fast as that of δ-methoxybutyl toluenesulfonate.

In solvolysis of 2-*o*-anisylethyl *p*-toluenesulfonate (I), there is no indication[3] of substantial competition of *o*-methoxyl participation, in the sense of I → II, with Ar_1-3[4] participation to yield III. On the other hand, with *o*-methoxyneophyl toluenesulfonate (VII), *o*-MeO-assisted ionization competes very successfully with the Ar_1-3-assisted process. The results obtained in a study of this solvolysis are now reported and discussed.

Results

***o*-Methoxyneophyl *p*-Toluenesulfonate.**—The *o*-methoxyneophyl alcohol was obtained from the sequence of reactions previously employed for neophyl alcohol[5,6] itself. This sequence involves formation of the neophyl chloride from methallyl chloride and anisole, followed by oxidation of the Grignard reagent of the chloride. Originally, the sequence of reactions was employed with the intention of preparing *p*-methoxyneophyl alcohol.[7] However, alkylation of anisole with methallyl

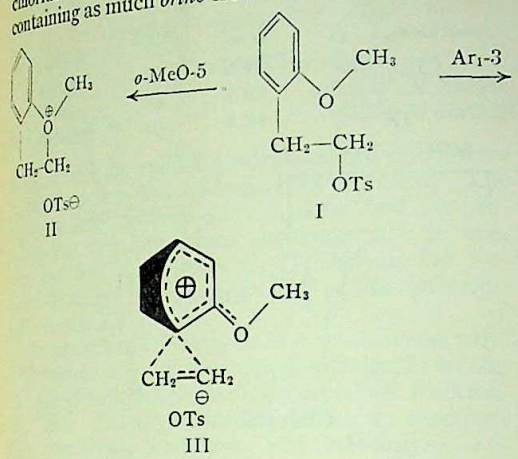
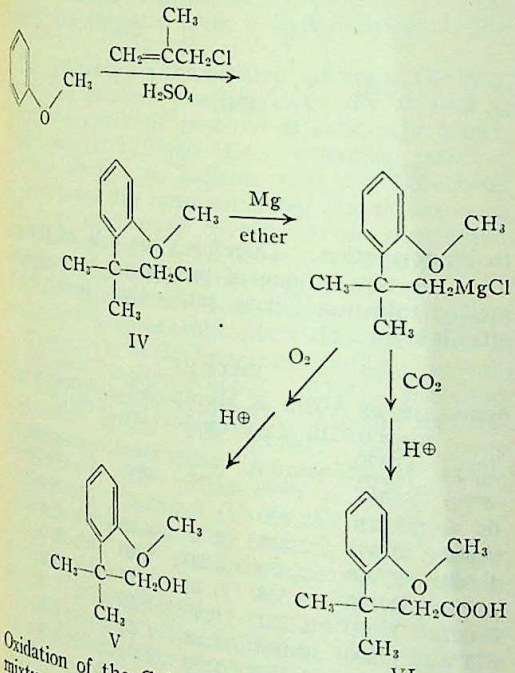
chloride and sulfuric acid yields a chloride mixture containing as much *ortho* isomer IV as *para*.



Carbonation of the Grignard reagent of the chloride mixture gave an acid mixture from which approximately equal quantities of β-*p*-anisylisovaleric and β-*o*-anisylisovaleric (VI) acids were isolated.



Oxidation of the Grignard reagent gave rise to a mixture of methoxyneophyl alcohols which led to an inseparable mixture of *p*-nitrobenzoates. Fortunately, the *p*-toluenesulfonate of *o*-methoxyneophyl alcohol (V) is considerably higher melting and less soluble than the *p*-isomer,[7] so that it was possible to obtain a *ca.* 50% yield of pure *o*-methoxyneophyl *p*-toluenesulfonate (VII) from the methoxyneophyl alcohol mixture.

Kinetics of Solvolysis.—The *o*-methoxyneophyl *p*-toluenesulfonate exhibited good first-order behavior in ethanolysis and formolysis, the pertinent rate constants being summarized in Table I. As indicated in Table I, nearly theoretical infinity titers were observed in ethanol and formic acid solvents.

TABLE I

[a] $\Delta H^{\ddagger} = 23.2$ kcal./mole; $\Delta S^{\ddagger} = -7.5$ e.u.

In acetic acid solvent, the solvolysis of *o*-methoxyneophyl toluenesulfonate (VII) appeared to stop at 63% completion at 75° and at a smaller figure at 49°. The data for a typical acetolysis which gave a low infinity titer are given in Table II. In these cases of acetolysis, good first-order rate constants were obtained when these were calculated on the basis of the experimental infinity titers employing equation 1. This point is illustrated in Table II.

$$2.303 \log \left[\frac{(\mathrm{HOTs})_\infty - (\mathrm{HOTs})_0}{(\mathrm{HOTs})_\infty - (\mathrm{HOTs})}\right] = kt \qquad (1)$$

TABLE II

	Mean	4.21 ± 0.10

[a] Per 5-ml. aliquot.

The inclusion of 0.03 *M* sodium acetate in the glacial acetic acid solvent brought the infinity titer nearly to the theoretical value, the first-order rate constant being slightly increased (Table I).

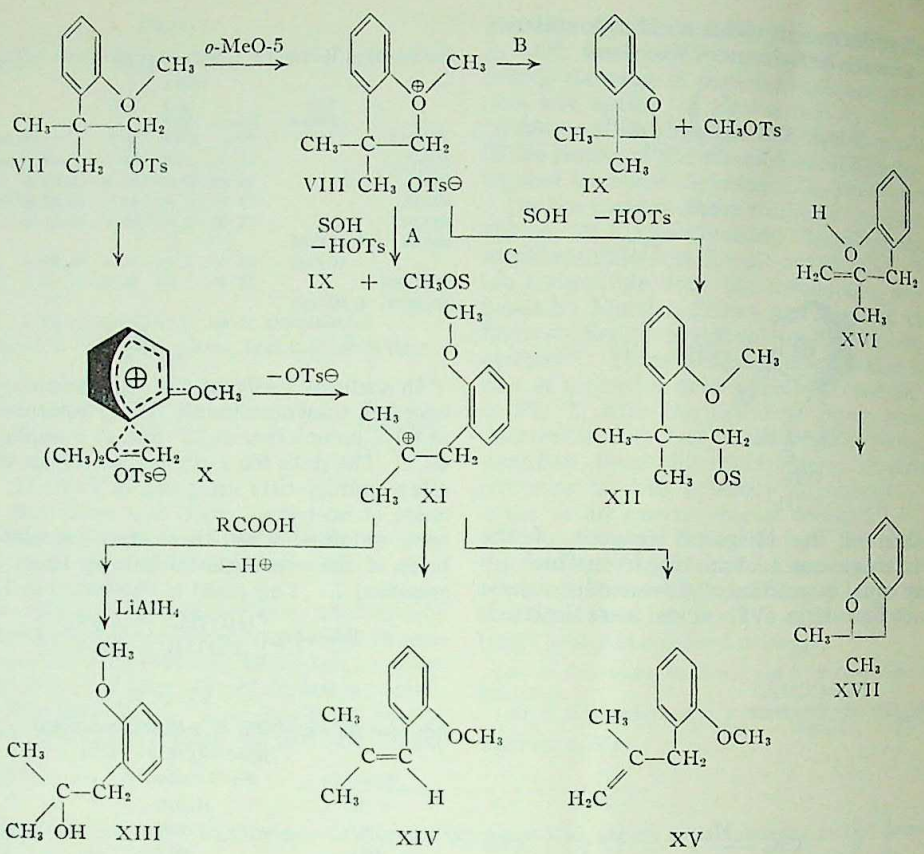
The low infinity titers observed in acetolysis appear to be connected with the formation of methyl toluenesulfonate. This substance solvolyzes[8] at a rate one-five-hundreth of that of the *o*-methoxyneophyl ester, explaining why the low infinity titer in acetolysis was relatively constant over many solvolytic half-lives of the *o*-methoxyneophyl toluenesulfonate. A rough determination of the rate constant of acetolysis of the slow material remaining after the first infinity titer was reached gave a value approximately equal to the previously[8] reported value for methyl toluenesulfonate.

It is clear that no significant amount of methyl *p*-toluenesulfonate is being formed in ethanolysis because the rate constant for *o*-methoxyneophyl *p*-toluenesulfonate is twice that for methyl *p*-toluenesulfonate.[8] A drifting rate constant would have been observed if methyl *p*-toluenesulfonate were formed. Also, there can be no formation of

[8] S. Winstein, C. Hanson and E. Grunwald, THIS JOURNAL, **74**, 1120 (1952).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri



methyl *p*-toluenesulfonate in formolysis, because *o*-methoxyneophyl *p*-toluenesulfonate solvolyzes 10^3 times as rapidly as the methyl ester,[8] yet high infinity titers are observed after only 10 half-lives of the neophyl ester.

In order to acertain the reason for the high infinity value observed in acetolysis of *o*-methoxyneophyl toluenesulfonate in the presence of added sodium acetate, the second-order rate constant for reaction of methyl *p*-toluenesulfonate with sodium acetate was measured. An acetolysis run on 0.0313 *M* methyl *p*-toluenesulfonate in acetic acid, 0.0310 *M* in sodium acetate, at 75° is summarized in Table III. Because of the importance of second-order substitution of methyl toluenesulfonate by sodium acetate, a downward trend is observed both in the integrated first-order constants or the instantaneous first-order constants, k_i, obtained from the slopes of a plot of ln $[(ROTs)_0/(ROTs)]$ *vs.* time. Second-order rate constants, k_2, were evaluated with the aid of equation 2, using for k_1 the previously[8] reported first-order constant for acetolysis of methyl toluenesulfonate at 75°. The relatively constant value for k_2 is listed in the last column of Table III, the mean value being 6.8×10^{-5} l. mole^{-1} sec.$^{-1}$.

$$k_i = k_1 + k_2(\mathrm{NaOAc}) \qquad (2)$$

The reaction of methyl toluenesulfonate with sodium acetate turns out to be too slow to account for the high infinity titers observed in acetolysis of *o*-methoxyneophyl toluenesulfonate on the basis of reaction of methyl toluenesulfonate, subsequent to its formation. Therefore, the role of the sodium acetate is one of preventing formation of methyl toluenesulfonate, rather than destroying it after it is formed.

Products of Solvolysis.—The products from acetolysis and formolysis of *o*-methoxyneophyl *p*-toluenesulfonate in solvent containing excess sodium acetate or formate, respectively, were treated with lithium aluminum hydride to reduce any esters to alcohols. By chromatography, each product was separated into an easily-eluted fraction and a more difficultly-eluted alcohol fraction.

The easily-eluted material in each case gave rise to two fractions on vacuum distillation. The lower-boiling material was inert to potassium permanganate in acetone, and its C, H and methoxyl

TABLE IV

PRODUCTS OF SOLVOLYSIS OF o-METHOXYNEOPHYL p-TOLUENESULFONATE

Solvent	Temp., °C.	[ROTs], 10^2 M	Added base	Reacn. time, hours	Total yield, %	% of product Olefin	Alcohol Tert.	Alcohol Prim.	Furan
EtOH	78	3.97	$CaCO_3$	5					46
AcOH	75	2.89	0.0310 M NaOAc	4	96	8	15	4	73
HCOOH	50	4.84	0.0515 M NaOCHO	2	92	32	42	..	26

analyses and ultraviolet absorption spectrum were proper for a dimethyl-4,5-benzodihydrofuran. The higher-boiling material gave a slow test for unsaturation with potassium permanganate in acetone and had the correct C, H analysis for 1-*o*-anisyl-2-methyl-1-propene (XIV) or its unconjugated isomer XV.

The product of ethanolysis of *o*-methoxyneophyl *p*-toluenesulfonate was examined sufficiently to isolate the dimethyl-4,5-benzodihydrofuran fraction. All three dimethylbenzodihydrofuran fractions from formolysis, acetolysis and ethanolysis appeared to be the same. The infrared spectra of the materials from formolysis and ethanolysis were compared and found to be identical. It is clear that the dimethylbenzodihydrofuran product is not 2,2-dimethyl-4,5-benzodihydrofuran (XVII) which was prepared from *o*-methallylphenol (X-VI).[9]

The differences in the infrared spectra of the synthetic and isolated materials, especially at 10.2 μ, where the synthetic material is relatively transparent, and at 11.3 and 14.4 μ, where the product has low absorption, indicate that the solvolysis product is not the synthetic one. For this reason, and from mechanistic considerations mentioned later, the structure of 3,3-dimethyl-4,5-benzodihydrofuran (IX) is assigned to the product.

The alcohol product from acetolysis of *o*-methoxyneophyl *p*-toluenesulfonate (VII) contained a large proportion of the rearranged tertiary alcohol, 1,1-dimethyl-2-*o*-anisylethanol (XIII), prepared from methyl *o*-methoxyphenylacetate and methylmagnesium iodide. The tertiary alcohol was conveniently characterized by means of its *p*-nitrobenzoate. The presence of *ca.* 20% of *o*-methoxyneophyl alcohol (V) in the solvolysis alcohol was demonstrated by treatment of a sample of the alcohol with *p*-toluenesulfonyl chloride in pyridine and acetolysis of the crude toluenesulfonate. The observed rate constant was that for *o*-methoxyneophyl toluenesulfonate (VII) and the observed infinity titer provided an estimate of the proportion of *o*-methoxyneophyl component in the solvolysis alcohol.

The alcohol product from formolysis of *o*-methoxyneophyl *p*-toluenesulfonate also gave rise to pure *p*-nitrobenzoate of 1,1-dimethyl 2-*o*-anisylethanol (XIII), the proportion of this material in the product apparently being very high.

In Table IV are summarized the results of the examination of the solvolysis products.

Discussion

Mechanism.—The absence of 2,2-dimethyl-4,5-benzodihydrofuran (XVII) in the solvolysis product indicates that cyclic ether does not arise from cyclization of olefin XIV or XV or rearranged tertiary solvolysis product such as the acetate of alcohol XIII. The formation of cyclic ether IX and the other solvolysis products requires a mechanism involving two competing anchimerically-assisted ionization processes in the solvolysis of *o*-methoxyneophyl *p*-toluenesulfonate (VII). One of the ionization modes is the Ar_1-3-assisted one; the other involves *o*-MeO participation, leading to the intermediate oxonium toluenesulfonate ion pair VIII. A convenient designation for the *o*-MeO participation in this specific case is *o*-MeO-5, the number 5 designating the size of the ring created by the anchimerically-assisted ionization.

From Ar_1-3-assisted ionization, tertiary solvolysis product, *e.g.*, acetate of alcohol XIII, and olefins XIV and XV are expected, just as in solvolysis of neophyl bromobenzenesulfonate.[10] From *o*-MeO-5-assisted ionization, the benzodihydrofuran IX and unrearranged *o*-methoxyneophyl substitution product XII are presumed to arise, the former by nucleophilic attack on methyl, the latter by such attack on C_α. The formation of methyl toluenesulfonate in the absence of sodium acetate, but not in its presence, is due to ion pair chemistry which has been studied[11] and discussed[12] further elsewhere. For present purposes, the *o*-MeO-5 reaction pathway will be subdivided into: A, leading to furan IX, but not methyl toluenesulfonate; B, leading to furan IX and methyl toluenesulfonate; and C, leading to *o*-methoxyneophyl substitution product XII.

Dissection of Solvolysis and Related Rate Constants.—The division of the solvolysis reactions into the Ar_1-3 and *o*-MeO-5 paths and the subdivision of *o*-MeO-5 into the A, B and C pathways may be carried out by reference to the composition of the reaction products summarized in Table IV. In Table V are summarized the resulting rough figures for percentage reaction along each reaction route.

TABLE V

ASSIGNMENT OF REACTION PATHS IN SOLVOLYSIS OF *o*-METHOXYNEOPHYL *p*-TOLUENESULFONATE

Solvent	Temp., °C.	Percentage reaction along path: Ar_1-3	*o*-MeO-5: Total	A	B	C
EtOH	78	<55	>45	45		
AcOH	75	25[a]	75[a]	31	40	4[a]
AcOH (0.031 M NaOAc)	75	25	75	68	3	4
HCOOH	50	73	27	*ca.* 27[b]	0	Small

[a] Assumed the same as in presence of sodium acetate. [b] Neglecting any possible *o*-methoxyneophyl alcohol in the product; the latter must be relatively small, judging by the much greater importance of Ar_1-3-assisted ionization than in acetic acid.

Having divided ionization of *o*-methoxyneophyl *p*-toluenesulfonate into Ar_1-3- and *o*-MeO-5-assisted portions, one may dissect the observed solvolysis rate constants into k_Δ^{Ar} and k_Δ^{OMe}, the rate constants corresponding to each one of the anchimerically-assisted ionizations. The estimated rate constants are summarized in Table VI, along with the ratios, $k_\Delta^{OMe}/k_\Delta^{Ar}$.

The ratios, $k_\Delta^{OMe}/k_\Delta^{Ar}$, in Table VI point out most clearly the large solvent dependence of the competition between the Ar_1-3 and *o*-MeO-5 reaction paths.

TABLE VI

ASSIGNMENT OF RATE CONSTANTS IN ACETOLYSIS AND FORMOLYSIS OF *o*-METHOXYNEOPHYL TOLUENESULFONATE

Solvent	Temp., °C.	k_Δ^{OMe}, sec.$^{-1}$	k_Δ^{Ar}, sec.$^{-1}$	$k_\Delta^{OMe}/k_\Delta^{Ar}$
HCOOH[a]	25	2.6×10^{-5}	7.5×10^{-5}	0.35
AcOH	75	3.7×10^{-4}	1.1×10^{-4}	3.4

[a] Assuming products the same at 25° as those observed at 50°.

The ratio of *o*-MeO-5 to Ar_1-3 drops from 3.4 in acetic acid to 0.35 in formic acid. While we have not explored how much of this change can be due to change in temperature, most of the change is due to much smaller sensitivity to solvent ionizing power[13] in the case of *o*-MeO-5-assisted ionization than for the Ar_1-3 variety.

It is worthwhile to consider the competition between Ar_1-3 and *o*-MeO-5-assisted ionizations of *o*-methoxyneophyl *p*-toluenesulfonate (VII) in terms of the individual k_Δ^{Ar} and k_Δ^{OMe} values and their relation to similar rate constants for other systems. Taking the k_Δ^{Ar} values for *o*-methoxyneophyl *p*-toluenesulfonate and contrasting them with the values for the neophyl,[6] *p*-methoxyneophyl[7] and *o*- and *p*-anisylethyl[3] systems, one obtains the comparison summarized in Table VII.

From Table VII, it is clear that k_Δ^{Ar} for *o*-methoxyneophyl is slower than for *p*-methoxyneophyl by factors of 15 in acetic acid and 11 in formic acid. The *gem*-dimethyl grouping increases k_Δ^{Ar} from the level observed with the anisylethyl systems by factors of only 9.7 in formic acid and 5.7 in acetic acid, when the anisyl group is *ortho*, but by factors of 107 and 77 when the anisyl group is *para*. It would seem that there is steric retardation of k_Δ^{Ar} in *o*-methoxyneophyl relative to *p*-methoxyneophyl, due to the accumulation of both the *o*-methoxyl and the *gem*-dimethyl groupings. Steric interferences not present in the *p*-methoxyneophyl case make it more difficult to reach the Ar_1-3 transition state. The steric retardation of Ar_1-3- assisted ionization serves to increase the $k_\Delta^{OMe}/k_\Delta^{Ar}$ ratio observed with the *o*-methoxyneophyl system.

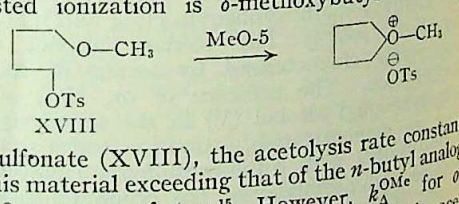
While the structure of *o*-methoxyneophyl *p*-toluenesulfonate (VII) is relatively unfavorable for Ar_1-3 participation, it is very suitable for *o*-MeO-5-assisted ionization. The k_Δ^{OMe} in this case is *ca.* 20 times as large as the whole solvolysis rate constant (at least mainly k_Δ^{Ar}) observed for the *o*-anisylethyl ester in acetic acid. A typical substance which is well-disposed toward MeO-5-assisted ionization is δ-methoxybutyl[2,12b,15] toluenesulfonate (XVIII), the acetolysis rate constant of this material exceeding that of the *n*-butyl analog by 3 powers of ten.[15] However, k_Δ^{OMe} for *o*-methoxyneophyl *p*-toluenesulfonate (VII) in acetic acid is approximately equal to that for the δ-methoxybutyl derivative XVIII, even though the *o*-methoxyl group is rendered less nucleophilic by resonance interaction with a benzene ring.

TABLE VII

SOME RELATIVE RATES INVOLVING ANISYL PARTICIPATION

Compound	Rel. k_Δ values HCOOH 25.00°	AcOH 75.00°
$(CH_3)_2C(OTs)CH_2$–	1.00[a]	1.00[a]
VII	72[b]	88[b]
I	6.47	5.5
	0.66[c]	0.99[e]
	0.67[d]	1.3[f]

[a] Based on data of A. H. Fainberg; $k = 1.16 \times 10^{-5}$ sec.$^{-1}$ in HCOOH at 25.00°, 2.00×10^{-5} sec.$^{-1}$ in AcOH at 75.00°. [b] Based on data[7] of R. Heck; $k = 8.31 \times 10^{-4}$ sec.$^{-1}$ in HCOOH at 25.00°, 1.77×10^{-3} sec.$^{-1}$ in AcOH at 75.00°. [c] $k = 7.7 \times 10^{-6}$ sec.$^{-1}$ in HCOOH at 25.00° by extrapolation of the value reported at 75.01°, assuming the same $\Delta H^\ddagger$ as for *p*-anisylethyl *p*-toluenesulfonate.[3] [d] $k = 7.8 \times 10^{-6}$ sec.$^{-1}$ in HCOOH at 25.00° by extrapolation of data reported at higher temperatures.[3] [e] $k^\circ_{ext.} = 1.98 \times 10^{-5}$ sec.$^{-1}$ in AcOH at 75.00°, reported by A. Fainberg.[14] [f] $k^\circ_{ext.} = 2.6 \times 10^{-5}$ sec.$^{-1}$ in AcOH at 75.00°, reported by A. Fainberg.[14]



XVIII

In a following paper, more cases of *o*-MeO-5 and related participations will be presented, and the connection between structure and rate of *o*-MeO-assisted ionization will be discussed further.

Experimental Part

o- and p-Methoxyneophyl Chloride Mixture.—To a cooled solution of 1226 ml. of concd. sulfuric acid and 774 ml. of water, heated to 70°, 162 g. of anisole and 166 g. of methallyl chloride were added with stirring. The reaction mixture was kept at 70–80° for 2 hr. After the mixture was cooled, the products were extracted with two portions of low-boiling

petroleum ether. The extracts were washed with water and sodium bicarbonate solution. After the extract was dried, the solvent was removed and the residue was vacuum distilled. After a small forerun of anisole, the chloride mixture, b.p. 91–100° (2 mm.), n^{25}D 1.5268, was collected. The nearly colorless product weighed 78 g. (26%). A redistilled sample, b.p. 111–112° (3 mm.), was analyzed.

Anal. Calcd. for $C_{11}H_{15}OCl$: C, 66.75; H, 7.61. Found: C, 67.21; H, 7.74.

***o*- and *p*-Methoxyneophyl Alcohol Mixture.**—To 8.3 g. of magnesium covered by 700 cc. of ether, 76 g. of the above *o*- and *p*-methoxyneophyl chloride mixture was added. Several grams of methyl iodide was added and the mixture was refluxed and stirred for 6 hr. Then, while the mixture was stirred at room temperature, a slow stream of dry oxygen was passed in until no further heat of reaction was observed. The reaction mixture was worked up in the usual way to yield 29.5 g. (43%) of methoxyneophyl alcohols, b.p. 93–98° (2 mm.), n^{25}D 1.5291. The residue remaining after the distillation crystallized on standing. Two recrystallizations from pentane gave 5–10 g. of what is probably a methoxyneophyl dimer, m.p. 83.5–84.5°.

Anal. Calcd. for $C_{22}H_{30}O_3$: C, 80.93; H, 9.26. Found: C, 80.65; H, 8.97.

The preparation of the *p*-nitrobenzoate from the alcohol mixture led to a mixture which could not be separated even after several crystallizations from methanol or ligroin.

***o*-Methoxyneophyl *p*-Toluenesulfonate.**—Tosylation of 28 g. of the *o*-methoxyneophyl alcohol mixture by the usual method afforded 27 g. (49%) of pure *o*-methoxyneophyl *p*-toluenesulfonate, m.p. 67–69°. The substance formed large prisms when crystallized from a mixture of carbon tetrachloride and petroleum ether (b.p. 60–80°). It decomposes in a few days at room temperature but is stable for months at 0°.

Anal. Calcd. for $C_{18}H_{22}O_4S$: C, 64.64; H, 6.63. Found: C, 64.84; H, 6.76.

β-*o*-Anisylisovaleric Acid.—A Grignard reagent was prepared from 230 g. of the *o*- and *p*-methoxyneophyl chloride mixture and 24 g. of magnesium. Dry carbon dioxide was passed into the Grignard solution until the ether became cold. Cold dil. hydrochloric acid was added and the ether phase was separated. After the ether solution was washed with water, the acid product was extracted with aqueous sodium bicarbonate. Acidification of the extract produced an oil. This was isolated and crystallized, first from a small volume of pentane and then four times from petroleum ether (b.p. 60–80°). The product, m.p. 83–85°, mainly the *p*-isomer, weighed 12 g. Concentration of the mother liquors yielded a crop of crude *o*-acid in the form of large prisms. Another crystallization from petroleum ether (b.p. 60–80°) produced 14 g. of pure β-*o*-anisylisovaleric acid, m.p. 70.5–71°.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.75. Found: C, 69.35; H, 7.94.

A mixed m.p. of the β-*o*-anisylisovaleric acid with the *p*-isomer described below was 55–67°.

β-*p*-Anisylisovaleric Acid.—Methyl β-(*p*-hydroxyphenyl)-isovalerate, b.p. 153–155° (1.5 mm.), was prepared by esterification of the acid[16] with methanol and hydrogen chloride.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.75. Found: C, 69.3; H, 7.86.

A solution of 0.695 g. of methyl β-(*p*-hydroxyphenyl)-isovalerate in 3.3 ml. of 1.03 *N* sodium methoxide in methanol was heated in a sealed tube for 5 hr. at 100–105° with 0.3 ml. of methyl iodide. The methanol was distilled, and the residue was treated with ether and water. The ether layer was separated, washed with two 4-ml. portions of 1 *N* sodium hydroxide solution, with water and then dried over magnesium sulfate. Saponification of the crude methyl β-*p*-anisylisovalerate was carried out by refluxing 0.424 g. with a solution of 0.25 g. of potassium hydroxide in 2 ml. of ethanol and 1 ml. of water for 4 hr. The acid was separated in the usual manner and recrystallized several times from ether–petroleum ether, m.p. 90–91°.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.75. Found: C, 69.30; H, 7.87.

(16) J. Corse and E. Rohrmann, THIS JOURNAL, **70**, 370 (1948).

Methyl *o*-Methoxyphenylacetate.—To a mixture of 20 g. of *o*-methoxyphenylacetic acid[17] and 100 cc. of ether was added an excess of diazomethane in ether. After 10 minutes the ether was evaporated and the residue was vacuum distilled. The ester, b.p. 94–98° (2 mm.), n^{25}D 1.5160, weighed 16 g.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71. Found: C, 67.11; H, 6.64.

1,1-Dimethyl-2-*o*-anisylethanol.—To a Grignard reagent prepared from 16 g. of methyl iodide and 3 g. of magnesium in 100 ml. of ether, 10 g. of methyl *o*-methoxyphenylacetate was added slowly. After a further 30 minutes of stirring, a cold saturated solution of ammonium chloride was added. The ether phase was separated and washed with water and aqueous sodium bicarbonate. After the ether phase was dried, the ether was evaporated and the alcohol was distilled in vacuum. The tertiary alcohol, 9.7 g., b.p. 87–89° (2 mm.), n^{25}D 1.5174, was a colorless, odorless liquid.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.04; H, 8.67.

The alcohol formed a *p*-nitrobenzoate readily when it was treated with *p*-nitrobenzoyl chloride in pyridine for 24 hr. After two recrystallizations from a mixture of ether and pentane, the ester formed long pale yellow needles, m.p. 77.5–78.5°.

Anal. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.81. Found: C, 65.61; H, 5.92.

2,2-Dimethylbenzofuran.—This material was prepared by the method of Bartz, Miller and Adams[9] and fractionated. The pure material had b.p. 97–98° (25 mm.) and n^{25}D 1.5161 [reported[9] b.p. 62° (7 mm.), n^{20}D 1.5190]. The ultraviolet spectrum in methanol showed $\lambda_{max.}$ 287 mμ, ε 840; 278 mμ, ε 1730; 271 mμ, ε 1670; and 227 mμ, ε 10,200.

Ethanolysis of *o*-Methoxyneophyl *p*-Toluenesulfonate.—A solution of 13.3 g. of *o*-methoxyneophyl *p*-toluenesulfonate in 1 l. of anhydrous ethanol was refluxed with 10 g. of calcium carbonate for 5 hr. The cooled solution was filtered, and most of the alcohol was distilled off through a fractionating column. The residue was again filtered and distilled rapidly. The distillate, 7.2 g., b.p. 90–130° (20 mm.), was fractionated through a 60-plate center-rod column using 10 ml. of purified diethyl phthalate as a pusher. Five fractions were collected. The first 3 fractions, combined weight 2.60 g., b.p. 89.5–100.5° (20 mm.), n^{25}D 1.5161–1.5168, were mainly 3,3-dimethylbenzofuran. The infrared spectrum of a fraction of b.p. 91.2–92.5° (20 mm.) and n^{25}D 1.5161 was essentially the same as the furan fraction obtained from the formolysis described below. Two higher boiling fractions were obtained from this fractionation, but they were not homogeneous and were not examined further.

Acetolysis of *o*-Methoxyneophyl *p*-Toluenesulfonate.—A solution of 12.0 g. of *o*-methoxyneophyl *p*-toluenesulfonate in 1200 cc. of 0.0310 *M* sodium acetate in dry acetic acid was heated at 75° for 4 hr. The cooled solution was then diluted with four liters of water and the products were extracted with several portions of pentane. The extracts were washed and concentrated, and then the residue was reduced with 1.5 g. of lithium aluminum hydride. The reduced product was chromatographed on 500 g. of activated alumina. The first fraction, eluted with 1.5 liters of pentane, gave two distinct fractions when it was distilled. The lower boiling fraction, b.p. 40–45° (2 mm.), n^{25}D 1.5175, weighed 3.35 g. This material was inert to potassium permanganate in acetone.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16; MeO, 0.00. Found: C, 81.01; H, 8.25; MeO, 0.90.

The higher boiling fraction, b.p. 58–60° (2 mm.), n^{25}D 1.5298, weighed 0.8 g., and it reacted slowly with potassium permanganate in acetone.

A second fraction was eluted from the alumina with one liter of ether. This material, b.p. 78–80° (2 mm.), n^{25}D 1.5166, weighed 1.2 g.

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95. Found: C, 73.06; H, 9.00.

A *p*-nitrobenzoate was prepared from 0.5 g. of the above alcohol fraction. The once crystallized product, 0.45 g., had m.p. 67–72.5°. A second crystallization from ether–

(17) F. Bergel, J. W. Haworth, A. L. Morrison and H. Rinderknecht, *J. Chem. Soc.*, 261 (1944).

Digitized by Arya Samaj Foundation Chennai and eGangotri

pentane gave 0.2 g. of material, m.p. 74–76°, mixed m.p. with the *p*-nitrobenzoate of 1,1-dimethyl-2-*o*-anisylethanol, 74.5–76.5°.

In order to determine the amount of *o*-methoxyneophyl alcohol in the alcohol fraction, 0.40 g. of this material was treated with 1 g. of *p*-toluenesulfonyl chloride in dry pyridine at room temperature for 30 minutes. The sulfonate was isolated in the usual way and dissolved in 50 ml. of 0.0310 *M* sodium acetate in dry acetic acid. The acetolysis rate constant was $3.5 \pm 0.3 \times 10^{-4}$ sec.$^{-1}$ at 75°, the infinity titer being taken after 20 hr.

Formolysis of *o*-Methoxyneophyl *p*-Toluenesulfonate.—To a solution of 3.5 g. of sodium formate in 720 cc. of dry formic acid, heated to 50°, was added 12 g. of *o*-methoxyneophyl *p*-toluenesulfonate. After 2 hr. at 50°, the reaction mixture was cooled and worked up exactly as described for the acetolysis. The chromatography yielded 1.8 g. of benzofuran, b.p. 41–42° (2 mm.), n^{25}D 1.5251, 1.2 g. of olefin, b.p. 60° (2 mm.), n^{25}D 1.5458, and 2.5 g. of alcohol, b.p. 78–82° (2 mm.), n^{25}D 1.5183.

The benzofuran fraction was redistilled to give material with n^{25}D 1.5178. The infrared spectrum of this material was essentially the same as that of the ethanolysis product mentioned above. In ultraviolet absorption in methanol, λ_{max} 285 mμ, ε 2170; 279 mμ, ε 2700; and 224 mμ, ε 4720.

The olefin fraction reacted slowly with potassium permanganate in acetone.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70. Found: C, 81.35; H, 8.71.

The alcohol fraction, 0.5 g., gave 0.2 g. of a *p*-nitrobenzoate of m.p. 76.5–77.5° after two crystallizations from ether-pentane. A mixed melting point with authentic material was 76.5–78°.

Kinetic Measurements.—Solvolysis rates were measured by the usual methods.[6,7] An attempt was made to follow the acetolysis of *o*-methoxyneophyl toluenesulfonate after the first infinity value. The solvolysis solution became yellow and difficult to titrate, a rough rate constant of *ca.* 6×10^{-7} sec.$^{-1}$ being obtained at 75°. A value of 8.5×10^{-7} sec.$^{-1}$ has been reported[8] for methyl *p*-toluenesulfonate at 75°.

EVIDENCE ON MECHANISMS OF HALOGEN AND TRITIUM RECOIL LABELLING REACTIONS

Sir:

Displacement reactions very different from ordinary atom and radical reactions have been observed between gaseous alkanes and iodine,[1a,1b] bromine,[1c] and chlorine[1d,1e] activated by the (n,γ) process. Tritium activated by the $Li^6(n,\alpha)H^3$ process in the presence of liquid or solid organic compounds gives superficially similar reactions.[2] Tritium is of particular interest in this connection because of its chemical differences from the halogens and because a much larger fraction of its recoil kinetic energy is available for internal energy of the activated complex.

We have used the $He^3(n,p)H^3$ reaction to produce tritons in gaseous alkanes[3] under conditions[4] similar to those for which the halogen reactions have been studied. With a given target compound a multiplicity of tritium containing compounds is formed which cannot be explained by "conventional" reaction steps. In the absence of scavengers about 45% of the tritium appears as HT, 30% in the alkane target species and the remainder in four to ten other products. Halogen scavengers decrease or eliminate the yield of tritiated products with more carbons than the target but have relatively little effect on the HT, or the tritiated target compound or fragments thereof.

The only reaction steps which seem capable of explaining the extensive chain-lengthening are ion-molecule reactions[8] (such as, for example, $T^+ + CH_4 \rightarrow CH_3T^+ + H_2$ and $CH_3T^+ + CH_4 \rightarrow C_2H_4T^+ + H_2$, followed by similar steps leading to further chain lengthening). Ion-molecule steps

Willard, THIS JOURNAL, in press; (d) J. C. W. Chien and J. E. Willard, *ibid.*, **75**, 6160 (1953); (e) J. E. Quinlan and J. E. Willard, unpublished.

(2) (a) R. Wolfgang, F. S. Rowland and C. N. Turton, *Science*, **121**, 715 (1955); (b) R. Wolfgang, J. Eigner and F. S. Rowland, *J. Phys. Chem.*, **60**, 1137 (1956); (c) F. S. Rowland, C. N. Turton and R. Wolfgang, THIS JOURNAL, **78**, 2354 (1956); (d) F. S. Rowland and R. Wolfgang, *Nucleonics*, **14**, 58 (1956).

(3) While this work was in progress, we received word from R. Wolfgang that he had observed the production of CH_3T and higher hydrocarbons from the $He^3(n,p)H^3$ reaction in CH_4.

(4) A typical run consisted of irradiating a 5-ml., thin-walled, quartz bulb containing 6 mm. He^3, 6 mm. H_2, and 1 atm. of alkane in the isotope tube of the CP 5 reactor of the Argonne National Laboratory for one hour. The neutron flux[5] was 3×10^{12} n.cm.$^{-2}$ sec.$^{-1}$ The bulb was broken in a stream of methane at the inlet of a 12 ft. long, 4 mm. i.d. spiral Pyrex column containing 30–80 mesh silica gel. The general technique was the same as reported earlier,[6] the main difference being that a flow proportional counter[7] was used to detect the radioactive components. The fraction of [illegible] in each component was estimated from the peak area; the identification of the minor components is tentative.

(5) The accompanying gamma flux was about 5×10^5 r./hr. That the gamma radiation was not the cause of the chain lengthening or the large fraction of tritium in the target compound seems evident from the three CH_4-He^3-H_2 samples which received about 7×10^5 r. from a Co^{60} source after the usual pile irradiation. This did not change the percentage of CH_3T much, but raised the percentage of HT slightly and lowered the percentages of the higher hydrocarbons somewhat.

also seem to be required[1c,9] to explain gas phase halogen atom recoil reactions. Reactions such as $CH_4T^+ + CH_4 \rightarrow C_2H_6T^+ + H_2$ which may not be observable at mass spectrometer pressures may be among those which contribute to chain lengthening. The absence of a scavenger effect on the yield of tritiated parent indicates that the neutral stable molecule is formed by a single step such as $T^+ + CH_4 \rightarrow CH_3T + H^+$, or $T + CH_4 \rightarrow CH_3T + H$, or that its formation from a species such as CH_4T^+ is not altered by halogen.

Although it usually is not possible to differentiate hot radical reactions from ion-molecule reactions in condensed phases, it seems plausible that ion-molecule steps such as seem to be required above may also be involved in tritium labelling in condensed phases[2] and in a number of other unique processes recently reported. These include the reactions of tritons[10] and C^{14} ions[11] accelerated by electric fields, and the tritium labelling method of Wilzbach.[12,13] It is probable that such steps also account[9] for part, but not all, of the products of halogen recoil reactions in solution.

TABLE I

PRODUCTS OF THE $He^3(n,p)H^3$ REACTION IN GASEOUS CH_4, C_2H_6, AND C_3H_8[a]

	Alkane reactant					
Tritiated[b] product	CH_4	CH_4 (I_2 or Br_2)	C_2H_6	C_2H_6 (Br_2)	C_3H_8	C_3H_8 (I_2)	C_3H_8 (Br_2)
	Per cent. of total T in each product						
HT	46	40	43	42	43	42	50
CH_3T	31	50	5	2	4	4	3
C_2H_5T	6.8	Trace	28	37	2.5	1.5	1.5
C_3H_7T	5	Trace	9	0	36	47	39

HYDROGEN LABELLING OF HYDROCARBONS USING IONIZING RADIATION

Sir:

Wilzbach has demonstrated that exposure to tritium gas is an effective method of labelling complex organic compounds.[1] It seems possible that such reactions are similar in mechanism to tritium recoil labelling by the $He^3(n,p)H^3$ [2] and $Li^6(n,\alpha)H^3$ [2] processes and to recoil labelling by the halogens,[2] which appear to involve ion-molecule steps.[2]

Typical distributions of tritiated products which we have obtained by gas chromatographic analysis[2] of mixtures of hydrocarbons with T_2 or HT, activated by self irradiation with about 2×10^7 roentgens of tritium beta radiation or by doses of about 5×10^6 roentgens of Co^{60} gamma rays are shown in Table I. Both chain lengthening and

chain degradation occur, as with activation by the $He^3(n,p)H^3$ process. Methane–HT mixtures irradiated with gamma radiation appear to show higher yields of tritiated pentanes and hexanes than of propane. The ratio of yields is changed by a change in the methane–H_2 ratio. Iodine scavenger causes a drop in the tritiated C_5H_{12} and C_6H_{14} components relative to the other components. In view of the chain lengthening observed, the conclusion seems nearly inescapable that these reactions are ion-molecule processes.[2] Quantitative studies on such systems should be rewarding by revealing the most probable stage of the chain lengthening process for reaction of the chain carrying species with hydrogen and with halogens.

Three possibilities must be considered for the primary step in these tritiation reactions: (1) the step $T\text{-}T \rightarrow T^+ + He^3$ (or, say, He^3T^+); (2) ionization of T_2 or HT by beta or gamma radiation; (3) ionization of the organic compound by beta or gamma radiation. The fact that reaction occurs in HT–CH_4 mixtures indicates that the molecule T_2 is not essential.

If reaction were initiated solely by ionization of H_2 and HT a G value of about 100 would be required to account for the yields of tritiated products obtained in Table I, assuming no isotope effect. Consequently it seems probable that much, if not all, of the reaction is due to ionization of the methane.

The ratios of tritiated C_4H_{10}, C_5H_{12} and C_6H_{14} to tritiated C_3H_8 produced from CH_4 are significantly higher when tritiation is induced by radiation

(Table I) than when it is induced by the $He^3(n,p)H^3$ process. This seems to indicate that the mechanisms are different. In the $He^3(n,p)H^3$ case the formation of each carbon chain presumably is initiated by attack of a tritium ion on a CH_4 molecule.

The many products formed in these reactions offer a valuable source of high specific activity labelled compounds when these non-parent "by-products" can be separated in carrier-free form by gas chromatography or otherwise.

CHEMICAL REACTION OF RECOIL TRITIUM WITH GASEOUS ALKANES[1]

Sir:

We have studied the reaction of high energy tritium, as produced by nuclear reaction, with gaseous methane and ethane. The reactions $He^3(n,p)H^3$ (0.78 Mev.) and Li^6 $(n,\alpha)H^3$ (4.7 Mev.) were used to supply the "hot" tritium. In the He^3 runs about 0.1 cm. He^3 was sealed with 10–60 cm. CH_4 in a $\sim$ 7 ml. quartz ampoule. In the Li^6 runs a film of normal lithium nitrate formed the inside coating of similar vessels. After irradiation in the Brookhaven reactor, carriers were added and the various tritium labeled species separated and counted, largely as described elsewhere.[2]

A summary of some of our results on the chemical state of the tritium following interaction with methane is shown in Table I. This distribution of

TABLE I

Higher tritiated hydrocarbons and iodides	5.3	3.7	43.9

activity is independent of the source of the tritium, the pressure and the temperature (range 30–200°). However, a drastic reduction of neutron flux, with accompanying decrease in radiation density, although having little effect on the production of CH_3T, seems to reduce significantly the yields of labeled higher hydrocarbons while increasing the amount of HT. The addition of 0.2 mm. of iodine as a radical scavenger has little effect on the yield of CH_3T but virtually eliminates the yield of higher labeled hydrocarbons and reduces the yield of HT.

Studies on the slowing of charged particles passing through matter[3] indicate that the tritium is uncharged on reaching its final reaction site. Taking this into account, our observations suggest two distinct modes of reaction of the tritium atom: (A) Most tritium combines by direct hot replacement reaction. For methane

$$T^* + CH_4 \longrightarrow CH_3T + H$$

$$T^* + CH_4 \longrightarrow HT + CH_3$$

Radical intermediates are definitely ruled out and Walden inversion probably is involved. (B) Some tritium escapes incorporation in stable molecules by hot reaction and becomes thermalized. Its reactions then become sensitive to radical scavengers, such as I_2. In their absence the tritium can react competitively to (1) abstract H to form part of the HT observed, or (2) combine with radiation produced radicals or ions to form the higher labeled hydrocarbons. (Production of the latter probably involves hydrocarbon chains lengthened by ion molecule reactions.[4])

The results observed with ethane are consistent with this picture. Most of the activity appears in HT and C_2H_5T with smaller amounts in CH_3T and higher hydrocarbons. Only C_3 and higher hydrocarbons are eliminated by I_2. This means that degradation products such as CH_3T from ethane are largely formed by direct hot replacement reactions (type A).

It has been demonstrated that neither radical intermediates nor a solvent cage, the central concepts of earlier theories of hot-atom reactions,[5] are necessary for hot reaction of hydrogen. Whether the reaction model postulated here holds also for recoil tritium reactions in the condensed phase remains to be seen. The similar product distributions in gaseous and liquid[2] alkanes are suggestive. But the retention of configuration observed in the solid phase[6] would require further explanation.

DEGRADATION OF BRAIN GANGLIOSIDE TO GLUCOCEREBROSIDE

Sir:

Since Klenk first described the brain gangliosides,[1] evidence has been presented that they are

(1) E. Klenk, *Z. physiol. Chem.*, **273**, 76 (1942).

macromolecular glycolipids[2-4] which contain neuraminic acid, sphingosine,[5] fatty acid (stearic),[6] hexoses, and a hexosamine. Earlier studies have demonstrated the hexoses to be exclusively glucose and galactose and the hexosamine to be exclusively galactosamine.[4,8] However, little is known of the manner in which these constituents are linked. A cerebroside frequently has been postulated to be the basic unit in the structure of the gangliosides. The present communication reports the successful hydrolytic degradation of a purified preparation of brain ganglioside to a glucocerebroside.

Bovine brain ganglioside was prepared as an ash-free fraction (I) homogeneous by electrophoretic and ultracentrifuge studies (minimal molecular weight 250,000), completely water-soluble, free of phosphatides (P 0.07%) and of dialyzable contaminants.[4,7,8] (I) contains nitrogen 2.9%, hexose 24.0% (expressed as galactose), and galactosamine 10.0%.

Optimal conditions for the isolation of the constituent glucocerebroside have been defined as follows: a 2% aqueous solution of I is autohydrolyzed at 100° for a critical time interval of 25 minutes, then exhaustively dialyzed. The dialyzate contains 66% of the neuraminic acid and 5.2% of the galactosamine of I. The non-dialyzable residue (II) accounts for 80% by weight of I. II is hydrolyzed with 0.09 *N* HCl (sealed tube, 100°, 16 hours) then exhaustively dialyzed. The resulting non-dialyzable residue (III), still water-soluble, is further hydrolyzed (0.09 *N* HCl, sealed tube, 100°, 5 hours). The hydrolyzate, which now contains a brown insoluble material (IV), is exhaustively dialyzed. IV is separated by centrifugation, dried *in vacuo*, and taken up in clear solution with warm methanol:chloroform (9:1). 12% of IV remains as an insoluble black residue which is discarded. When this solution (40 mg./cc.) is allowed to cool to room temperature, birefringent spherocrystals (MCS) are formed. To date, yields of MCS represent between 26 and 30% by weight of I. MCS crystals contain no neuraminic acid and no galactosamine. The analysis, compared with that expected for a glucostearocerebroside crystallized with one mole of water,[9] is

	N, %	C, %	H, %	Hexose (as glucose), %
Found	1.86	67.13	10.95	21.8
Calcd. for $C_{48}H_{91}O_8N(H_2O)$	1.88	67.65	11.14	22.0

MCS is insoluble in water, slightly soluble in pure chloroform, very soluble in mixtures of chloroform:methanol. MCS shows slight liquefication at 165°, then melts sharply between 172–174°. The iodine number is 23.2. In chloroform:methanol (2:1) (1 mg./cc.), it is levorotatory ($[\alpha]^{20}D$ −2.08°). The infrared spectrum is consistent with that of a cerebroside.[10] A sample of crystalline MCS gave these spacings by X-ray diffraction[11]: 2.41, 4.10, 9.1, 10.4, 15.6, 21.1, 30.6, 49.2, 55.5, and 63.5 Å.

Hydrolysis of MCS in *N* HCl (sealed tube, 100°, 16 hours) liberated the hexose quantitatively. This was shown to be exclusively glucose by paper chromatography. The remaining water-insoluble residue contained 2.3% nitrogen, as expected for a ceramide. It is yet to be established whether the base is sphingosine or dihydrosphingosine.[12]

The melting point, specific rotation, iodine number and the elementary analysis, distinguish MCS from the previously described cerebrosides phrenosine, cerasine and nervone.[13] A glucostearocerebroside has not been described previously. Its presence as the basic constituent of brain ganglioside would be consistent with the demonstration by Klenk that the constituent fatty acid of brain ganglioside is stearic acid.[6] The isolation of this glucocerebroside is of interest with regard to the over-all structure and biosynthesis of the gangliosides.

SYNTHESIS OF ±-CRYPTOPLEURINE[1]

Sir:

The vesicant alkaloid cryptopleurine[2] has interesting physiological properties[3] and has been stated to possess a skeletal structure of a novel type. Although the alkaloid could not be degraded to compounds of known structure,[3] chemical,[3,4] spectroscopic,[4] and, in particular, crystallographic (X-ray)[5] evidence was adequate to allow the base to be designated as 2′,3′,6′-trimethoxyphenanthro-[9′,10′,2,3]quinolizidine (I).

By the use of the general methods described earlier[6] we have accomplished the first synthesis of ±-cryptopleurine. Condensation of 6-nitroveratraldehyde with homoanisic acid yielded 6-nitro-3,4,4′-trimethoxy-α-phenylcinnamic acid (m.p. 185–186°; *Anal.* Calcd. for $C_{18}H_{17}NO_7 \cdot H_2O$: C,

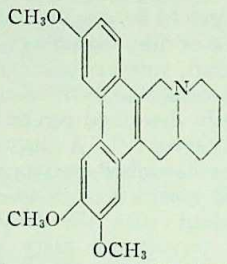
57.29; H, 5.08; N, 3.71. Found: C, 57.11; H, 4.77; N, 3.90). Reduction yielded the corresponding amino derivative (m.p. 206–207°) which when diazotized underwent the Pschorr cyclization to yield 2,3,6-trimethoxyphenanthrene-9-carboxylic acid (m.p. 222°; Calcd. for $C_{18}H_{16}O_5,H_2O$: C, 65.44; H, 5.49. Found: C, 65.54; 5.36). The phenanthroic acid was converted to the ethyl ester (m.p. 136.5–137°), which was reduced to the corresponding carbinol (m.p. 184–187°; *Anal.* Calcd. for $C_{18}H_{18}O_4$: C, 72.56; H, 6.17. Found: C, 72.46; H, 6.08) by the action of lithium aluminum hydride.



I, Base II, Methiodide

The bromide obtained from 2,3,6-trimethoxyphenanthryl-9-carbinol was not purified, but allowed to react immediately with pyridine-2-aldehyde. The salt thus obtained was cyclized by heating it in polyphosphoric acid at 80° for five hours. The cyclization product, presumably a 2,3,6-trimethoxydibenzo[h,j]acridizinium salt, could not be recrystallized satisfactorily and therefore was converted to the chloride by means of ion exchange and hydrogenated directly using platinum oxide catalyst. The product, purified by chromatography, melted at 199–200° (lit.[4] m.p. 197–198°; *Anal.* Calcd. for $C_{24}H_{27}NO_3$: C, 76.36; H, 7.21; N, 3.71. Found: C, 75.85; H, 7.17; N, 4.00) did not depress the melting point of an authentic sample,[7] and had ultraviolet and infrared spectra like those reported for cryptopleurine. The methiodide (II, m.p. 272–274°, lit.[4,8] 270–272° did not depress the melting point of an authentic sample of ±-cryptopleurine methiodide, and the infrared spectra (potassium bromide plate method) of the two substances were identical.

(7) We are indebted to Dr. E. Gellert for making this comparison for us and for furnishing us with a sample of ±-cryptopleurine methiodide.

(8) E. Gellert, *Australian J. Chem.*, **9**, 489 (1956). Since Dr. Gellert's method for obtaining the ± base from natural (optically active) cryptopleurine is somewhat involved, he has taken pains to demonstrate rigorously that the optically inactive methiodide is actually ±-cryptopleurine methiodide.

RECEIVED MAY 11, 1957

PHASE EQUILIBRIUM IN THE HYDROTHERMAL SHRINKAGE OF COLLAGEN

Sir:

The shrinkage of collagen has been shown to denote a first order transition between crystalline and amorphous phases.[1,2] This being the case, the stress τ_{eq} required to maintain a state of equilibrium between the phases should be related to the temperature T according to an analog of the Clausius–Clapeyron equation[3,4]

$$d(\tau_{eq}/T)/d(1/T) = (\Delta\bar{H}/V_c)/(\Delta\bar{L}/L_c) \quad (1)$$

where $\Delta\bar{H}$ and $\Delta\bar{L}$ are the latent enthalpy and length changes accompanying melting and subsequent swelling in the excess of surrounding solvent, V_c and L_c are the volume and length of the (dry) crystalline fiber, and τ_{eq} is the stress referred to the cross section of the fiber in the same state. Tobolsky, Haselkorn and Catsiff[5] have attempted recently to apply this relationship to the spontaneous shrinkage temperature T_s for bovine tendon at various stresses τ_s, the sample being immersed in water. Their results, like those similarly obtained a number of years ago by Wöhlisch,[6] yield a value of about 1.7 cal. $g.^{-1}$ for the latent enthalpy.[7]

We wish to point out that the temperature for the onset of shrinkage is substantially higher than that required for equilibrium between crystalline and amorphous phases. The values of τ_s and T_s which pertain to the shrinkage phenomenon as ordinarily determined should not therefore be employed in the foregoing equation, which is applicable only at thermodynamic equilibrium. We have found, however, that the equilibrium stress τ_{eq} at a given temperature T_m may be determined readily by the procedure outlined below.

Fresh rat-tail tendons were cross-linked (*i.e.*, tanned) with formaldehyde in order to suppress flow in the amorphous phase. A single tanned fiber about 10 cm. in length was suspended vertically between a fixed lower clamp and an upper clamp attached to a strain gage. The fiber and clamps were immersed in thermostated 3 *M* KCNS solution and the fiber was allowed to undergo partial contraction, such that one or more totally amorphous (shrunken) regions formed adjacent to (native) crystalline regions. The length was then adjusted to yield a force which remained constant for at least 30 minutes. Close approach to equilibrium is indicated by the fact that a small change in force, induced by slight alteration of the length, was succeeded by a change in the force toward the equilibrium value. The observed force is independent of the degree of shrinkage of the fiber, provided that a crystalline section remains. By measuring the thus established τ_{eq} as a function of temperature, we have obtained the results summarized below for two samples differing in degree of cross-linking.

The first two rows of the table emphasize the disparity between T_s and T_m^i, the equilibrium melting temperature established by extrapolation to zero force. The latent enthalpies $\Delta\bar{H}/V_c$ per unit volume of collagen given in the fifth row have been calculated from eq. (1) using the results in the

third and fourth rows. The negative contribution to $\Delta\bar{H}$ from the heat of dilution of collagen, estimated from the temperature coefficient of the degree of swelling in the amorphous state, has been deducted to obtain the latent heats of fusion expressed in cal. cc.$^{-1}$ and in cal. per mole of peptide units, respectively, in the last two rows of the table.

The values of ΔH_u are in satisfactory agreement with previous results derived from calorimetric measurements (1180 cal.[8]) and from depression of the melting point of collagen by glycol (2200 cal.[1]). The heat and entropy of fusion compare favorably with those for other crystalline polymers, contrary to the conclusions reached by Tobolsky and co-workers.[5]

Tanning with quinone yields more stable cross linkages, thus permitting investigation of the phase equilibrium in pure water at temperatures up to 70° under stress. Experiments on this system are in progress.

Similar experiments have been carried out on the shrinkage of racked rubber cross-linked by gamma radiation.[9] The heat of fusion obtained through the use of eq. (1) stands in good agreement with independent values.

RECEIVED MAY 7, 1957

THE NUCLEAR MAGNETIC RESONANCE SPECTRUM OF RIBONUCLEASE[1]

Sir:

We wish to report the observation of a nuclear magnetic resonance spectrum of the protein ribonuclease. In previous investigations[2] of macromolecules in solution, it had been reported that deoxyribonucleic acid markedly altered the proton magnetic resonance spectrum of water. The two proteins studied concurrently, hemocyanin and ovalbumin, neither modified the water spectrum nor exhibited independent peaks attributable to protein protons, at the concentrations used. We have found that concentrated aqueous solutions of bovine serum albumin (20%) gave no protein peaks, when the solutions were treated as below. An observable spectrum for ribonuclease might be attributed to internal flexibility of the molecule, absent in the other proteins, although there are other possible explanations.

Bovine pancreatic ribonuclease (Armour Lot No. 381–059) was dialyzed for 12 hours against several changes of glass-redistilled water and then equilibrated for 20 hours with a similar dialysis bag containing only water. Both solutions were deionized by passage through a column of ion-exchange resins.[3] The final ribonuclease concentration was about 15%, as determined spectrophotometrically. Investigation of the ribonuclease solution in a Varian High Resolution NMR Spectrometer operating at 40 Mc. showed a small protein peak in addition to the large water peak. Exchange of the protein solution with deuterium oxide removed the interfering protons of water, as well as the exchangeable protons of ribonuclease. Using a sample tube 4.9 mm. in inner diameter, we obtained the detailed spectrum shown in Fig. 1. The sharp peak indicated by the arrow decreased in relative intensity with successive exchanges and hence is due to residual water protons. The control solution described above showed only an unmodified water peak before exchange with D_2O and no spectrum at all afterward, making it unlikely that the peaks are due to low molecular weight contaminants in the ribonuclease preparation, the dialysis casing, or the resin column.

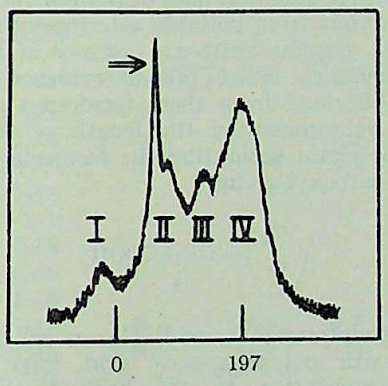

Fig. 1.—Nuclear magnetic resonance spectrum of ribonuclease.

The scale shown was established using the aromatic peak of toluene in an introduced capillary as zero. Since the spectrum range is the range of usual proton chemical shifts and since it does not change noticeably with concentration, it seems that we have an essentially unbroadened spectrum of the non-exchangeable protons of ribonuclease.

Because of their location, peaks I and IV can be assigned tentatively to aromatic hydrogens and to hydrogens on aliphatic carbon atoms attached only to other aliphatic carbons. The relative areas of each peak, after subtracting the estimated contribution of water protons, obtained from several spectra of two independently prepared samples were: I, 9 ± 1%, II, 26 ± 2%, III, 18 ± 3%, IV, 47 ± 3%. From the known composition

of ribonuclease, of the 664 non-exchangeable hydrogens 7.1% are aromatic and 45.0% are on aliphatic carbon atoms attached only to other aliphatic carbons. Of the remaining protons, 19.0% are on α carbons, 8.1% are on carbons attached to carboxyls and amides, 6.0% are on carbons with hydroxyl substituents, 5.4% are on carbons attached to sulfur, 4.2% are on carbons bonded to positively charged nitrogen, 3.9% are on carbons attached to aromatic nuclei, and 1.2% are on carbons bound to amide nitrogen. All of these categories could reasonably be expected to give rise to peaks between the extremes, but their positions in peaks II and III cannot be assigned with certainty at this time.

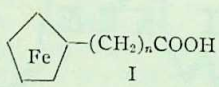
FERROCENE BRIDGING AND HOMOANNULAR CYCLIZATIONS[1]

Sir:

The question of homoannular *vs.* heteroannular intramolecular acylation in substituted ferrocenes has been raised recently by Nesmeyanov.[2] We wish to report here examples of both of these types of cyclizations from suitable ω-ferrocenylaliphatic acids[3] (I), together with an instance of intermolecular acylation, and to present evidence that the product obtained from these ferrocenyl aliphatic acids is determined by the length of the polymethylene chain separating the ferrocene nucleus from the carboxyl group.



I

β-Ferrocenylpropionic acid[3] (Ia, $n = 2$), when treated with polyphosphoric acid, gave heteroannular cyclization to the bridged compound 1,1′-(α-ketotrimethylene)-ferrocene,[4] m.p. 144–144.5°.[5] *Anal.* Calcd. for $C_{13}H_{12}FeO$: C, 65.03; H, 5.04; Fe, 23.26; mol. wt., 240. Found: C, 64.50; H, 5.04; Fe, 23.98; mol. wt. 281 (ebull., benzene), 324 (ebull., butanone). The infrared spectrum contains ketone bands at 1682 and 1266 cm.$^{-1}$, but no bands near 1110 or 1004 cm.$^{-1}$. Presence of 1110 and 1004 cm.$^{-1}$ bands would indicate an unsubstituted cyclopentadienyl ring.[3,6] The ultraviolet spectrum of this ketone is highly characteristic in that it shows no maximum near 225 or 270 mμ, regions where maxima have been shown to occur for ketones conjugated with the ferrocene nucleus.[7] Such spectral behavior is reasonable for a compound of this structure since the stereochemistry of the 3-carbon bridge prevents coplanarity, and thus conjugation, of the carbonyl with the adjacent ring.

γ-Ferrocenylbutyric acid[3] (Ib, $n = 3$), when treated with either polyphosphoric acid or trifluoroacetic anhydride, gave as the major product the homoannular cyclized ketone, 1,2-(α-ketotetramethylene)-ferrocene,[8] m.p. 85.4–85.7°, λ_{max} 226, 270 mμ, ϵ_{226} 17,600, ϵ_{270} 7,500, infrared bands: 1679, 1281, 1109, 1003 cm.$^{-1}$. *Anal.* Calcd. for $C_{14}H_{14}FeO$: C, 66.19; H, 5.55; mol. wt., 254. Found: C, 66.59; H, 5.69; mol. wt., 286 (ebull., butanone).

δ-Ferrocenylvaleric acid[3] (Ic, $n = 4$), with either polyphosphoric acid or trifluoroacetic anhydride, gave the homoannular product, 1,2-(α-ketopentamethylene)-ferrocene, m.p. 65.5–66.5°, λ_{max} 227, 269 mμ, ϵ_{227} 15,500, ϵ_{269} 7,400, infrared bands: 1655, 1290, 1110, 1004 cm.$^{-1}$. *Anal.* Calcd. for $C_{15}H_{16}FeO$: C, 67.19; H, 6.02; mol. wt., 268. Found: C, 66.99; H, 6.18; mol. wt., 314 (ebull., butanone). The shift in the infrared carbonyl band to lower frequency[9] and the reduction in the extinction coefficient in the ultraviolet spectrum,[10] when compared to similar spectral features of the lower, homologous, ketone from IIb, containing a 6-membered ring, are in agreement with like shifts found between the corresponding 7- and 6-membered benzocyclanones.[9,10]

The principal product from the treatment of ϵ-ferrocenylcaproic acid[3] (Id, $n = 5$) with polyphosphoric acid was a red-brown solid, apparently polymeric,[11] insoluble in usual organic solvents, decomposing slowly above 200°. The material exhibits strong infrared ketonic absorption (1660 cm.$^{-1}$), weaker carboxyl absorption (1725, 2700, 2620 cm.$^{-1}$) and gives analytical data consistent with those for a condensation trimer, as $H[C_{16}H_{24}Fe(CH_2)_5CO]_3OH$, though it is more likely a mixture of compounds of varying molecular weight. *Anal.* Calcd. for $C_{48}H_{56}Fe_3O_4$: C, 66.68; H, 6.53; Fe, 19.38. Found: C, 66.76; H, 6.58; Fe, 18.95.

(11) Homoannular cyclization of Id would require the formation of an 8-membered ring expected to form with difficulty. A similarly difficult cyclization would be anticipated from ferrocenylacetic acid (I, $n = 1$), which must give either a highly strained 4-membered benzocyclobutanone ring or a 2-carbon bridge, for which the interannular distance probably is too great.[12] In preliminary experiments in polyphosphoric acid, no ketonic product has been obtained.

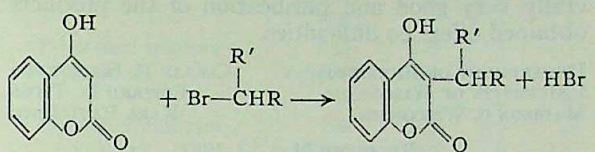
A NEW SYNTHETIC APPROACH TO SOME 3-ARALKYL-4-HYDROXYCOUMARINS[1]

Sir:

Since the introduction of the anticoagulant Dicumarol[2], 3,3′-methylenbis-(4-hydroxycoumarin) for clinical purposes,[2] interest in the synthesis of new 3-substituted-4-hydroxycoumarins and in new methods of synthesizing them has been maintained. While the reactivity of the 3-position of 4-hydroxycoumarin (I) is well known,[3,4,5] the direct alkylation of the 3-position of 4-hydroxycoumarin with reactive halides under acidic conditions has not been reported. Grüssner[6] had reported the alkylation of 4-hydroxycoumarins with reactive allyl and substituted allyl bromides under alkaline conditions. This method leaves much to be desired with respect to the yields obtained (usually 10–15%) and the scope of the procedure.

saturated compounds and which upon catalytic hydrogenation give the desired 3-aralkyl-4-hydroxycoumarins.

In a recent paper Ziegler and Roszmann[8] reported the synthesis of 3-substituted benzyl-4-hydroxycoumarins by condensing 4-hydroxycoumarin and substituted benzyl alcohols directly using phosphorus oxychloride as the catalyst and solvent.



I II III–XII

We have found that 4-hydroxycoumarin (I) can be alkylated readily in the 3-position by heating it in the molten state with certain reactive aralkyl halides (II) at temperatures of 130–180°. The 3-aralkyl-4-hydroxycoumarins (III–XII) are readily isolated in the pure state and usually in very good yields.

Alkylation of 4-hydroxycoumarin with certain aralkyl bromides (II) (or chlorides) in the molten state (length of heating period and temperature vary depending on the bromide used) gave 3-aralkyl-4-hydroxycoumarins (III–XII) in good yields. The physical and analytical data for the compounds reported herein are in the table.

TABLE I

3-SUBSTITUTED-4-HYDROXYCOUMARINS

	R	R′	M.p.,[a] °C.	Yield, %	Formula	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found

[a] Melting points are uncorrected. [b] I. M. Heilbron and D. W. Hill, *J. Chem. Soc.*, 1705 (1927), report a m.p. of 205°. [c] H. Pauli and K. Lockemann, *Ber.*, **48**, 28 (1915), report a m.p. 205–206°. [d] H. Junek and E. Ziegler, *Monatsh.*, **87**, 218 (1955), report a m.p. 202° and a yield of *ca.* 10% for VII and a m.p. 175–176° for VIII. [e] F. Litvan and W. Stoll, U. S. Patent 2,647,681, Aug. 11, 1953, report a m.p. 179°. [f] A. Grüssner and B. Hegedüs (see ref. 7) report a m.p. 179–180° for VIII, a m.p. of 201–202° for IX, a m.p. 178–180° for X, no yields were reported.

Recently Grüssner and Hegedüs[7] reported a novel, mutiple-step procedure for the preparation of 3-aralkyl-4-hydroxycoumarins, in which organometal compounds are condensed with 3-acyl-4-hydroxycoumarins to form tertiary carbinols which are in turn dehydrated to the corresponding unsaturated compounds.

Benzylation of the 3-position of 4-hydroxycoumarin by heating with benzyl *p*-toluenesulfonate[9] in the molten state at 100–120° gave 3-benzyl-4-hydroxycoumarin (III) in 15% yield.

The synthesis of some of the 3-aralkyl-4-hydroxycoumarins listed here by the older procedures would be very tedious if indeed it could be realized.[10,11] The recent method of Grüssner and

Hegedüs[7] has made it possible to synthesize various 3-aralkyl-4-hydroxycoumarins not realizable heretofore by the conventional methods.[10,11] The primary advantage of the method reported herein resides in the fact that the aralkyl halides are either commercially available or can be made readily in the laboratory by conventional methods. The alkylation of 4-hydroxycoumarin is direct without passing through intermediates, the yields are generally very good and purification of the products obtained offers no difficulties.

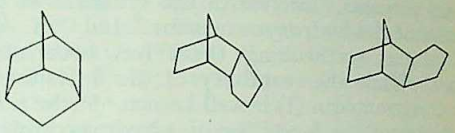
A SIMPLE PREPARATION OF ADAMANTANE

Sir:

Because of the analogy with the structure of the diamond, the highly symmetrical molecule, adamantane (tricyclo[3.3.1.1^{3,7}]decane) (I), has occasioned interest for many years.[1] The total synthesis of this hydrocarbon, first isolated from petroleum naphtha[2] in minute yields,[3] has been accomplished several times, utilizing a number of modifications of the same general approach.[1,4] The over-all yields of even the best of these methods, involving a moderately large number of steps, did not exceed a few per cent.; therefore, investigations of the chemistry of this compound have been hindered to a large extent by its unavailability. We wish to report a facile two-step preparation of adamantane from the very readily available compound, dicyclopentadiene (II).

endo-Trimethylenenorbornane[5] (tetrahydrodicyclopentadiene, III), which can be prepared from II in essentially quantitative yield by hydrogenation,[6] was refluxed with 10 per cent. of its weight of $AlBr_3$ or $AlCl_3$ overnight.[7] At the end of this time the products were distilled directly from the reaction pot, with no attempt at fractionation. The precipitation of adamantane was completed by cooling the distillate to Dry-Ice temperature; a yield of about 10 per cent. of crude I could be obtained by filtration through a coarse filter. Additional I could be obtained by subjecting the filtrate to fractional distillation through an efficient column. The forecuts, b.p. to 185°, contained a large number of components. The main fraction, b.p. 185.0°, $n^{20}D$ 1.4871, consisted of *exo*-trimethylenenorbornane (IV),[8] the expected product of the reaction.[9] The yield of this material, about 50 per cent., could be improved considerably by conducting the isomerization at lower temperatures. From the higher boiling cuts, b.p. to 195°, approximately 5 per cent. additional crude I was recovered. After washing with ethanol, fractional sublimation of the combined samples of I gave a 12–13 per cent. yield of pure adamantane, m.p. 269.6–270.8° (sealed tube). Reported m.p. 268.5–270°.[1] *Anal.* Calcd. for $C_{10}H_{16}$: C, 88.16; H, 11.84. Found: C, 88.31; H, 11.99. The infrared spectrum[10] and mass spectral pattern[11] of the rearrangement product further established its identity as adamantane.



Since, as would be anticipated, IV, under the same conditions, gave a similar yield of I, it may be possible to improve the yield of I considerably The driving force for the rearrangement is undoubtedly the result of the fact that I, in contrast to III and IV, possesses an arrangement of atoms uniquely free from angular and conformational strain. Conceptually, it is possible to visualize several routes for the conversion of III or IV into I. The simplest of these necessitates only three steps involving carbon-to-carbon rearrangements. The possible mechanisms of these unusual transformations will be commented on in greater detail later.

SELENIUM AS AN INTEGRAL PART OF FACTOR 3 AGAINST DIETARY NECROTIC LIVER DEGENERATION

Sir:

Factor 3 is a dietary agent which prevents liver necrosis in the rat.[1] Concentrates of Factor 3 also protect against multiple necrotic degeneration (heart, liver, kidney and muscle necrosis) in the mouse,[2] as well as against exudative diathesis in the chick.[3] These fatal diseases result from a multiple deficiency. They are produced by diets which are low in cystine and simultaneously defi-

cient in vitamin E and Factor 3. Each of these substances protects by itself. Details of the rat assay for Factor 3, using a ration based on Torula yeast as the sole source of protein, have been described.[4]

During the fractionation of Factor 3 from acid hydrolysates of natural source materials we detected that at least two chemically closely related substances with Factor 3 activity were present. These have been designated α- and β-Factor 3.[5] α-Factor 3 was found to be water soluble, strongly anionic, stable against oxidation, but sensitive to reducing agents. Dry ashing eliminated Factor 3 activity entirely.

The fractionation of α-Factor 3 has led to highly concentrated, semi-crystalline preparations. Some of these were found to develop a characteristic, garlic-like odor upon addition of alkali. This observation led to the discovery that selenium is an integral part of Factor 3. The element is present in bound form. Qualitative tests for selenium were observed only upon decomposition of active preparations. Various α-Factor 3 fractions were analyzed for selenium; for this purpose the reaction with codeine[6] was adapted to the Beckman spectrophotometer.[7] It is seen that Factor 3 activity is correlated with the selenium content (Table I).

TABLE I

SELENIUM DETERMINATIONS IN FACTOR 3 PREPARATIONS

Prepn. no.[a]	Units of F3[a,b] in aliquot analyzed	μg. Se[c] found
4737	Inactive	<1
4759	Inactive	<1
4760	72	7
4197B	330	3.5
4757	410	9
4741	430	12

[a] Fractions of greatly varying degrees of purity, prepared from dried, defatted kidney powder hydrolysate. [b] Dietary rat assay against liver necrosis; ref. 4. [c] Standardized against the selenium analog of cystathionine (M. J. Horn and D. B. Jones, *J. Biol. Chem.*, **139**, 649 (1941)). The authors wish to thank Dr. M. J. Horn for a generous sample of this material.

The conclusion that selenium is an essential part of the active organic material is borne out by the finding that inorganic selenium salts are remarkably effective in protecting against necrotic liver degeneration (Table II). As little as 13.33 μg. of sodium selenite, *i.e.*, 4 μg. of the element, in 100 g. of diet suffice to afford complete protection. This amounts to a daily intake of about 0.250 μg. of selenium per rat. Protection was also obtained by the daily subcutaneous injection of 0.167 μg. of selenium as sodium selenite. Preliminary indications are that potassium selenate is less potent. Potassium tellurite and sodium arsenate were without effect. The latter substance is known to antagonize selenium poisoning successfully in various species.[8]

TABLE II

EFFECT AGAINST DIETARY NECROTIC LIVER DEGENERATION

Supplement[a]	Salt mg. per 100 g. of diet	Element μg. per 100 g. of diet	No. of animals Total	No. of animals Dead on 30th day
None (Controls)	...	...	18	17[b]
Sodium selenite	0.0199	6	10	0

Sodium arsenate	.470	100	5	5
($Na_2HAsO_4 \cdot 7H_2O$)	.047	10	5	5

[a] Composition of the basal diet: *Torula* feed yeast 30, sucrose 59, vitamin-E free lard 5, salts 5, vitamins (in lactose) 1; K. Schwarz, *Proc. Soc. Exp. Biol. Med.*, **77**, 818 (1951). [b] Inbred animals of the Fisher strain were used. The average survival time on the basal diet is 21 days. The incidence of necrotic liver degeneration is 100%. The tests were terminated after 30 days.

Our results show that, at least for the rat, Factor 3 is not an essential *organic* dietary constituent, since it can be replaced by selenite. The specific potencies of various inorganic and organic selenium compounds remain to be established. Most of the selenium in normal diets appears to be organically bound. The dose needed for the prevention of dietary necrotic liver degeneration amounts to less than 1% of the chronic toxic dose, which has been placed at 300–400 μg./100 g. of ration.[9]

In comparison with previously reported values for vitamin E and cystine,[10] selenium is exceedingly effective in the prevention of necrotic liver degeneration. When applied in form of sodium selenite it is approximately 500 times as active as vitamin E and 250,00 times as active as L-cystine. The element has been shown to be constantly present in tissues of higher animals.[11] It can be inferred from our results that *selenium is an essential trace element.* A characteristic defect, respiratory decline, is present in oxidative metabolism of liver slices from animals on necrogenic diets several weeks before necrosis occurs[12]; this suggests that selenium may act in intermediary metabolism by participating in oxidation reduction reactions.[13,14]

CYCLIZATION OF ACETYLENE-d_2 TO BENZENE-d_6

Sir:

Benzene-d_6 may be prepared directly from acetylene-d_2 at room temperature by use of a modified silica–alumina catalyst. Previously described methods of preparation of benzene-d_6 required either high-temperature (650°) pyrolysis[1] of acetylene-d_2 or the exchange[2] of benzene with D_2SO_4. Both of these methods are inherently wasteful of deuterium in that the pyrolysis reaction results in a number of undesirable deuterium-containing products while the exchange reaction requires a number of exchanges. Also, the subsequent separation and purification procedures are laborious and time-consuming. On the other hand, the preparation described here is relatively easy and efficient. No products other than benzene-d_6 are formed in the reaction.

The deuterium content of the benzene-d_6 depends only on the purity of the deuterium oxide[3] used to form acetylene-d_2 from calcium carbide. Prior to reaction with deuterium oxide, the calcium carbide is heated to 600° to remove all traces of hydrogen or acetylene from the solid. By this means acetylene-d_2, analyzed mass spectrometrically to contain 99.5% D, is prepared.

The modified catalyst is prepared by repeatedly exposing Houdry Type M-46 silica–alumina cracking catalyst (previously dried at 275°) to diborane.[4] The drying temperature is not critical but does determine the amount of bound water[5] retained by the catalyst and, consequently, the amount of diborane that will react with the hydroxyl groups on the surface.[6]

In a typical preparation approximately 300 cc. of acetylene-d_2 was circulated through a 3-cm.-thick bed of the modified catalyst (10 g.) in a closed system whose total capacity was 600 cc. As it was formed, the product was collected in a trap cooled by Dry Ice. After circulation for forty-five minutes the Dry Ice was replaced by liquid nitrogen to condense the unused acetylene-d_2. The catalyst was then heated to 150° *in vacuo* to recover any adsorbed benzene-d_6. The benzene-d_6 was separated from the acetylene-d_2 by high-vacuum fractionation. Under these conditions approximately 50% of the acetylene-d_2 had been converted to benzene-d_6. By mass spectral analysis the benzene-d_6 was found to contain 2.7% of the C_6D_5H species (equivalent to 0.45%H). The mass spectrum of the product compared favorably with that of the API[7]; however, the product prepared here had a slightly higher deuterium content.

When the acetylene-d_2 was first exposed to the catalyst bed, an appreciable amount of heat was evolved; consequently, for larger scale preparations it may be advisable to cool the catalyst.

Significantly, there was no exchange of deuterium or hydrogen between the modified catalyst and the acetylene or benzene. It was possible to prepare, alternately, benzene and benzene-d_6 on the same catalyst bed without forming partially-deuterated products. However, when a mixture of acetylene and acetylene-d_2 was passed through the modified catalyst, the product consisted of both even and odd numbered deuteriated benzenes with deuterium and hydrogen statistically distributed among these species. A detailed study of the cyclization reaction, directed toward shedding light both on the mechanism of cyclization of acetylene and the catalytic nature of silica–alumina gels, is being carried out and will be reported later.

RESOLUTION OF DL-MEVALONIC ACID AND THE SYNTHESIS AND BIOLOGICAL ACTIVITIES OF DL-3-HYDROXY-3-METHYLGLUTARALDEHYDIC ACID

Sir:

The discovery of mevalonic acid, a new acetate-replacing and growth factor for lactobacilli, was reported recently,[1,2] and its structure was proven to be 3,5-dihydroxy-3-methylpentanoic acid (I).[3,4] The synthesis of DL-mevalonic acid has been reported,[3,4,5] and it was found to have one-half the microbiological activity of the natural compound.[3,4]

Fractional crystallization of the amides obtained by reaction of DL-mevalonic acid lactone with (+)-α-phenyl-1-naphthalenemethylamine yielded an amide melting at 151–152° (*Anal.* Calcd. for $C_{25}H_{25}NO_3$: C, 76.00; H, 6.93; N, 3.85. Found: C, 76.28; H, 6.90; N, 3.81) $[\alpha]^{25}D + 29°$ (*c*, 1.1 in chloroform). Alkaline hydrolysis of this amide yielded mevalonic acid (isolated as the crystalline N,N′-dibenzylethylenediammonium salt, m.p. 125–126°; *Anal.* Calcd. for $C_{28}H_{44}N_2O_3$: C, 62.66; H, 8.26. Found: C, 62.60; H, 8.28) which had microbiological activity for *Lactobacillus acidophilus*, ATCC 4963,[1] equal to that of the natural isomer.

When it became known[6] that mevalonic acid is a precursor in the formation of cholesterol, consideration of alternative biosynthetic reactions led to an evident interest in the closely related aldehyde, 3-hydroxy-3-methylglutaraldehydic acid (mevaldic acid, II). This new aldehyde has now been synthesized for study in "isoprenoid" biosynthetic systems.

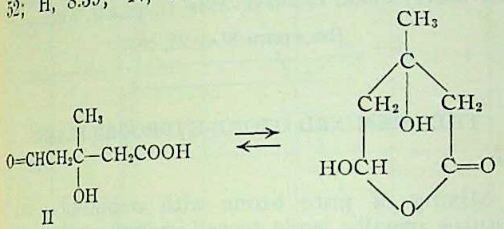
yielded ethyl DL-3-hydroxy-3-methyl-5,5-dimethoxypentanoate (III), b.p. 61–63° (0.1 mm.), $n^{25}D$ 1.4353. (*Anal.* Calcd. for $C_{10}H_{20}O_5$: C, 54.53; H, 9.15. Found: C, 54.79; H, 8.95.) Hydrolysis of III with sodium hydroxide yielded DL-3-hydroxy-3-methyl-5,5-dimethoxypentanoic acid (IV) which was isolated as the crystalline N,N′-dibenzylethylenediammonium salt, m.p. 107–107.5°. (*Anal.* Calcd. for $C_{32}H_{52}N_2O_{10}$: C, 61.52; H, 8.39; N, 4.48. Found: C, 61.32; H, 8.73; N, 4.60.) Hydrolysis of IV at 25° with 0.1*N* hydrochloric acid yielded DL-3-hydroxy-3-methylglutaraldehydic acid (II) in solution. The presence of the unstable and reactive aldehyde II was proven by reduction of it with either hydrogen over a platinum catalyst or with sodium borohydride in alkaline solution to give DL-mevalonic acid (I) in apparently quantitative yield as based on microbiological assay. Varying the time of acid hydrolysis of IV from 15 minutes to 5 hours did not appreciably reduce the high yield of DL-mevalonic acid, although dehydration and decarboxylation of II to 3-methylcrotonaldehyde was observed when more vigorous hydrolysis conditions were employed. After either reduction step, the DL-mevalonic acid was isolated as its crystalline N,N′-dibenzylethylenediammonium salt in *ca.* 30% yield. This product was shown to be identical with an authentic sample of N,N′-dibenzylethylenediammonium bis-(DL-mevalonate) by comparison of the infrared spectra, by a mixed melting point determination and by microbiological assay with *Lactobacillus acidophilus*, ATCC 4963.



II

Solutions of the aldehyde were prepared from the acetal immediately before biological testing. The microbiological activity of DL-3-hydroxy-3-methylglutaraldehydic acid for *Lactobacillus acidophilus* was found to be about 1/200 that of DL-mevalonic acid. The corresponding dimethylacetal (IV) was essentially inactive in this test. The effect of the aldehyde II on the incorporation of acetate into cholesterol was studied. Experiments (Table I) show that DL-3-hydroxy-3-methylglutaraldehydic acid suppresses the incorporation of 1-C^{14}-labelled acetate into cholesterol by rat liver homogenate to about the same degree as mevalonic acid. The corresponding acetal was inactive in this system. Work is in progress to prepare the labelled aldehyde so that it can be studied in this and other biosynthetic systems.

TABLE I

INHIBITION OF THE INCORPORATION OF 1-C^{14}-LABELLED ACETATE INTO CHOLESTEROL

Each flask contained 5 ml. of rat liver homogenate, 1 mg. each of ATP and DPN, and 0.2 mg. 1-C^{14}-acetate (2.44 μcurie). Compounds were added as indicated. Final volume was 10 ml. Gas phase was 95% O_2–5% CO_2. Incubation with agitation was carried out at 37° for 4.5 hr. Cholesterol was isolated and counted as the digitonide.

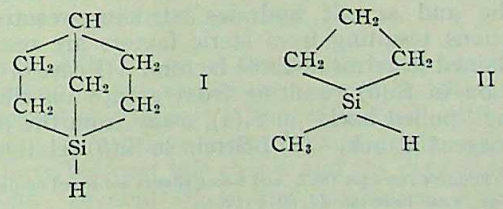
STEREOCHEMISTRY OF HYDRIDE ION DISPLACEMENT FROM SILICON. ENHANCED RATES AT BRIDGEHEAD AND 4-RING SILICON ATOMS[1]

Sir:

The reactions of triorganosilanes, R_3SiH, with hydroxide ion in 95% ethanol have received much study and proceed $R_3SiH + OH^- + SH \rightarrow R_3SiOH + H_2 + S^-$, where SH represents solvent. Hydroxide is not consumed and hydrogen formation (which is quantitative) follows a pseudo first order rate law. These reactions are first order with respect to both silane and hydroxide, $-d[\text{silane}]/dt = k_2[\text{silane}][OH^-]$,[2] and are thus formally similar to SN2 displacements on carbon from the standpoint of kinetics.

In this communication we wish to record data on the reactivities of bridgehead (I) and 4-ring (II)



silicon hydrides relative to the reactivities of acyclic and other previously known cyclic silicon hydrides.[3,4]

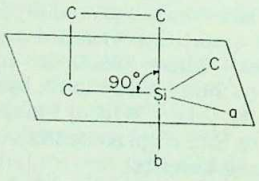
Digitized by Arya Samaj Foundation Chennai and eGangotri

For reactions of R_3SiH with OH^- in 95% ethanol at 35° relative rates (k_2) are, for $(C_2H_5)_3SiH$ = 1; I, 10^3; II, 10^4–10^5; $(CH_2)_4Si(CH_3)H$, 10; $(CH_2)_5Si(CH_3)H$, 10^{-1}. For $(C_2H_5)_3SiH$ at 35°, k_2 = 0.1 min.$^{-1}$, mole^{-1} l.[5,6]

The corresponding disiloxane, bis-(1-silabicyclo-[2.2.1]heptyl) oxide,[3] m.p. 76°, was isolated in 40% yield (62 mg.) from the kinetics runs with I and perfectly linear pseudo first order plots were obtained. The 4-ring silane, II, gives 60% of the theoretical hydrogen at an extremely fast rate and 40% at a different rate which is smaller than the first by a factor of about three powers of ten. The latter rate has been shown to comprise hydrogen evolution from *sym*-di-*n*-propyldimethyldisiloxane which is formed by ring-opening of II (C-Si cleavage by OH^-) in competition with the evolution of hydrogen from the 4-ring silane.[7]

Thus, it is clear that displacement of hydride ion by hydroxide ion proceeds *far more rapidly* at bridgehead[8] and 4-ring silicon atoms than at silicon in ordinary a-cyclic and 5- as well as 6-ring silicon hydrides. These results comprise a complete reversal of the structure-reactivity relationships observed for displacements at carbon when the same comparisons are made.[9]

The above facts are in accord with the hypothesis outlined in our earlier communication.[3] Thus, in the reaction of II with hydroxide the geometry of the Si(5) addition compound would approximate one of two (idealized) structures: (1) a = H, b = OH; (2) a = OH, b = H.



On the above model of Si(5) complex for II with hydroxide ion[10] and similar models for I and other cyclic and acyclic hydrides, structure-reactivity relations resulting from steric factors are readily explained in terms of three factors: (1) ease of formation of Si(5) resulting from groups on silicon being "pulled back" in Si(4), away from the path of reagent attack. (2) I-Strain in Si(5) relative to Si(4).[11] (3) Steric strain in Si(5) relative to Si(4) due to increased "crowding" of groups in the former.[12]

(5) Relative rates for the 5- and 6-ring silanes are based on data in R. West, THIS JOURNAL, **76**, 6015 (1954).

(6) Salt effects on k_2 resulting from change in KOH concentration should not appreciably affect the above relative rates tabulation which covers the range 0.003 *N* to 0.2 *N* KOH; see J. E. Baines and C. Eaborn, *J. Chem. Soc.*, 813 (1955).

(7) In 95% ethanol at 35° the 4-ring silane gives 60% of the theoretical hydrogen with an ammonia–ammonium iodide buffer (0.5 *N* NH_3, 0.05 *N* NH_4I) at a rate which corresponds to a half-life of 7.5 minutes. The same reagent gives *no hydrogen* in a reasonable time with the highly reactive triphenylsilane.

(8) Energies of activation, E_a, for $(C_2H_5)_3SiH$ and I are 16 kcal./mole and 7 kcal./mole, respectively. The latter value was calculated from rate data at 0 and −24° using 0.0579 *N* KOH. Relative rate for I at 35° is a calculated value based on the E_a.

(9) For a recent excellent summary of data on effects of ring size on reactivity, see A. Streitwieser, Jr., *Chem. Rev.*, **56**, 666–670 (1956).

(10) There are, of course, four possible structures of Si(5) for II which would have the H-Si-OH angle near 90°, but two of these would be energetically unfavorable since the C-Si-C angle would be constrained from an ideal angle of 120° to *W*90° by the silacyclobutane system.

(11) H. C. Brown and M. Borkowski, THIS JOURNAL, **74**, 1894 (1952), and other earlier papers on the elegant I-Strain hypothesis.

(12) Relative rate (k_2) for t-$C_4H_9Si(CH_3)_2H$ is 10^{-2}. Unpublished work of L. H. Sommer and W. P. Barie, Jr.

THE PREMIXED OZONE-HYDROGEN FLAME[1]

Sir:

Mixing of pure ozone with combustible substances usually leads to self-ignition, explosion or detonation and *premixed* pure ozone–fuel flames have not been reported. They are interesting not only because of the higher enthalpy content of the O_3–fuel *vs.* the O_2–fuel system, but primarily because the combustion kinetics in the flame front of the O_3-systems can be expected to be substantially faster than for the corresponding O_2–systems.

We have described recently the combustion flame of ozone to oxygen.[2] We also found that pure ozone can be mixed with pure hydrogen at −78° and even at 20° and 1 atm. without explosion and with no, or practically no, reaction for several hours.

Pure ozone–hydrogen mixtures of any desired composition were prepared by mixing known volumes of the two gases. The mixtures were burned at −78° initial temperature using the same technique as before.[2] (The Reynolds numbers of all flames were below 2000.) The burning velocities were determined by the standard schlieren method. The same apparatus was used to measure the burning velocity of the H_2–O_2 system. The results are presented in Fig. 1. The experimental burning velocities at 195°K. initial temperature and 1.0 atm., were for 6.0, 12.0, 18.2, 18.5, 25.0 and 100.0 mole % O_3, respectively, 207 ± 5, 664 ± 57, 1290 ± 20, 1330 ± 30, 1680 ± 80 and 270 ± 7 cm./sec.

Mixtures of 94.0 to 75.0% H_2 (rest pure ozone) could be burned readily. These O_3–H_2 flames are brighter than the corresponding O_2 flames but like the latter their luminosity is low. The stoichiometric mixture, *i.e.*, 3.0 vol. H_2 + 1.0 vol. O_3, which could be appropriately called "super-knall gas," burns very rapidly at a velocity of 1680 ± 80 cm./sec., whereas "knall gas," classically considered the fastest burning gas mixture, burns at 610 cm./sec. or 1/2.75 as rapidly. In mixtures on the ozone-rich side of the stoichiometric point the flame front degenerates very rapidly to a detona-

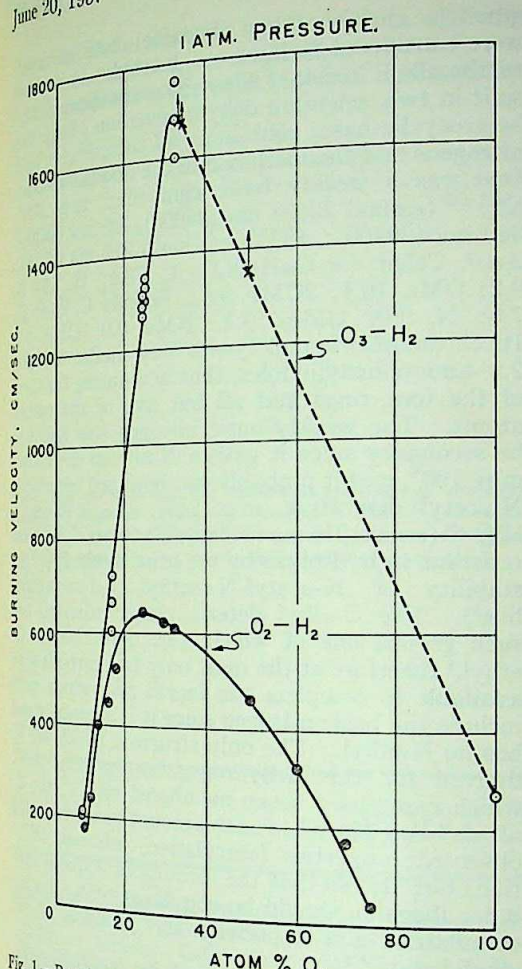

Fig. 1.—Burning velocities of $O_3 + H_2$ and $O_2 + H_2$ mixtures at 195°K. initial temperature and 1 atm. pressure.

tion front; it has not been possible as yet to burn such mixtures successfully.

The expected substantially faster burning velocity of the H_2–O_3 *vs.* the H_2–O_2 system has thus been proven experimentally. An intensive study of other O_3 flames is warranted.

THE CONFIGURATION OF BASE-DENATURED β-LACTOGLOBULIN[1]

Sir:

It has been shown by Cannan, Palmer and Kibrick[2] that titration curves of β-lactoglobulin, in acid and neutral solutions at 25°, obey the Linderstrøm-Lang equation,[3] with a value for the electrostatic interaction factor w which is reasonable for a molecule of molecular weight 40,000. Above *p*H 10, however, the titration curves were found to be steeper, indicative of a considerably smaller value of w. A change in the properties of this protein near *p*H 10 is in accord with the finding of Groves, Hipp and McMeekin[4] that β-lactoglobulin becomes denatured near this *p*H. The titration curve above *p*H 10 thus represents the behavior of the denatured protein.

To investigate this behavior further, we have studied the dissociation of the phenolic groups of β-lactoglobulin, using the spectrophotometric method of Crammer and Neuberger.[5,6] The results are reported in the form of the logarithmic plot of Fig. 1.[7] The ordinate of such a plot represents the effective *pK* of the groups being titrated. According to any simple theory, such as the Linderstrøm-Lang theory, it should *increase* with increasing net negative charge because of the attractive force between this charge and the dissociating protons. In contrast to this prediction, Fig. 1 shows *p*H–log $\alpha/(1-\alpha)$ to be essentially independent of charge. This same phenomenon is served in serum albumin,[8] for the phenolic and amino groups above *p*H 11, and for the carboxyl

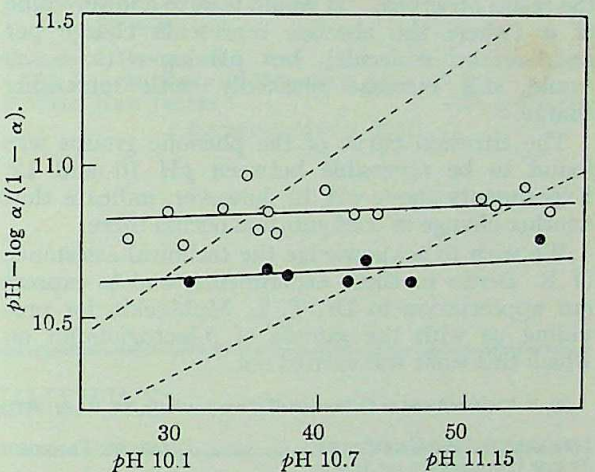

Fig. 1.—Titration of the phenolic groups of β-lactoglobulin at 25° and ionic strengths 0.08 (○) and 0.27 (●): the dotted lines show the predicted slopes for a compact sphere of molecular weight 35,000 to 40,000 at ionic strength 0.08 (upper line) and 0.27 (lower line). For a molecular weight of 17,500 the slopes of these curves would be reduced to about 0.6 of these values. The *p*H values are those at ionic strength 0.08; at ionic strength 0.27 the corresponding *p*H values are roughly 0.2 *p*H unit lower.

(7) The charge at a given *p*H is based on a molecular weight of 40,000 and was taken from the titration curves of Cannan, *et al.*[2] Above *p*H 10.8 the charges represent an extrapolation of their results. Neither the assumed molecular weight nor the accuracy of the extrapolation affects our conclusions, for *p*H–log $\alpha/(1-\alpha)$ is an experimental parameter independent of these variables, and we wish only to show that this parameter is virtually independent of charge.

groups below *p*H 4. It was interpreted as indicating that serum albumin exists below *p*H 4 and above *p*H 11 in an expandable configuration, resembling the configuration to be expected of a simple flexible polyelectrolyte with relatively few cross-links. In such a configuration an increase in charge is accompanied by an increase in charge separation, so that the force acting on the dissociating protons remains virtually unchanged.

Figure 1 thus indicates that above *p*H 10 β-lactoglobulin also exists in an expandable configuration. The work of Townend and Timasheff[9] suggests that, in addition, the molecular weight above *p*H 10 could well be much lower than 40,000. Dissociation by itself, however, will not account for the result observed. It would lead to a lower value of w (where the abscissa represents charge per *undissociated* molecule), but *p*H–log $\alpha/(1-\alpha)$ would still increase markedly with increasing charge.

The titration curve of the phenolic groups was found to be reversible between *p*H 10 and 12. Experiments above *p*H 12, however, indicate that another change in configuration occurs there.

We wish to acknowledge the technical assistance of R. Berdo in these experiments, and to express our appreciation to Dr. T. L. McMeekin for providing us with the sample of β-lactoglobulin on which this work was carried out.

IBOGA ALKALOIDS. II.[1] THE STRUCTURES OF IBOGAINE, IBOGAMINE AND TABERNANTHINE

Sir:

The principal base of *Tabernanthe iboga Baillon*, the pentacyclic alkaloid ibogaine $C_{20}H_{26}N_2O$, has been shown to contain a 5-methoxyindole moiety,[1,2] but apart from the isolation of 3-methyl-5-ethylpyridine[3] no clue as to the nature of the hydroaromatic portion of the molecule is available. We have now found contrary to current belief that the C-alkyl[4] of ibogaine is a C-ethyl since propionic acid can be shown to be an important component of the volatile acids formed in the Kuhn-Roth determination.[5] This result eliminates from discussion the structure proposals for ibogaine[6] and voacangine[7] (a carbomethoxy ibogaine) both of which were considered to have a C-methyl. In contrast to the alkali fusion,[1,3] where ibogaine appears to be split in two, selenium dehydrogenation affords two heterocyclic bases containing all the carbons, both nitrogens and the methoxyl of the original alkaloid. One was a weakly basic compound, m.p. 208°; $\lambda_{max}^{95\%\ alc}$ (ε max) 226–8 mμ (34600), 308 mμ (16100), 340 mμ (20400); $\lambda_{max}^{0.1NHCl}$ (ε max) 317 mμ (25250). *Anal.* Calcd. for $C_{20}H_{22}N_2O$: C, 78.4; H, 7.2; N, 9.2; OMe, 10.1; 2CMe, 9.8. Found: C, 78.4; H, 7.5; N, 9.0; OMe, 10.1; NMe, 0.0; CMe, 6.7. Its chromophoric moiety was very similar to model 2,2[1]-aminophenylindoles, thus accounting for three of the four rings and all but five of the carbon atoms. The weakly basic nitrogen was found to be secondary since it gave a N-nitroso derivative, m.p. 196°, and it probably was hindered because its N-acetyl derivative, m.p. 246°, $\nu_{C=O}$ 1640 cm.$^{-1}$, $\lambda_{max}^{95\%\ alc}$ (ε max) 216 mμ (34580), 321-2 mμ (27,200) was resistant to hydrolysis by the usual methods (*cf.* the stability of N-acetyl-N-methyl-2,6-dimethylaniline[8]). The C-alkyl determination indicated two such groups one of which must have been a C-ethyl,[5] therefore at the most only two carbons were available to complete the fourth ring which must include the basic nitrogen since it is secondary and has no N-alkyl. The only structure which can be derived for this dehydrogenation product is II which contains a seven-membered ring C, the C-alkyls being placed so as to account not only for the observed properties (acetylation, infrared, oxidation) but also so that the formula Ia deduced from it for ibogaine should be consistent with other accumulated facts especially the products of the alkali fusion.[1,3]

The structure of the second selenium degradation product, the indoloquinoline III, m.p. 176°, follows from its analytical data, infrared and ultraviolet spectra, $\lambda_{max}^{95\%\ alc}$ (ε max) 237 mμ (39030), 276 mμ (43930), 298 mμ (22750), 333 mμ (5766), 349 mμ (2857); $\lambda_{max}^{0.1NHCl}$ (ε max) 219 mμ (27700), 230 mμ(28130), 269–71 mμ (43130), 296–7 mμ (27800), 310 mμ (19910), 327–35 mμ plateau (9450). *Anal.* Calcd., for $C_{20}H_{26}N_2O$: C, 78.9; H, 6.6; 3CMe, 13.8. Found: C, 78.5; H, 6.8; CMe, 8.8.

In view of the parallelism which has been demonstrated between the chemistry of ibogaine and its companion alkaloids,[4] tabernanthine can now be represented as Ib and ibogamine as Ic. In agreement with this deduction ibogamine on dehydrogenation with selenium affords products analogous to those obtained from ibogaine, *i.e.*, a weakly basic substance, II (MeO = H), m.p. 214° (*Anal.* Calcd. for $C_{19}H_{20}N_2$: C, 82.6; H, 7.3. Found: C, 82.4; H, 7.4), and a base III (MeO = H), m.p. 196–7°. *Anal.* Calcd. for $C_{19}H_{18}N_2$: C, 83.3; H, 6.6. Found: C, 83.2; H, 6.6. A confirmation of the proposed structures of the selenium degradation products has been provided by MacPhillamy, Lucas and Dziemian of these laboratories, who synthesized the indoloquinoline III (MeO = H) which

was found to be identical in all respects with the compound obtained from ibogamine.

It is possible that the work reported here and the structure Ia[9] derived for ibogaine may prove applicable to the group of indole alkaloids which are known to furnish 3,5-dialkylpyridines by drastic methods of degradation.

BOOK REVIEWS

Introduction to Solid State Physics. Second Edition. By CHARLES KITTEL, Professor of Physics, University of California, Berkeley, California. John Wiley & Sons, Inc., Publishers, 440 Fourth Avenue, New York 16, New York. 1956. xvii + 617 pp. 16 × 23 cm. Price, $12.00.

This book is the first volume in a new series on the science and technology of materials. It is intended as an introductory textbook in solid state physics for students of physics, chemistry, and engineering. The second edition is about two hundred pages longer than the first and is superior, both in the clarity of the explanations and in the extent of the material. A good general knowledge of physics and mathematics is required for complete understanding of the argument, but the non-mathematical reader will find a large amount of interesting and helpful information. Although the chemical topics of heterogeneous catalysis, thermal and photochemical decomposition, and adsorption are neglected, the neglect is compensated by a thorough discussion of the topics that are included and by excellent references at the end of each chapter.

The sections on the classification of solids and on crystal structure have been greatly expanded and clarified by the use of two-dimensional crystal models. The discussions of lattice energy, lattice vibrations, elastic constants, heat capacity, thermal and dielectric properties, ferroelectrics and diamagnetism and paramagnetism are essentially unchanged. However, they have been modernized and recent data are included.

The free electron theory of metals and the band theory of solids are introduced relatively early in the book and they are used to explain the properties of metals, alloys, insulators and semiconductors. Again, the theoretical discussion is supplemented by two-dimensional models. New information about cyclotron resonance and transistor manufacture is included.

The discussion of ferromagnetism, antiferromagnetism and superconductivity has been modernized and placed after the theoretical sections.

The description of imperfections in solids has been rewritten. The discussion of lattice vacancies, diffusion, color centers and excitons is improved. The problem of describing three-dimensional dislocation structures with two-dimensional pages has been reasonably well solved, and several striking pictures of dislocation phenomena have been included.

Occasionally, some humor enlivens the grim procession of solid state phenomena. The author describes the difference of e^{-3000} between the experiments of Volmer and Schultze and the theory of growth of ideal crystals, and then states, "This has been referred to as an all-time record for disagreement between observation and theory." At another point, he reports, "The highest surface recombination velocities are found for sand-blasted surfaces; the lowest velocities are found for surfaces polished smooth and then etched with empirical solutions. A certain amount of magic is thought to be involved in a good etch." This is a real challenge to the chemist to help the alphysicist.

The new series on materials begins well. If succeeding books maintain the high standards set by this one, they will be a valuable addition to the library of every chemist who is interested in solids.

pH Measurements. Their Theory and Practice. By VICTOR GOLD, B.Sc., Ph.D., Reader in Physical Organic Chemistry, King's College, University of London. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y., 1956. 125 pp. 11 × 17 cm. Price $2.25.

This little monograph covers quite thoroughly the subject of *p*H measurements, particularly from the theoretical side. It discusses the theory of proton transfer equilibria, of galvanic cells, the definition and interpretation of the *p*H scale. The determination of *p*H by potential measurements and by optical methods is described. There is a discussion of *p*H relations in the ionization of acids and bases, including titrations of strong and weak acids and bases. Buffers are also discussed. The relation between *p*H and reaction ve-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

locities is considered. One chapter is devoted to measurements in non-aqueous solvents.

The author states in the preface that the book is intended primarily for non-specialists. A large amount of information has been condensed into a small book. The treatment of *p*H is rigorous and the reviewer doubts that a person with only a small background of physico-chemical theory will find it as useful as the author hopes.

WILLIAMS, University of Toronto, Toronto, Canada. Interscience Publishers, Inc., 250 Fifth Avenue, New York 1, New York. 1956. vii + 556 pp. 16 × 23.5 cm. Price $11.00.

The most recent volume of this well known series contains a number of notable reviews.

A lucid account of the situations most frequently encountered in the interpretation of the kinetics of enzyme-catalyzed reactions is given by Alberty. The general discussion, which is characterized by its restraint and avoidance of complicated reaction representations whose consideration at the present time can be no more than a demonstration of facility in algebraic manipulation, will be welcomed by many investigators who are seeking a summary of the more common representations with their corresponding rate equations expressed in terms of a consistent set of symbols. This article also contains a brief description of the kinetic behavior of six enzyme systems, *i.e.*, alcohol dehydrogenase, cholinesterase, α-chymotrypsin, fumarase, peroxidase and urease, that have been studied more or less extensively in recent years.

Chance and Williams have provided a welcome summary of their views on the functions of the respiratory chain in terms of spectroscopically detectable electron transport components of intact mitochondria, on how the process of respiratory control can be used to localize sites of energy conservation, on possible mechanisms for the conservation and phosphorylation processes and how such mechanisms can operate in isolated mitochondria, in intact cell suspensions or in solid tissue. The fluid and controversial nature of interpretations in this area of enzymology is emphasized by the timely and well documented article of Wainio and Cooperstein entitled "Some Controversial Aspects of the Mammalian Cytochromes" appearing later in the same volume.

Surveys of the present status of two important types of enzyme-catalyzed processes, *i.e.*, phosphate transfer and the formation of oligosaccharides *via* transglycosylation are provided by Axelrod and Edelman, respectively. Each of these articles is presented in a critical vein and they are valuable additions to the literature of enzyme chemistry.

Mahler has considered the nature and functions of the metalloflavoproteins and De Renzo the chemistry and biochemistry of xanthine oxidase. Both provide an authoritative account of two areas of enzymology that are in an early stage of development.

Of the remaining three chapters only that of Jeener on "Ribonucleic Acids and Virus Multiplication" appears to be of stature comparable to those noted above. The article by Mandl and Neuberg entitled "Solubilization, Migration and Utilization of Insoluble Matter in Nature" clearly belongs to an earlier period of chemistry and De Busk's review of the "Metabolic Aspects of Chemical Genetics" appears inadequate when compared with many recent reviews of this currently popular field.

The practice, initiated with Volume II of this series, of providing both author and subject cumulative indices is continued in the present volume.

PASADENA 4, CALIFORNIA

Methods in Enzymology. Volume III. Preparation and Assay of Substrates. Edited by SIDNEY P. COLOWICK and NATHAN O. KAPLAN, McCollum-Pratt Institute, The Johns Hopkins University, Baltimore, Maryland. Academic Press Inc., 111 Fifth Avenue, New York 3, N. Y. 1957. xxiv + 1154 pp. 16 × 24 cm. Price, $26.00.

This volume is divided in the following sections: I, Carbohydrates; II, Lipides and steroids; III, Citric acid components; IV, Proteins and derivatives; V, Nucleic acids and derivatives; VI, Coenzymes and related phosphate compounds; VII, Determination of inorganic compounds. The seven sections contain one hundred and fifty procedures which were used by the authors in their investigations. This type of presentation no doubt offers the most desirable results. Occasionally, however, there is evidence of incompleteness, perhaps because of an author's limited interest. For example, on p. 334 the preparation of lecithin from beef hearts is described. It is stated that the $BaCl_2$-precipitate can be processed for cardiolipin but no directions are given for the procedure. Cardiolipin is also an important product since both compounds are employed in certain serological tests for syphilis. While much useful detail is presented on lecithin, nothing is said about cardiolipin.

On p. 414 a method for the determination of α-keto acids is described. This method has been in use for many years. It may be of interest, however, to note that Neish (*Rec. trav. chim.*, 72, 105 (1953)) has shown recently that the 2,4-dinitrophenylhydrazones of α-ketoglutaric acid and pyruvic acid may be separated by paper electrophoresis. In this method the separated nitro compounds, after extraction from filter paper, are reduced in acid solution and estimated by polarography. The electrophoretically separated hydrazones may also be determined colorimetrically (Tauber, *Anal. Chem.*, 27, 287 (1955)).

The reviewer notes with regret that the modern scientist at times is oversimplifying his method of writing. For example, on p. 334 "The cadmium-free chloroform solution is evaporated to dryness and taken up in 180 ml. of anhydrous ether," when what is meant is that the residue is taken up in ether. On the same page the term "amount" is used several times when volume and quantities were intended. On p. 416 and p. 417 one is directed to "incubate" samples for coupling of α-keto acids with hydrazine at 25 ± 2°. What is really meant is to place the samples in a water-bath at ± 2° for a certain number of minutes. Many enzymes, coenzymes and substrates which are difficult to prepare are now commercially available at reasonable prices. Mention should have been made of this fact more extensively in the individual contributions.

There is no serious defect in this extremely important volume. Editors, authors and publisher rendered a great service to biochemistry for making the appearance of these volumes possible.

Ionic Association. I. Derivation of Constants from Conductance Data

BY RAYMOND M. FUOSS

RECEIVED MARCH 1, 1957

By combining the Fuoss–Onsager conductance equation with the law of mass action, a generalized conductance equation is obtained which includes the case of association of free ions to ion pairs. This equation can then be transformed into a linear equation in appropriate variables. It is shown that limiting conductance, ion size and association constant may be obtained by graphical treatment of conductance data at low concentrations ($\kappa a < 0.2$). A viscosity correction is also required if one ionic species is bulky compared to the solvent molecules.

When the classical mass action constant describing the dissociation of ion pairs is less than about 0.01, it can be easily determined to a good approximation from conductance data by application of a suitably modified form of the Ostwald dilution law.[1] But when the fraction of solute present as ion pairs is small, as is the case for ionophores[2] in solvents of high dielectric constant, the constant calculated by this method is necessarily incorrect, because it is forced by the method of calculation to absorb other (now calculable) effects which also lead to terms of the same order in concentration as the one due to association. When the phoreogram lies above the Onsager tangent, the older method cannot give even a poor approximation; from the classical point of view, the only conclusion which can be drawn is that "dissociation is complete," although there may be good reason to suspect that some association nevertheless is occurring.

The origin of the ambiguity lies in the form of the conductance function. If higher terms from long range interactions are ignored, the conductance equation would simply be

$$\Lambda = \Lambda_0 - Sc^{1/2} - cA_0/K \qquad (1)$$

where S is the Onsager coefficient

$$S = \alpha\Lambda_0 + \beta \qquad (2)$$

and K is the mass action constant. But the square root term is only the leading term of the relaxation and electrophoresis functions, and coefficients of terms of order c and c log c clearly would be included in the value of K derived from (1). When $K << 1$, the error is small, but when K approaches unity, the other terms can completely mask association. A recent calculation[3] of the next higher long range terms now provides a means of modifying (1) so that realistic values of K can be obtained, regardless of the magnitude of K.

Before starting the derivation, it seems advisable to introduce a change in nomenclature, which will place proper emphasis on the molecular mechanism under consideration. Traditionally, we speak of "dissociation" constants of electrolytes, following the proposal of Arrhenius that neutral molecules of solute electrolyte partially dissociate into free ions in solution. We now know that in the case of ionophores the ions exist *ab initio;* in a suitable environment, they may cluster to pairs or to higher aggregates under the influence of mutual attraction. Since the primary act therefore is the association of free ions rather than the dissociation of neutral molecules, it appears preferable to introduce the symbol A for the association constant which describes the associative equilibrium

$$A^+ + B' \rightleftharpoons A^+ \cdot B' \qquad (3)$$

We therefore write

$$[A^+ \cdot B']/[A^+][B'] = A \qquad (4)$$

where the bracketed quantities refer to activities. As usual, we shall assume that f_{AB} is unity and use the Debye–Hückel equation to calculate the activity coefficient f of the free ions. If γ denotes

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the fraction of solute present as free ions, (4) then becomes

$$(1 - \gamma)/c\gamma^2 f^2 = A \quad (5)$$

whence

$$\gamma = 1 - Ac\gamma^2 f^2 \quad (6)$$

where

$$-\ln f = \beta' c^{1/2}\gamma^{1/2}/(1 + \kappa a\gamma^{1/2}) \quad (7)$$

and the other symbols have their usual meanings.

At low concentrations ($\kappa a \gg 0.2$), the conductance equation for unassociated electrolytes can be approximated closely[4] by

$$\Lambda = \Lambda_0 - Sc^{1/2} + Ec\log c + J_1 c(1 - \alpha c^{1/2})(1 - J_2 c^{1/2}/J_1) + O(c^2) \quad (8)$$

where

$$0.4343E = (\kappa^2 a^2 b^2/24c)\Lambda_0 - \kappa ab\beta/16c^{1/2} \quad (9)$$

$$b = e^2/aDkT \quad (10)$$

$$J_1 = \theta_1\Lambda_0 + \theta_4 \quad (11)$$

$$\theta_1 = (\kappa^2 a^2 b^2/12c)[g(b) + \ln(\kappa a/c^{1/2}) + 0.9074] \quad (12)$$

$$g(b) = (1 + 2b)/b^2 \quad (13)$$

$$\theta_4 = \alpha\beta + 8\beta\kappa a/9c^{1/2} - \theta_2 \quad (14)$$

$$\theta_2 = (\beta\kappa ab/8c^{1/2})[\ln(\kappa a/c^{1/2}) + 0.8504] \quad (15)$$

$$J_2 = \theta_3\Lambda_0 + 8\beta\kappa^2 a^2/9c \quad (16)$$

and

$$\theta_3 = [(ab\kappa/c^{1/2})^3 2^{1/2}/24b][g(b) - 1.0774] \quad (17)$$

(It will be noted that E, the coefficient of the c log c term, is independent of ion size and concentration, although the symbols a and c appear in (9); the θ's, on the other hand, are functions of a, both explicitly and also implicitly through b, but naturally are independent of c, which only appears in the ratio $\kappa^2/c = \pi e^2 N/125DkT$.)

Now let us assume that the conductance Λ_i due to the free ions is given by (8), if c is replaced consistently by $c\gamma$ which gives the actual concentration of free ions (in equivalents per liter). Then

$$\Lambda = \gamma\Lambda_i \quad (18)$$

where Λ is the observed equivalent conductance Combining (18) and (6) immediately gives

$$\Lambda = \Lambda_i - Ac\Lambda\gamma f^2 \quad (19)$$

and substitution of (8) (with $c\gamma$ in place of c) then gives

$$y = J_1 - Ax - J_2 c^{1/2}\gamma^{1/2} \quad (20)$$

where

$$y = \Delta\Lambda/c\gamma(1 - \alpha c^{1/2}\gamma^{1/2}) \quad (21)$$

$$\Delta\Lambda = \Lambda + Sc^{1/2}\gamma^{1/2} - Ec\gamma\log c\gamma - \Lambda_0 \quad (22)$$

and

$$x = \Lambda f^2/(1 - \alpha c^{1/2}\gamma^{1/2}) \quad (23)$$

At low concentrations, the J_2 term is small and may be neglected in first approximation, so that

$$y \approx J_1 - Ax \quad (24)$$

Therefore a plot of y against x should be linear; the slope evaluates the association constant A, and

$$J_1 = y(0) + A\Lambda_0 \quad (25)$$

where $y(0)$ is the ordinate at $c = 0$. From the value of J_1, a can then be found by interpolation on a J_1–a plot.

In order to begin the above computation of $\Delta\Lambda$ and f it is, however, necessary to have values for Λ_0 and γ. Extrapolation by Shedlovsky's method[5] gives a suitable starting value for Λ_0; the value found by this method is usually a little too small. At low concentrations, y is approaching 0/0; if the incorrect value of Λ_0 is inserted in (22), y will obviously approach $\pm\infty$ as concentration approaches zero. Hence, if the initial y *vs.* x plot shows a minimum, a larger value of Λ_0 should be used; if it becomes sharply concave downward at low concentrations, a smaller value is needed. For γ, the approximation

$$\gamma_0 = \Lambda/(\Lambda_0 - Sc^{1/2}\Lambda^{1/2}/\Lambda_0^{1/2}) \quad (26)$$

is used; the E and J_1 terms have opposite signs and to a considerable extent the errors so made compensate if both are neglected in (26). Then having determined J_1 by (25) (and hence a) to first approximation, the calculation may be repeated with γ to second approximation, given by

$$\gamma = \Lambda/(\Lambda_0 - Sc^{1/2}\gamma_0^{1/2} + Ec\gamma_0\log c\gamma_0 + J_1 c\gamma_0 - J_2 c^{3/2}\gamma_0^{3/2}) \quad (27)$$

Finally

$$y' = y + J_2 c^{1/2}\gamma^{1/2} \quad (28)$$

is plotted against x', also computed to second approximation, using (27) in (7) and (23). For $A \leqslant 15$, the values of a and A obtained from the original y–x plot do not differ by more than a few per cent. from those obtained from the y'–x' plot.

When A becomes small, *i.e.*, when the phoreogram lies near (or above) the Onsager tangent, γ may be safely approximated by unity in calculating the various interionic terms which appear in y and x. When A drops to values near unity, the y–x plot becomes practically horizontal within experimental error; in this case, it is necessary to have data for the salt in solvents of lower dielectric constant. These serve to determine a and hence J_1 and J_2 if we may assume that a is independent of composition in mixed solvents. Then one plots Λ''' against $c\Lambda f^2/(1 - \alpha c^{1/2})$; the slope is equal to A. Here Λ''' is defined as

$$\Lambda''' = \Lambda'' - J_1 c + J_2 c^{3/2} \quad (29)$$

where

$$\Lambda'' = (\Lambda + \beta c^{1/2} - Ec\log c)/(1 - \alpha c^{1/2})$$

and

$$\Lambda''' = \Lambda_0 - A[c\Lambda f^2/(1 - \alpha c^{1/2})] = \Lambda_0 - As \quad (30)$$

The intercept at $c = 0$ is the final value of Λ_0.

When large ions, such as quaternary ammonium ions (or picrates) are involved, a modification of (8) becomes necessary. These bulky ions interfere with the motion of the balancing counter ions, which in effect are moving in a medium of higher viscosity than that of the pure solvent. We recall that the equivalent conductance is proportional to the mobility which in turn is inversely proportional to the viscosity of the solvent medium to first approximation. In order to estimate this correction, we shall assume that the viscosity η at non-zero concentrations is given by the Einstein equation

$$\eta = \eta_0(1 + 5\phi/2)$$

where ϕ is the volume fraction of solute. If we assume that the cations have a hydrodynamic radius R, then

$$\phi = (4\pi R^3/3)(Nc/1000) = \delta c \qquad (31)$$

where N is Avogadro's number. Then the conductance equation becomes

$$\Lambda = [\Lambda_0 - \beta c^{1/2}/(1 + \kappa a)](1 + \Delta X/X)(1 + 5\delta c/2)^{-1} \qquad (32)$$

because viscosity appears in the denominator of both limiting mobility and the electrophoresis term. If $(1 + 5\delta c/2)^{-1}$ is approximated by $(1 - 5\delta c/2)$ in (31) and the same expansion is made as before, the final result, which replaces (24), is

$$y = J_1 - 5\Lambda_0\delta/2 - Ax \qquad (33)$$

This means that a plot of y against x should still be linear, with slope equal to A, but the ordinate at $c = 0$ ($x = \Lambda_0$) is now

$$y(0) = J_1 - 5\Lambda_0\delta/2 - A\Lambda_0 \qquad (34)$$

Hence if J_1 is known (*i.e.*, if a can be evaluated), δ and hence R are known. Examples of the various cases discussed will be given in the following paper. As will be emphasized there, it would be futile to attempt to apply the equations developed in this paper to data of low precision ($\pm$ 0.1% or worse).

There are several other corrections due to the actual volume of the ions which should be considered in the next higher approximation. The first is the modification of K which accounts for the fact that an ion and a solvent molecule cannot simultaneously occupy the same site.[6] The second is the change of dielectric constant produced by the ions: a decrease with respect to that of the solvent could be expected as a consequence of dielectric saturation in the close vicinity of ions, or merely due to a dilution effect if one species of ions were essentially paraffin, as is the case with quaternary ammonium ions. Both of these effects would lead to terms of order $c^{1/2}$ in the conductance equation. There may well be, of course, other still unknown terms. Over the range of concentration where we propose to apply the present analysis ($\kappa a < 0.2$), these terms are small. At higher concentrations, where the formally computed values of these terms would become numerically significant compared to the $c^{1/2}$, c and $c \log c$ terms, their inclusion appears to be irrelevant, because the continuum model for the ion atmosphere no longer is a valid physical approximation.[4] Consequently there is no need to contemplate the difficult and tedious task of integrating the equation of continuity to the next higher order of approximation in order to obtain the $c^{3/2}$ and $c^{3/2} \ln \kappa a$ terms.

(6) H. Falkenhagen, M. Leist and G. Kelbg, *Ann. Phys.*, (6) **11**, 51 (1952); M. Eigen and E. Wicke, *Naturwiss.*, **38**, 453 (1951); M. Dutta and S. N. Bagchi, *Ind. J. Phys.*, **24**, 2 (1950); S. N. Bagchi, *J. Ind. Chem. Soc.*, **27**, 4 (1950).

Finally we consider the association constant A. If association is solely due to electrostatic forces, then a correlation between A and the dielectric constant of the solvent should appear. The relation proposed by Bjerrum[7] has been found to describe ion association satisfactorily in solvents of low dielectric constant,[8] but $Q(b)$ contains a completely arbitrary cut-off limit at $r = e^2/2DkT = ab/2$. This limit is an artifact; convergence of the integral can be attained[9] by a more careful definition of ion pairs than that proposed by Bjerrum. But even so, the statistical approach to the problem still suffers from the esthetic handicap that ions which are not in actual contact still are counted as pairs. The Bjerrum cut-off also leads to another unrealistic situation: beyond a precisely and sharply definable critical limit of dielectric constant, ion association should cease abruptly. Actually, just as soon as the point charge model for the ions is replaced by one in which the ions are assigned a non-zero electrostatic radius a, we are admitting the existence of non-conducting ion pairs at any value (however high) of dielectric constant, because a non-zero size can only manifest itself when ions come into actual contact, and for the duration of the contact the pair can only react as a dipole to the external field. The dilemma can be neatly circumvented by a thermodynamic approach, as proposed by Ramsey,[10] who used a Born cycle to show that

$$K^{-1} \approx e^b \qquad (36)$$

in solvents of low dielectric constant. If the entropy terms[11] are included, (36) becomes

$$A = \exp(b + \Delta S/R) = A_0 e^b \qquad (37)$$

Here b is the Bjerrum parameter $e^2/aDkT$ defined by (10). If other interactions in addition to charge-charge forces are involved

$$A = A_0 \exp(b + u/kT) \qquad (38)$$

where u is the potential of the mean force concerned. For example, if one ion carries a dipole

$$u = \mu e/a^2 D \qquad (39)$$

provided a continuum model may be used. Arguments presented by Gurney appear to justify the use of the macroscopic dielectric constant in the cases of ion–ion and ion–dipole contacts.[12]

Ionic Association. II. Several Salts in Dioxane–Water Mixtures

By Raymond M. Fuoss and Charles A. Kraus

Received March 1, 1957

A new method of mathematical analysis is applied to conductance data for several salts in dioxane–water mixtures. It is shown that the association constant A is a simple function $A_0 \exp(e^2/aDkT)$ of the dielectric constant of the solvent mixture, unless a dipole is present in one of the ions (*e.g.*, the bromate ion), when an additional ion–dipole free energy appears in the exponent. Data for quaternary ammonium salts show the presence of a previously unsuspected linear term in conductance, which is due to the viscosity increase produced by bulky ions. Consequently solution viscosity rather than solvent viscosity should be used in treating conductance. Finally, it is concluded that the Bjerrum theory of ion association and the Fuoss–Shedlovsky extrapolations should both be replaced by the methods used in the present analysis.

In the preceding paper,[1] it was shown that association constants may be derived from conductance data, even when the fraction of ions associated to pairs is small. A fundamental prerequisite is that the data be of high precision (± 0.02% at least); at a concentration of 0.005 N, for example, an association constant $A = 5$ corresponds to only about 2.5% association. A further prerequisite is that data be available over a range of values of dielectric constant; the range must be wide enough to include solvent mixtures in which the association constant has a value of at least 10. The reason for the latter requirement is simply that association gives a leading term of order concentration in the conductance equation, and there are also present linear terms from long range ionic interaction. When A is small, the difference of the interaction term $J_1(a)$ and $A\Lambda_0$ can be determined but the quantity cannot be resolved into its components. When one (or both) of the ions is bulky compared to the solvent molecules, an additional linear term $(5\Lambda_0\delta c/2)$ also appears, which can only be separated from the coefficient of the linear term if A and $\mathring{a}$ are independently known. From the data in solvents of low dielectric constant, the ion size a can be determined; given the ion size, A can be calculated for the solvents of higher dielectric constant, within the validity of the assumption that the parameter a is independent of composition. Recent work by Kraus[2] and co-workers satisfy the criteria described above. (There are many data of high precision in the literature for aqueous solutions, but they cannot be examined for ionic association because, if association occurs for say the alkali halides in water, it is so slight that it is undetectable by our present analysis; a small A would be absorbed in $J_1(a)$, and merely appear as a slightly different value of ion size from the one which should have been found.) In this paper, we shall present an analysis of several cases where the method is applicable. They will serve to show that conductance can become a considerably more powerful research tool than has previously been realized, in that it can serve to evaluate parameters characteristic of ions in addition to the limiting conductance.

Sodium Bromate.[2]—The conductance of this salt has been measured in water–dioxane mixtures covering the range $78.48 \geqslant D \geqslant 31.53$. When treated by the method appropriate for unassociated electrolytes,[3] the data give linear Λ''' *vs.* c plots and extrapolate to an unambiguous value of Λ_0, but the value of a required to make the Λ''' *vs.* c plot horizontal is only 3.00 Å., which seems unrealistically small. Hence, despite the fact that the conductance curve lies above the Onsager tangent, we are led to suspect ion association. In 55% dioxane, the phoreogram is catabatic, clearly indicating association. On the basis of the Bjerrum theory, it would be possible to have ion association at low dielectric constants, with an abrupt cessation of pairing above a critical value of the dielectric constant.[4] But this critical value is merely the consequence of a device used by Bjerrum to avoid divergence of an integral and corresponds to no physical reality; it seems more reasonable to assume that, as the dielectric constant is raised, the fraction of solute present as ion pairs gradually decreases at a given stoichiometric concentration, but never completely vanishes. Indeed, as already has been pointed out,[1] just as soon as a non-zero ion size is introduced into the model, the existence of ion pairs is tacitly admitted, because a non-zero size can only make itself visible experimentally by the effects of actual contacts of ions, and for the duration of the contact, neither ion can be considered to be "free" in any of the senses implied by that adjective. Availability of data for a salt over a range of dielectric constant in which the phoreogram starts below the Onsager tangent and crosses it as dielectric constant increases provides an ideal means of testing the above hypotheses.

For the four mixtures of lower dielectric constant, the functions y and x defined by equations 21 and 22 of the preceding paper were computed; the corresponding plots are shown in Fig. 1. For the 55 and 50% mixtures, the calculation was made to second approximation, as described in the previous paper. It should be emphasized that y is extremely sensitive to experimental error at low concentrations, because it contains in the numerator a *difference* which approaches zero as c approaches zero, while the denominator is proportional to c itself. For example, at 5×10^{-4} N in the 55% mixture, an error of only 0.020 A-unit in Λ makes an error of 10% in y. Hence relatively more weight is given to the points at higher concentrations; the latter must, of course, satisfy the condition $\kappa a < 0.20$, in order to permit application of the model

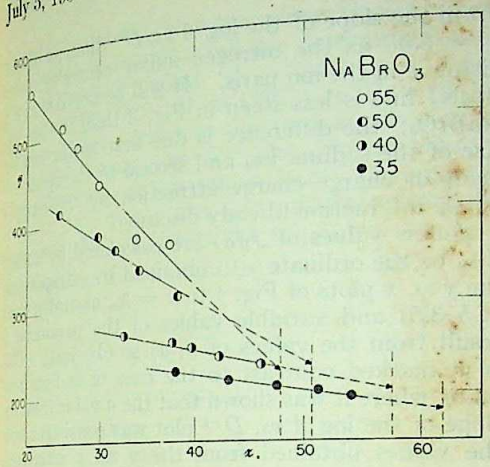

Fig. 1.—Extrapolation plots for sodium bromate in low range of dielectric constants.

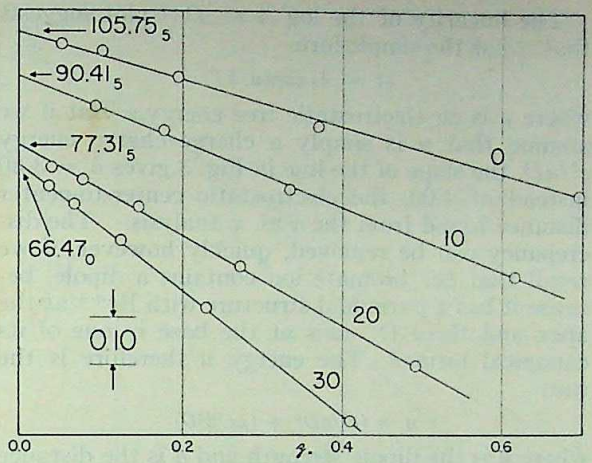

Fig. 2.—Extrapolation plots for sodium bromate in high range of dielectric constants.

and method.) Within experimental error, the plots are linear; the slopes determine the association constants A immediately. Extrapolation to $x = \Lambda_0$ gives the ordinate

$$y(0) = J_1(a) - A\Lambda_0$$

from which $J_1(a)$ is evaluated, because the product $A\Lambda_0$ is now known. Then from a plot of $J_1(a)$ against a, the value of a is determined. The results of these calculations are shown in the last four lines of Table I; it will be noted that the parameter a remains substantially constant.

TABLE I

SODIUM BROMATE IN DIOXANE–WATER MIXTURES AT 25°

% Dioxane	D	A	$J_1(a)$	a	λ_0
0	78.48	0.50	191	(4.00)	105.755
10	70.33	0.68	202	(4.00)	90.415
20	61.86	0.90	225	(4.00)	77.315
30	53.28	1.33	272	(4.00)	66.47
40	48.91	2.10	307	3.96	61.785
50	44.54	2.73	360	3.94	57.66
55	35.85	6.87	570	4.03	50.74
	31.53	11.8	790	4.17	47.92

At dioxane contents of less than 35% ($D > 50$), the y *vs.* x plots are so nearly horizontal that no reliable value of the slope (and hence of A) could be obtained; that is, the (nearly) constant ordinate evaluates the quantity $(J_1 - A\Lambda_0)$ but separation of the terms is no longer possible. We therefore assumed that a remained constant at 4.00, and computed Λ''', using $a = 4.00$ to evaluate J_1 and J_2, and plotted Λ''' against $z = c\Lambda f^2/(1 - \alpha c^{1/2})$; according to equation 30, the plot should be linear with slope A and intercept Λ_0. The graphs are shown in Fig. 2, where for compactness in presentation, the ordinate scales are shifted vertically by arbitrary amounts. The values of Λ_0 are indicated by the arrows. The unit of the vertical scale is shown by indicating 0.10 Λ-unit between the vertical lines at the lower left; this distance corresponds to about 0.10% for the aqueous system and 0.15% for the 30% mixture. The points lie on the lines within 0.0C%. The numerical results are summarized in the upper half of Table I.

$$\Lambda''' = \Lambda_0 - Az$$

The A column of Table I thus contains two sets of values: four values directly determined as slopes of the y–x plots where a was simultaneously evaluated with A and Λ_0, and four values from the slopes of the Λ''' *vs.* z plots, whose construction required an *a priori* value of a. For the latter, we used the average of the first four values; the self-consistency of the ensemble of values of the constants is tested in Fig. 3, where log A is plotted against the reciprocal of the dielectric constant. Both sets of points line on the same graph, which moreover is linear. If a were not a constant, the lowest points in Fig. 3 obviously could not lie on a prolongation of the line through the top four, except by an amazing compensation.

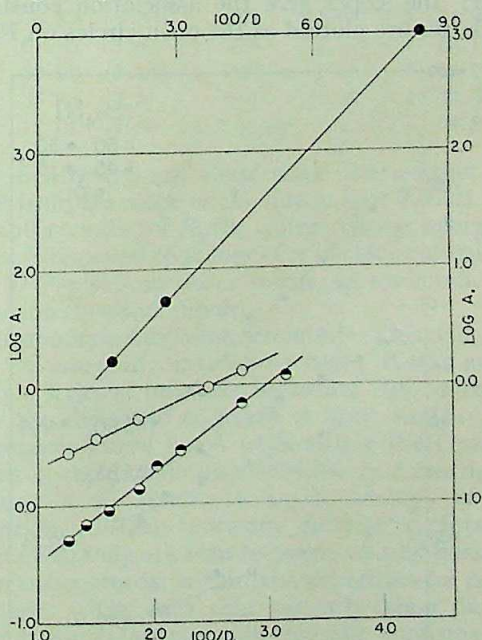

Fig. 3.—Dependence of association on dielectric constant: ○, tetrabutylammonium iodide, from y *vs.* x plots; ◓, sodium bromate, from y *vs.* x plots; ◒, sodium bromate, from Λ''' *vs.* z plots; coördinates left and below. ●, tetraisoamylammonium nitrate, from y *vs.* x plots; coördinates, right and above.

The linearity of the log A *vs.* D^{-1} plot suggests that A has the simple form

$$A = A_0 \exp(u/kT)$$

where μ is an electrostatic free energy. But if we assume that u is simply a charge–charge energy e^2/aD, the slope of the line in Fig. 3 gives $\mathring{a} = 3.30$ instead of 4.00, the electrostatic center-to-center distance found from the y *vs.* x analysis. The discrepancy can be removed, quickly however, if we recall that the bromate ion contains a dipole, because it has a pyrimidal structure with Br^{+++} at the apex and three O^- ions at the base in one of its canonical forms.[5] The energy u therefore is the sum

$$u = (e^2/aD) + (\mu e/d^2D)$$

where μ is the dipole strength and d is the distance from the center of the cation to the electrostatic center of the dipole. For $10^8 d = 2.00$, $10^{18}\mu = 1.03$ and for $10^8 d = 4.00$, $10^{18}\mu = 4.10$, if we set $\mathring{a} = 4.00$ above. These values lie in an entirely reasonable range.

This result naturally suggests a conductimetric study of a variety of other ions; nitrates, for example, should give the same value of a from the y *vs.* x plot and the log A *vs.* D^{-1} plot, because the nitrate ion is electrically symmetrical.[5] Chlorates, on the other hand, should have a steeper log A *vs.* D^{-1} plot than corresponds to the a determined from the y *vs.* x plot. Conversely, conductance data should be helpful in determining previously unknown structures.

Tetrabutylammonium Iodide.[2]—The conductance was measured in water and in four dioxane–water mixtures, covering the range $35.85 \leqslant D \leqslant 78.48$. As is shown in Fig. 4, the y *vs.* x plots are linear; the slopes give the association constants. The latter are plotted as the open circles on Fig. 3.

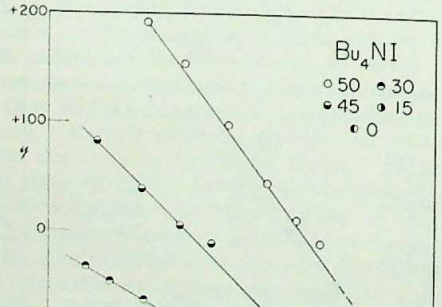

Fig. 4.—Extrapolation plots for tetrabutylammonium iodide. Abscissa scales: 50%, as shown; 45%, $(x - 10)$; 30%, $(x - 20)$; 15%, $(x - 30)$; 0%, $(x - 60)$.

From the slope of the log A *vs.* D^{-1} line, we obtain $\mathring{a} = 5.55$ as the nitrogen–iodine center-to-center distance in the ion paris. It will be noted that the Bu_4NI line is less steep in Fig. 3 than the one for $NaBrO_3$; the difference is due first to the smaller size of the sodium ion and second to the reinforcement of charge–charge attraction by the charge–dipole interaction already discussed.

If now values of $J_1(a)$ are calculated by adding $A\Lambda_0$ to the ordinate $y(0)$ obtained by extrapolating the y *vs.* x plots of Fig. 4 to $x = \Lambda_0$, absurdly small (1.5–3.5) and variable values of the parameter $\mathring{a}$ result from the values of $J_1(a)$ so obtained. This is in marked contrast to the case of sodium bromate, where it was shown that the $\mathring{a}$ value from the slope of the log A *vs.* D^{-1} plot was consistent with the values obtained from the y *vs.* x intercepts, *i.e.*, remained constant over the entire range of solvents investigated. Clearly, an effect is appearing in Bu_4NBr which is absent (or at least negligible) in the case of $NaBrO_3$. The outstanding physical difference between the two salts is the disparity in size of the cations; the tetrabutylammonium ion, according to molecular models, should exclude a spherical volume $7–8 \times 10^{-8}$ cm. in radius, while the sodium ion is about the same size as a water molecule. Using equation 34 of the preceding paper in the form

$$5\Lambda_0\delta/2 = J_1(a) - y(0) - A\Lambda_0$$

and using $\mathring{a} = 5.55$ to evaluate $J_1(a)$, the values of δ obtained are shown in the fifth column of Table II. The next column gives the corresponding values of the hydrodynamic radius R, calculated as

$$R = 7.32\delta^{1/3} \times 10^{-8}$$

The resulting quantity is reasonably constant and agrees remarkably well with the value expected on the basis of the model, assuming the Einstein formula to give the viscosity contribution due to the large cations. It should be mentioned that earlier work on the viscosity of bolaform electrolytes[6] shows that the Einstein limit of 5/2 for the ratio of specific viscosity to volume fraction is approached as these ions approach spherical shape. Introduction of the $(5\delta c/2)$ term into the conductance equation is thus not completely an *ad hoc* hypothesis. The fact that the viscosity term leads to reasonable R values argues for its reality; granting this, the long debated question of solution viscosity *versus* solvent viscosity as the pertinent variable in conductance theory appears to have found its answer.

TABLE II

TETRABUTYLAMMONIUM IODIDE IN DIOXANE–WATER MIXTURES AT 25°

% Dioxane	D	A	$J_1(5.5)$	δ	$\mathring{R}$	Λ_0
0	78.48	2.73	245	0.98	7.3	96.30

only at 20 and 50% was the concentration range wide enough to permit a reliable determination of slope (A) and intercept ($J_1 - 5\Lambda_0\delta/2 - A\Lambda_0$). The span from D = 61.86 (20%) to D = 35.85 (50%) is rather narrow to use to evaluate $\mathring{a}$ from the slope of the log A *vs.* D^{-1} plot, but fortunately some older data on this salt in 79.8% dioxane are available[7]; the y *vs.* x plot (second approximation) is shown in Fig. 5. From the slope, we obtain A

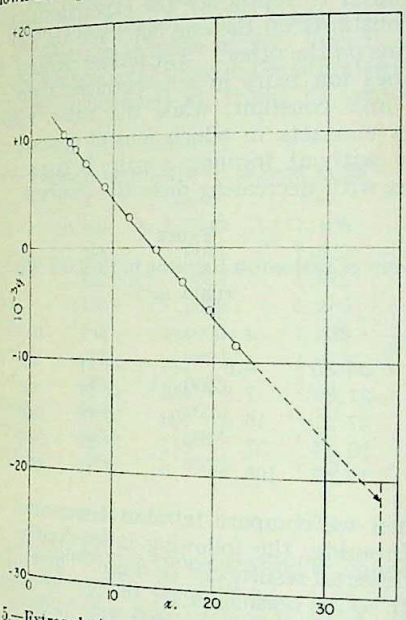

Fig. 5.—Extrapolation plot for tetraisoamylammonium nitrate in 79.8% dioxane.

= 1050. This point, together with the points for the 20 and 50% mixtures, establish a satisfactory straight line (solid points, Fig. 3): A = 0.354 exp(96.1/D). Equating the exponent to $e^2/aDkT$, we find $\mathring{a}$ = 5.83. This equation was then used to evaluate A for the 0, 10 and 30% mixtures, and the corresponding values of J_1 and J_2 were computed, using $\mathring{a}$ = 5.83. Using these constants, the quantity was then computed; if the conductance obeys the equations derived in the previous paper, Λ^{IV} includes the effect of both ion association and ion atmosphere, leaving only the viscosity term to be evaluated. From equation 33, we have

$$\Lambda^{IV} = \Lambda''' + Az$$

$$\Lambda^{IV} = \Lambda_0 - 5\Lambda_0\delta c/2$$

The corresponding plots are shown in Fig. 6; they are linear, well within the limit of experimental error, and δ is determined from the slopes. For the 20 and 50% mixtures, δ was determined from $y(0)$ as for tetrabutylammonium iodide, using $\mathring{a}$ = 5.83 to evaluate $J_1(a)$; for the 79.8% mixture, the $(J_1 - A\Lambda_0)$ term is so large that it completely masks the $5\Lambda_0\delta/2$ term. From Fig. 5, $J_1(a)$ = 1.47 × 10⁴; calculated for $\mathring{a}$ = 5.83, J_1 = 1.20 × 10⁴. Considering the sensitivity of $J(a)$ to a when b is large (low dielectric constant) and the uncertainty in determining J_1 from the graph when A is so large, we consider the agreement

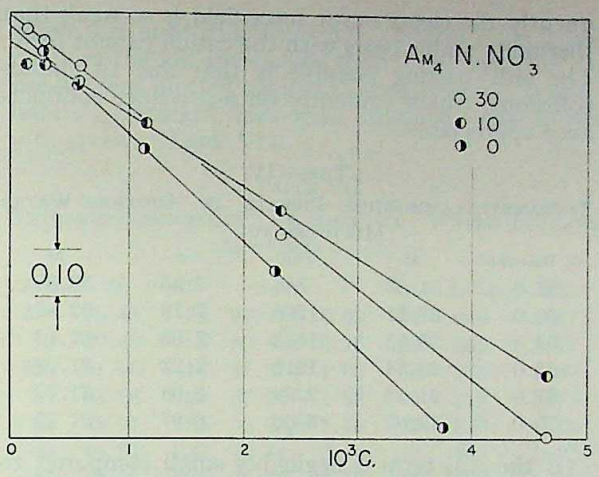

Fig. 6.—Extrapolation plots for tetraisoamylammonium nitrate in 0, 10 and 30% dioxane.

satisfactory. Other details of the calculation are summarized in Table III. Again, an entirely reasonable value of the hydrodynamic radius is found; since this constant in effect collects *all* of the residual uncertainties of the calculation in this particular example, we are inclined to place considerable confidence in both the data and the theoretical treatment, because such agreement among six sets of data has practically zero probability of being fortuitous.

TABLE III

TETRAISOAMYLAMMONIUM NITRATE IN DIOXANE–WATER MIXTURES AT 25°

% Dioxane	D	A	$J_1(5.83)$	δ	$\mathring{R}$	Λ_0
0	78.48	(1.20)	248	1.02	7.3	89.275
10	70.33	(1.38)	252	1.04	7.4	74.845
20	61.86	1.67	274	1.17	7.7	63.13
30	53.28	(2.14)	320	1.13	7.6	54.04
50	35.85	5.2	. 643	1.53	8.4	42.575
80	12.01	1050	1.2×10^4	..	..	34.8

We finally remark that, since the a-value obtained from the slope of the line in Fig. 3 leads to a satisfactory value of R, the charge–charge energy is all that is required to account for the slope of the log A *vs.* D^{-1} plot; in other words, as expected, the nitrate ion shows no dipole.

Tetramethylammonium Picrate.[8]—This salt presents an unusually interesting case: it was measured in a series of mixtures including 70% dioxane, where the dielectric constant is only 19.07. The conductance curve lies a little below the Onsager tangent in the dioxane-rich systems, and one might be tempted to assume a small amount of ion association. When, however, the y *vs.* x plots are constructed, they are seen to be practically horizontal; in other words, within the experimental error, A is zero. The fact that no association due to Coulomb forces appears for this salt confirms the generally accepted picture of the picrate ion: the single negative charge is not localized at the phenolic oxygen but is distributed over the peripheral π-electron system of the whole molecule. Conse-

quently the electrostatic force field is so weak that thermally stable pairs with the cation cannot form. The only pairing possible is that due to chance collisions, which evidently do not reduce conductance appreciably.

TABLE IV

TETRAMETHYLAMMONIUM PICRATE IN DIOXANE–WATER MIXTURES AT 25°

% Dioxane	D	$J_1(a)$	$\mathring{a}$	Λ_0
55.0	31.53	848	7.35	33.335
60.0	27.21	1269	7.78	32.425
62.5	25.15	1533	7.85	32.12
65.0	23.14	1812	7.22	31.935
67.5	21.12	2290	7.08	31.77
70.0	19.07	3030	6.97	31.75

If the $A\Lambda_0$ term is negligibly small compared to the other terms, then

$$y(0) = J_1 - 5\Lambda_0\delta/2$$

and the problem is to separate the components. In the mixtures of higher dielectric constant, J_1 and the hydrodynamic terms are of comparable magnitude; as the dielectric constant decreases, J_1 increases rapidly while δ remains constant, according to our hypotheses. The data were therefore treated as follows. A series of a-values were chosen, and Λ''' was computed and plotted against concentration. If the association term is negligible

$$\Lambda''' = \Lambda_0 - 5\Lambda_0\delta c/2$$

Each value of a will obviously give a straight line with a different slope; from the slopes in the water-rich mixtures, $\delta(a)$ was thus determined. Plots of $\delta(a)$ against the selected a-values were then made for the systems with 0, 20, 35 and 45% dioxane. Ideally, these curves should have intersected at a single point, corresponding to the unique values of a and δ theoretically required to describe the system. Actually, the curves gave a cluster of intersections: the range of $\mathring{a}$-values was from 7.48 to 8.00 (average, 7.73) while the δ-values ran from 0.39 to 0.55, averaging to 0.48. Both values seem quite reasonable. If we assume that $\delta \sim (R_1^3 + R_2^3)$ and further assume equal radii for the two ions as a rough approximation, $\delta = 0.48$ leads to $R = 4.54$ for the equivalent hydrodynamic radius. Then, using $\delta = 0.48$ to calculate $5\Lambda_0\delta/2$ for the dioxane-rich systems, values of $J_1(a)$ were obtained from the (practically constant) values of $y(c) \approx y(0)$. The corresponding values of $\mathring{a}$ were then obtained by interpolation on J_1–a plots. The results are shown in Table IV; there is a slight systematic trend to lower values as D decreases, but the average of 7.38 is in excellent agreement with the values obtained as described above in the water-rich mixtures. The decrease in $\mathring{a}$ may foreshadow the onset of association, which must eventually occur in solvents of sufficiently low dielectric constant. But when J_1 is so large, a small Ax term is practically invisible.

Tetrabutylammonium Bromide.[8]—This salt was also measured over the range 0–70% dioxane. Even a rough estimate shows that its association at a given value of dielectric constant is *less* than that for the iodide; it was only possible to obtain reliable values of A from the slopes of the $y(c)$ vs. $J(a)$ plots in the mixtures containing 50% or more dioxane. These values gave a straight line on a log A *vs.* $1/D$ plot, which can be represented by the equation $A = 0.11 \exp(133/D)$; the corresponding $\mathring{a}$-value is 4.21. On the other hand, if we calculate $\mathring{a}$ from $J_1(\mathring{a})$ obtained from the intercepts $y(0)$, using $\delta = 0.535$ (see later), the values shown in Table V result. Unlike tetrabutylammonium iodide and tetraisoamylammonium nitrate, a different ion size is required to reproduce the experimental association constants on the one hand and the long range J_1-terms on the other. The former constant, which describes ion pairs in semi-permanent contact, is small and constant, while the latter, which describes contacts in which ions of opposite charge collide without forming a pair, is larger and increases with decreasing dielectric constant.

TABLE V

TETRABUTYLAMMONIUM BROMIDE IN DIOXANE–WATER MIXTURES AT 25°

% Dioxane	D	A	$y(0)$	Λ_0	$J_1(a)$	$\mathring{a}$
50	35.85	4.6	345	43.71	605	5.22
55	31.53	7.8	456	41.54	835	5.42
60	27.21	16.4	600	39.76	1305	6.24
65	23.14	37	615	38.32	2090	6.90
70	19.07	103	0	37.11	3870	8.12
